FOREWORD

BY

THE RT. HON. LORD CADMAN OF SILVERDALE,
G.C.M.G., HON. LL.D., D.SC.

Past President of the Institution of Petroleum Technologists.

IT is with great pleasure that I contribute this foreword to the SCIENCE OF PETROLEUM, because I have, on many occasions, stressed the overwhelming importance of science in industry.

In no branch of human endeavour has the application of exact knowledge been so apparent as in the exploring, winning, refining, transport, distribution, and utilization of mineral oil. At every point in the long road that leads from the oil well to the consumer investigation and research have been employed with almost spectacular results.

The world to-day would be immobilized without copious supplies of the derivatives of petroleum. On the ground, in the air, on the surface of the waters and under the sea speedy transport is provided. Both in peace and in war oil is a unique necessity. The lamp in the cottage, the stove in the kitchen, the incubator at the farm, the omnipresent candle in the home, the asphalt surface of the road, the innumerable varieties of lubricants in every factory, machine, and prime mover—in every direction in our modern civilization oil plays its part.

In the following pages are given the latest developments of every phase of the industry, and there is displayed in almost every section the impact of current scientific thought on the multitudinous problems that are arising almost day by day. The whole work gives a vivid and comprehensive picture of present activities and future possibilities.

PREFACE

THE petroleum industry may be said to have originated with the discovery of an efficient commercial method of producing burning oil. There were several attempts to do this on a small scale in the early part of the nineteenth century, but none of these was of any commercial importance until Selligue produced shale oil in France in 1838 and James Young started in 1848 to refine crude petroleum from the Riddings Colliery in Derbyshire, and subsequently applied his well-known process to torbanite and oil shales. The commercial success of his process encouraged the search for crude petroleum in the United States of America, and the discovery of the Drake Oil Well in 1859 initiated the American petroleum industry. For many years the main products of the industry were burning oil and crude lubricants, and it is only during the present century that the petroleum industry has become one of the major industries of the world. In 1900 the motor-car was still a curiosity; marine turbine and Diesel engines were in their infancy; and aeroplanes did not exist. To-day the annual production of oil exceeds 240,000,000 tons; there are nearly 40 million motor vehicles on the roads; more than half the ships of the world are fuelled with oil; and air transport has become almost commonplace. Indeed, the exploitation of oil has brought about in the twentieth century a revolution quite as great in its consequences as the industrial revolution of the nineteenth century; and if we are sometimes acutely conscious that it has added to the problems and dangers of modern civilization, we should not forget that it has brought occupation and happiness to many millions of people.

Science has played an important and indispensable part in the development of the oil industry. Forty years ago the methods of winning and refining oil were wasteful to a degree which would be thought intolerable to-day. The volatile constituents of petroleum were then but a dangerous by-product in the manufacture of burning oil which was obtained from the crude oil by simple distillation. But soon the rapid growth of the automobile industry created a demand for the volatile fractions which could not be met by straightforward distillation of petroleum. Laboratory research had already shown on a small scale that the high-boiling constituents of natural oil could be converted by heating into volatile fractions. Burton, in the United States, applied this knowledge on the commercial scale, and can justly be regarded as the pioneer of the modern cracking industry. The results of his work have been remarkable. Even in 1912 only 13 per cent. of crude petroleum was sold as motor spirit; to-day the proportion is 50 per cent. Immense units capable of processing 10,000 tons of crude a day are becoming common; and in one commercial operation oil is separated into a range of motor spirits, burning oils, gas oils, lubricating oils, and residue, under accurately controlled conditions which vary according to the nature and quantity of the products required.

The 'cracking' of petroleum by thermal decomposition was first employed merely to increase the quantity of light spirit available; but in recent years quality has been a prime consideration. In the early motor-cars thermal efficiency was of no great importance, and cylinder pressures were limited by purely engineering difficulties. For these reasons the importance of the chemical nature of the fuel used was not recognized. But with the advent of the aircraft engine, thermal efficiency became of great importance, cylinder pressures were consequently increased; and the engineer, having solved his own

immediate mechanical problems, found that further advances were limited by the quality of the fuel available, owing to its tendency to detonate or 'knock'. It was soon conclusively shown by experiments that the tendency to knock varied considerably with the nature of the hydrocarbon constituents of light fuel, and, in particular, that aromatic hydrocarbons, which were excluded by the original specifications for aviation spirit, were in fact beneficial. These researches received a great stimulus by the remarkable discovery of Midgley and Boyd that the presence of lead tetraethyl in minute amounts was able to stop detonation. Since then an immense amount of scientific work has been done on this single phase of oil technology, with the result on the one hand that our knowledge of the processes of combustion at high temperatures and pressures has been greatly enlarged, and on the other that the refiner has been able steadily to meet the ever-increasing demands of the engine designer for fuel of the highest quality. The natural gas from petroleum wells is now stripped of its light hydrocarbons which have a high anti-knock value. Other hydrocarbon constituents of the gas may be dehydrogenated to olefines which in turn are polymerized by heat, with or without the aid of catalysts, to form non-detonating hydrocarbons. Iso-octane, the standard of anti-knock value, is synthesized on the large scale from iso-butene. Ten years ago the average compression ratio of motor-car engines was 4 to 1; that it is now 6 to 1, with obvious improvement in performance and efficiency, is due fundamentally to the work of the chemist and chemical engineer.

The compression-ignition engine now threatens to supplant the more familiar petrol engine altogether as the prime mover for heavy road traction. Here again the refining industry has been called upon to provide an appropriate fuel and to meet demands for quality which required a study of chemical characteristics, and of flame propagation under the most diverse conditions. And as a by-product of its main activities the industry is rapidly growing in importance as a source of intermediates for the chemical manufacturing industry.

There have been equally striking advances in recent years in the methods employed for locating new sources of supply. Fifteen years ago it was realized that the known reservoirs were insufficient to meet the growing demand for many years, and fears were expressed that the supply of mineral oil would soon be exhausted. The annual consumption is now double what it was then, and yet anxiety for the future is no longer acute. This is due on the one hand to the development of methods of exploration which have made possible the exploitation of oil-pools at great depths, and on the other to better control of production. The life of an oil-pool consists normally of a short period of rapidly expanding production followed by a long period of steady decline. Waste was the proverbial accompaniment of all the early oilfield producing practice. The spectacular gushers with their associated loss of oil and gas were by no means the most serious instances of such waste, for there can be little doubt that the lack of control of the reservoir resulted in a very poor recovery of oil. This was suspected by all thoughtful oil operators, but could not be properly assessed until the reservoirs were scientifically examined. It is now agreed that the percentage of oil recovery is at a very unsatisfactory level, and new methods of production are rapidly replacing the older. These involve the conservation of the reservoir gas and its efficient utilization in the process of oil recovery, the recirculation of gas in the reservoir or the introduction of water-flush to drive the oil to the wells, and the return of unmarketable material to the pool. The present tendency is to attempt to introduce a uniform plan of oil production in each oil-pool.

Oil-pools are much more haphazard in their occurrence than coalfields, and their discovery has become increasingly difficult and expensive as the shallower and more obvious areas have been exhausted. Each new region of petroleum exploration presents its own particular problems with which the oil geologist must contend before drilling for new pools can be properly directed. The earlier conception of the simple anticlinal occurrence fits only a modicum of the structural accumulations, and a whole series of favourable and unfavourable conditions for oil accumulation are now recognized. Thus the modern technique of oil discovery is concerned not merely with the geological structure, but with the whole geological history of an area, and it is only by such studies that the inevitable increase in the cost of exploratory drilling due to the greater depth of exploration has been offset by a greater measure of certainty in the search. The need to elucidate geological structures with greater accuracy and to deal with the areas of inadequate geological exposure has led to the adoption of various methods of geophysical exploration. Among the more successful of these in oilfield practice are the Gravimetric and Seismic Surveys. The former, by the development of exceedingly sensitive instruments, is able to detect minute local changes in the horizontal and vertical components of gravity and thus to reveal the variations in rock density underground. The latter method depends on the artificial production of seismic waves, and where the conditions are favourable, is capable of determining the geological structure with a high degree of accuracy. The adoption and improvement of such methods has extended the areas which can be explored successfully, and has led to the discovery of many new oil-pools. The development of electrical coring has been an invaluable aid both in exploratory drilling and in the normal exploitation of oilfields. Its ability to detect the differences between oil and water sands underground has led to a great increase in the efficiency of oil production.

As the shallower fields have become exhausted the average depth of drilling has steadily increased, and exploratory wells have now attained a limit of 12,800 feet. Even this extreme depth is not, perhaps, so remarkable as the fact that economic producing wells of depths ranging from 10,000 to 11,000 feet are now regarded as normal in some oilfields. Drilling to these depths can be done speedily, economically, and with complete control, in spite of the difficulties connected with the increase in rock pressures. Most of the advances in drilling technique have occurred during the last decade and are associated with the improvement of the rotary method of drilling. Initially only suitable for soft strata, it has been adapted for practically all formations by the introduction of new steels and hard cutting alloys into the design of the drilling bits. The problem of high rock pressures has been overcome by the careful physical and chemical control of the mud-flush, whilst the exclusion of extraneous water-bodies has been dealt with by the use of special cements which will set under abnormal conditions. The tendency of deep wells to deviate from the vertical has involved the introduction of careful control of every phase of the drilling operation, and it is only by the adoption of precise methods in the place of the older haphazard conditions that the present success has been attained.

Fears of shortage of supply, coupled with the desire to be nationally self-sufficient in times of war, have also intensified research into methods of producing oil from coal and shales, with the result that it has been conclusively shown that the Bergius method of hydrogenating coal under high pressure, and the Fischer method of obtaining hydrocarbons from carbon monoxide and hydrogen in the presence of catalysts, are both technically successful on the large scale; and although neither process can compete,

under normal economic conditions, with the production of oil from natural sources, yet they may each find a limited utility for special purposes. In any case they provide a welcome insurance for the future, should natural sources fail for unforeseen reasons, and the knowledge and technical skill which has been gained in the course of their development has already been applied with success in other directions.

Whatever phase of oil technology is examined one finds the same fascinating record of scientific and technical progress. During the last few years there have been introduced entirely new methods for the production of lubricating oils, on the supply and quality of which the machinery of the world depends. Practically the whole of the world's supply of lubricants comes from mineral oil. Lubricants derived from some vegetable oils are high in quality, but the amount available is relatively small. In spite of intensive scientific research much remains to be discovered about the essential nature of a lubricant; no laboratory tests have yet been devised which can be completely relied on to give a quantitative measure of lubricating properties. It is known now, however, that certain types of chemical compounds have specially good properties, and that certain mixtures are beneficial; and it is on the basis of this knowledge, and of an accumulation of practical experience, that modern methods for refining lubricating oils are based. A great variety of solvents, such as nitrobenzene, dichlorodiethyl ether, phenol, cresols, and furfural, are now used in practice to extract from certain petroleum distillates the undesirable constituents and to produce a refined lubricating oil of suitable viscosity possessing a relatively low temperature coefficient of viscosity and an enhanced stability towards heat and oxidation.

Crude oil can now be transported cheaply in pipelines over very long distances; the recently completed line in Iraq from Mosul to the Mediterranean is over 1,000 miles long, and was built up entirely of welded sections. The natural gas associated with oil, which may be an appreciable proportion by weight of the crude oil produced, and which was formerly entirely wasted, is now either largely conserved in the reservoir by better control of production, or, as in the United States, is transported through thousands of miles of pipe for use as a domestic and industrial fuel. Propane and butane, which occur in large quantities in natural gas, are separated and sold in bottles in considerable quantities as a portable gaseous fuel. In 1936 the equivalent of 100,000,000 gallons of petrol was sold in the form of bottled gas in the United States. Petroleum technology is indeed unique in that it is concerned with all operations from the discovery and winning of oil to the delivery of refined products to the retailer, and even to the consumer.

The records of all these and many other recent advances in the science and technology of petroleum are scattered in innumerable journals and in the archives of industrial companies. The purpose of the present work is to provide a balanced and comprehensive treatise that shall be critical in treatment and embrace every aspect of the prospecting, production, refining, and transport of mineral oil and gas. The Editors realize that inevitably a certain amount of overlapping has occurred, but they have endeavoured, within the limits and scope of the work, to allow each Contributor freedom to develop his own treatment of his special subject.

They are very grateful to the many Contributors who have taken so much trouble over the preparation of their articles, and have shown so much forbearance in accomodating their contributions to the requirements of a large collaborative work. The Associate Editors have given invaluable advice and assistance in the planning and preparation. Besides thanking collectively 316 Contributors and 24 Associate Editors, they also

ı to thank for their extra labour Professor A. ' .gerton, Professor A. L. Beale, Dr. F. H. Garner, Professor V. C. Illing, Mr. J. Kewley, Mr. W. D. R. Pye, Mr. C. A. P. Southwell, and Mr. A. L. Ward, who have done .di ..a.ı could have been expected of them as Associate Editors. Dr. G. D. Hobson, Dr. D. A. Howes and Mr. S. E. Coomber have also given extra assistance.

The Editors and the Publisher deeply deplore the death of four contributors who have passed away since their articles were written. These are C. A. Andrews, Paul de Chambrier, S. G. S. Panisset, and Conrad Schlumberger.

The work could not have been accomplished without the devoted labours of Miss K. Clements, Mr. L. V. W. Clark, Mr. D. C. Field, Dr. F. C. Hall, Dr. T. G. Hunter, and Mr. C. E. Wood, of the Department of Oil Engineering and Refining at the University of Birmingham, England. They have done the major part of the detailed and secretarial side of the editing. An important share of the secretarial work has also been done by Miss G. W. Dawson.

The Institution of Petroleum Technologists, and its secretary, Mr. S. J. Astbury, and its librarian, Miss B. M. H. Tripp, have given all aid in their power to assist the work. They have made the arrangements for preparing the indexes, and compiled the Index of Names. Mr. G. S. Sweeting, Mr. A. J. Haworth, and Mr. E. N. Tiratsoo, of the Imperial College of Science and Technology, have done the laborious work of compiling the Index of Subjects.

Finally, the Editors wish to record their indebtedness to Mr. J. G. Crowther of the Oxford University Press for all the help they have received from him during the course of their work.

SECTION 1
NOMENCLATURE

NOMENCLATURE OF CRUDE OIL AND ITS PRODUCTS

By Ing. ROBERT SCHWARZ
Vienna

THE industry of the production of crude oil and the distillation of mineral-oil products which is spread over the whole world naturally created different definitions for the various products according to their historical development whereby in some countries the same terms are used for different products.

The uncertainty in the definition of the various terms used in the oil literature, as well as the large number of them, often led to serious mistakes. Many national and international committees and petroleum congresses have tried in vain to stipulate unique terms. Considering the historical development of some expressions and the American attempts at standardization by the American Society for Testing Materials, the German nomenclatures suggested by Professor Dr. von Höfer, the preliminary resolutions of the International Tariff Union, and the different customs declarations, a table has been made out with the endeavour to include in it all the present common terms used in the various countries in science and trade. To be sure in each case which product may be concerned, it must be known with certainty the province and the country from which the product comes. In the scientific literature on petroleum, however, the accuracy of the nomenclature has been improved in the last few years; but in the commercial language, used in the mineral-oil trade, many wrong and inadequate terms for the various products of the industry still exist.

To characterize the present immense confusion, it will be sufficient to indicate only a few typical examples of this industry both with regard to production as well as to distillation and trade.

The raw material, viz. the crude oil, is known in the United States as 'Crude Oil' or 'Petroleum'. In general only the word 'crude' will be added to the names of the localities where the crude oils are produced, so, for instance, 'Pennsylvania Crude', 'Texas Crude', 'Mexican Crude'.

In Russia for crude oil the term 'Neft' is generally in use, and in Roumania sometimes the old term 'Pacura'.

The development of internal combustion engines has increased the demand for light products, which are known in France as 'Essences', in America as 'Gasoline', and in Germany as 'Benzin'.

In America the motor fuels, made from the direct distillation of crude petroleum, are called 'Straight-run Gasoline', whereas others are known as 'Cracked Gasoline', also 'Navy Gasoline' or 'Artificial Gasoline'. Motor fuels from natural gas seldom have trade names, and never with regard to the export trade, because these motor spirits, produced generally from wet or dry gas, are generally used as blending materials for cracked gasolines. The mixture consists of natural gasoline or straight-run gasoline.

In the mineral oil trade we find many terms which are not clearly defined. So, for instance, 'Aviation Gasoline', 'Motor Gasoline', 'Mineral Spirits', 'Benzinum Purificatum' (for pharmaceutical purposes), and even expressions like 'Regular Gasoline', 'Aero Gasoline', 'Export Gasoline', 'Domestic Gasoline', &c.

For kerosine we find terms like: 'Water-white Kerosine', '300 Mineral Seal Oil', 'Signal Oil', 'Gas Oils for Diesel', 'Bunker Oil B', 'Bunker Oil A', 'Straw Oil'. To give the rather endless list of names of lubricating oils, paraffin waxes, petroleum jellies, goudrones, asphalts, bitumens, is quite impossible.

The oldest term known for liquid bitumen—in Germany called 'Erdöl' or 'Petroleum', 'Steinöl', 'Bergöl', 'Bergbalsam', especially 'Quirinusöl' (Tegernsee)—is 'Naphtha' or more correctly 'Nafta'.

In the following list some of the oldest terms for crude petroleum in the various countries are given:

- In England: 'Naphtha';
- in France: 'Naphte', 'Bitume liquide', 'Huile de naphte';
- in the Slav countries: 'Ropianka';
- in Roumania: 'Petrol', 'Păcură', 'Percureli';
- in Spain: 'Aceite de montana';
- in Argentine: 'Brea al quitron';
- in Tscherkessia: 'Kuda';
- in Japan: 'Sekinoyu', 'Kusodsu' (if water white), 'Sekischitza';
- in China: 'Shy-yu';
- in Burma: 'Yenan'.

The more viscous, tar to pitch-like natural bitumens have corresponding names like: 'Erdteer', 'Bergteer', 'Erdpech', 'Bergpech'. Dioscorides called them 'Pittolium' and 'Pittasphaltos', and Pliny 'Pissasphaltus', also 'Maltha' (soft paraffin wax). Some foreign indications run as follows:

- in English: 'Mineral Tar', 'Mineral Pitch';
- in French: 'Bitume visqueux', 'Bitume glutineux', 'Poix minéral', 'Graisse minérale';
- in Spanish: 'Brea'.

Of special importance appear the divergencies of the terms for the same product as used in the various countries. So, for instance, the English (American) word 'Petroleum' means 'Crude Oil', whereas in Germany only 'Rohöl' or 'Erdöl roh' and 'Naphta roh' respectively are used for this product. In the German-speaking countries the term 'Petroleum' is used only for the product which corresponds with the English 'Kerosine' ('Kerosene'), 'Paraffin Oil', and 'Paraffin'. In French the term for 'Crude Oil' is 'Huile brute' or 'Pétrole brut'.

This is rather one of the most characteristic examples for the variety of products of the same name in the various countries.

The English term 'Petrol' or 'Motor Spirit', and in America the term 'Gasoline' or more popularly 'Gas', is equal to the German definition for 'Benzin' (Motorbenzin) which in French is called 'Essence'.

'White Spirit', or 'Solvent Naphtha', called in America for short 'Naphtha', is equal to the German definition 'Lösungsbenzin' or 'Testbenzin'.

Comparatively little confusion exists for the term 'Gas Oil' and 'Fuel Oil'. The term 'Gas Oil' is used in England, America, and France ('Huile solaire'), and even in Russia.

The German expression 'Gasöl' has with regard to the pronunciation nearly the same sound.

The term 'Fuel Oil' (Residue) is nearly equal to the French word 'Residus'.

A special term is 'Ozokerit' which is called in Germany 'Bergwachs', on the Caspian Sea 'Naphthgil' or 'Neftgil', in America 'Gumbed', in France 'Cire fossile' or 'minérale'.

'Asphalt'—known also as black 'Erdharz' (black earth resin), 'Grubenharz' (pit resin)—is *already* mentioned by Herodotus, Aristotle, Strabo, Dioscorides, Pliny, and many others. Dioscorides, chapter 101, says: 'A certain substance, a filtrate of Babylonian asphalt, is called Naphtha of white colour; it can be also dark in colour. It is very inflammable.' The Bible often refers to it. In the following there are some older foreign terms for asphalt:

in English: 'Glance pitch';
in French: 'Bitume compact';
in the Slav language: 'Smola';
in the Hebrew language: 'Hemar' and 'Kofer';
in the old Arabian language: 'Chumal';
in the new Arabian language: 'Elhumar';
in the Assyrian language: 'Kupru', 'Amaru', 'Idulu';
in the Sumerian, that is, the Old-Babylonian language: 'Mur', 'Aschit';
in the old Syrian language: 'Abu th-thâbun (father of soap)';
in the Japanese language: 'Dorekioei', 'Teirekisa'.

'Kir', 'Kar', 'Katrau', 'Katirau' means an earth-paraffin-like, soily asphalt, found on the peninsula Apscheron near Baku.

In the Persian language:

'Maidan-i-Naphtun' or 'Maidan-i-Naphtek' means Oil Field;
'Naphte Sefid' is equal to White Kerosine;
'Sar-i-Naphtek' is equal to Oil Well.

The word 'Petroleum' comes from 'Petrae' (rock or stone) and 'Oleum' (oil), literally, therefore, stone oil. The word 'Kerosine' is derived from 'Ker', which in the Greek language means 'Wax', and the Latin 'Cerum'. 'Naphta', in Russian 'Neft', has been used in Galicia and Russia for crude oil. In America the word 'Naphtha' was used for heavy gasoline.

For motor spirit the most fantastic names were common, such as: 'Canadol', 'Rhigolen', 'Hydrier'; 'Gasolin' for light motor spirits, and 'Petroleumäther' (Kerosine-Ether), but 'Ligroin', 'Benzin', 'Naphtha' for heavy spirits. As time went on the trade names changed for the different products. 'Kerosene', at first introduced on the market by the Kerosene Oil Company, was substituted later on by illuminating oil made from crude oil, which first came to Europe in 1862 under the name 'Pittoel'. 'Kentucky Kerosine' was sold as 'American Medicinal Oil'. In England, for a long time, the American kerosine was considered as American paraffin oil in contradistinction to the kerosine produced from Scotch shale oil. The German term 'Petroleum' for illuminating oil does not correspond with the English definition, where the term 'Petrol' is used for motor fuels, nor with the American definition, where the term 'Petroleum' (Kerosine) is used for crude oil. The definition 'Keroselen' was used for paraffin oil, rectified stone oil, and photogen. On the other hand, the term 'Keroselen' was synonymous for a product which was called in Germany 'Petroläther'. The definition for heavy products is not a unique one. Solar oils were derived originally from brown coal tar and shale oil respectively. Later on, heavy kerosine was called in Russia solar oil like the refined intermediate fraction derived from kerosine.

With regard to the term 'Kerosene' the following may be stated. The English pronunciation of the English term 'Kerosene' is equal to the German pronunciation of the German term spelled 'Kerosin'. According to the suggestions of the Bureau of Standards the correct spelling of the English term is 'Kerosine'. In French 'Kerosine' is called 'Essence', also 'Essence à Pétrole' or 'Pétrole lampant'.

Confusion exists in regard to the nomenclature for asphalts, bitumens, and pitches. This depends on the classification and definition respectively, which conventional or scientific opinion is prepared to establish for mineral oil. At any rate, only the products derived from crude oil are to be termed 'Bitumen'.

The American Society for Testing Materials has published tentative definitions under A.S.T.M. Designation D. 288–35 T (cf. *Nomenclature of Petroleum Products—Nash and Hall*), while the Deutscher Normenausschuss (German Committee for Standardization), under DIN E 6511 and 6512, has drafted a list of standardized terms (in German) of the various mineral-oil products. A draft nomenclature of a 'Proposed Dictionary of Terms for the Petroleum Industry—ISA. 28' has been tentatively submitted for criticism by the International Standardization Association.

The following table (p. 6) includes comparative terms for the Nomenclature of Petroleum and Petroleum Products in various countries.

THE NOMENCLATURE OF PETROLEUM PRODUCTS

By Professor A. W. NASH, M.Sc., M.Inst.P.T., and F. C. HALL, Ph.D., A.M.Inst.P.T.
Department of Oil Engineering and Refining, University of Birmingham, England

THE nomenclature of petroleum and petroleum products is of an extensive and diverse character. In common with that of other industries, collaterally developed in more than one country, it suffers from a certain lack of uniformity and precision. The adoption of a uniform terminology, particularly in the English-speaking countries, is the subject of work in progress by the Institution of Petroleum Technologists in Great Britain, the American Society for Testing Materials in the United States, and similar bodies in other countries. A short list of tentative definitions of terms relating to petroleum has been issued by the American Society for Testing Materials and published under Designation D. 288–36T in *A.S.T.M. Standards on Petroleum Products and Lubricants*, 1936. Definitions for the following terms are included:

Crude Petroleum.	Oil Shale.
Crude Shale Oil.	Petroleum Grease.
End-point.	Petroleum Naphtha.
Engine Distillate.	Petroleum Spirits.
Fuel Oil.	Topped Crude Petroleum.
Gas Oil.	Tops.
Gasoline.	Weathered Crude Petroleum.
Kerosine.	

In the following pages is given a list of definitions for the more common terms relating to petroleum and its products, which may be encountered in the technical literature dealing with refining, testing, and marketing. Included in this are the definitions for petroleum products tentatively adopted by the American Society for Testing Materials.

The nomenclature of the bitumens and asphalts, and the nomenclature of crude oil and mineral oil products in different countries, are dealt with in separate contributions and are not included herein.

Free use has been made of many authorities in compiling these definitions, to whom acknowledgement is made.

ABSORPTION GASOLINE. Natural gasoline made by the oil absorption process.

ABSORPTION OIL, STRIPPING OIL, SCRUBBING OIL, WASH OIL. An oil used in the absorption process for absorbing volatile hydrocarbon oil vapours from a gas, exemplified in the recovery of gasoline from natural (casing-head) gas, and of benzole from coke-oven gas. The oil should have an initial boiling-point considerably higher than the final boiling-point of the absorbed spirit.

ACID SLUDGE, ACID TAR. The sludge produced during the chemical refining of hydrocarbon oils with sulphuric acid. It contains free sulphuric acid, hydrocarbon material, and complex organic derivatives of sulphur acids, and may vary from a mobile tar (gasoline refining) to a viscous pitch-like material (lubricating-oil refining).

AIR-BLOWN ASPHALT. *See* Blown Asphalt.

ASPHALT. In England the term asphalt is applied to natural or mechanical mixtures in which asphaltic bitumen is associated with inert mineral matter, and should be qualified by another term indicating the origin of the product.

In the United States the following definition is adopted: Black to dark brown solid or semi-solid materials which gradually liquefy when heated, in which the predominating constituents are bitumens, all of which occur in the solid or semi-solid form in nature or are obtained by refining petroleum, or which are combinations of the bitumens mentioned with each other or with petroleum or derivatives thereof. (A.S.T.M. Designation D. 8–33.)

ASPHALT-BASE CRUDE PETROLEUM. *See* Base of Crude Petroleum.

ASPHALTIC BITUMEN. Natural or naturally occurring bitumen, or bitumen prepared from natural hydrocarbons by distillation or oxidation or cracking; solid or viscous, containing a low percentage of volatile products; possessing characteristic agglomerating properties, and substantially soluble in carbon disulphide.

AVIATION GASOLINE, AVIATION SPIRIT. A special grade of gasoline suitable for use in aeroplane engines. A product of high volatility, knock rating, and degree of refining.

BASE OF CRUDE PETROLEUM. The 'base' of a crude petroleum is descriptive of the chemical nature of its main constituents. A petroleum may be described as paraffin base, asphalt base, or mixed base (intermediate base), according as paraffin wax, asphalt, or both paraffin wax and asphalt are present in the residue after distillation of the lighter components. Typical representatives of these three classes are Pennsylvanian, Mexican, and Mid-Continent petroleums respectively. The term 'naphthene base', sometimes used synonymously for 'asphalt base', is preferably retained for such crude petroleums as Russian, of non-paraffinic character, but containing a relatively low proportion of asphalt (the term 'asphalt' referring to the U.S. definition). A more precise system of nomenclature and method of differentiation is that of the United States Bureau of Mines.

BENZINE. An indefinite term, the use of which is to be avoided, which is loosely applied to any refined, volatile, hydrocarbon distillate, especially that obtained from the fractional distillation of petroleum. To be distinguished from the aromatic hydrocarbon *Benzene*.

BENZINUM PURIFICATUM. The 'Purified Petroleum Benzine' of the United States Pharmacopoeia. A purified distillate from American petroleum, of sp. gr. 0·634–0·660 at 25° C. and distilling completely between 35 and 80° C.

BENZOLE, BENZOL. Commercial name applied to benzene, not necessarily pure, and to liquid distillates containing a high proportion of benzene and its homologues (toluene and xylene). The term '50/90's Benzole' refers to a product of which 50% distils up to 100° C. and 90% to 120° C., while '90's Benzole' ('90 per cent. benzole') yields 90% between 80 and 100° C. See Motor Benzole.

BITUMENS. Mixtures of hydrocarbons of natural or pyrogenous origin, or combinations of both frequently accompanied by their non-metallic derivatives, which may be gaseous, liquid, semi-solid or solid, and which are completely soluble in carbon disulphide. (A.S.T.M. Designation D. 8–33.)

BITUMINOUS EMULSION. A liquid product for application to road surfaces, in which a substantial amount of

asphaltic bitumen or other bituminous road-binder is suspended in finely divided condition in an aqueous medium by means of one or more suitable emulsifying agents.

BLACK OIL. A term generally applied to any dark-coloured lubricating oil of relatively high asphalt content, suitable for rough uses or heavy lubrication.

It has been used in Great Britain to designate such petroleum products as gas oil, diesel oil, and fuel oil, to the exclusion of gasoline, white spirit, kerosine, and lubricating oils, but its use in this connexion is to be deprecated.

BLAU GAS. A mixture of gaseous and volatile hydrocarbons with hydrogen, used for fuel purposes and prepared by the thermal decomposition (high-temperature cracking) of hydrocarbon oils. The gas may be compressed and liquefied before use, in which case hydrogen and other uncondensable gases will be absent.

BLOWN ASPHALT. Asphalt (U.S. definitions), or Asphaltic bitumen, obtained by blowing air through petroleum residua, or natural bituminous substances, heated during the blowing process.

BLOWN OILS. Products obtained by the action of air upon oils at an elevated temperature. The process is carried out to change the physical characteristics, e.g. to increase the viscosity.

BLUE OIL. Term frequently applied, in Great Britain, to *Pressed Distillate*.

BOTTOMS. The residue left in a still after distillation; the undistilled liquid and condensate drawn off from the bottom of a fractionating tower, dephlegmating column, or similar apparatus.

BOTTOM SEDIMENTS, 'B.S.'. The sediment which settles out from a crude petroleum or fuel oil during storage, usually an emulsified mixture of oil and water with wax, asphalt, mud, and other extraneous material.

BRIGHT STOCK. High-viscosity lubricating oils, prepared from cylinder stock by dewaxing and earth filtration. The term is also applied to viscous distillate stocks from certain mixed-base and naphthene-base crudes. Bright stocks are used chiefly as a blending medium in the production of lubricating oils for automobile and aeroplane engines.

BURNING OIL. Term commonly applied to kerosine and similar oils suitable for burning in lamps and stoves.

BUTANE. Generic name for the paraffin hydrocarbons of formula C_4H_{10}, *n*-butane (b.p. $+0{\cdot}6°$ C.) and *iso*-butane (b.p. $-10{\cdot}2°$ C.). The term is applied to commercial liquefied (fuel) gases, containing chiefly butane and/or the unsaturated *butenes*, and separated from natural and refinery gases.

CABLE OIL. An oil used for the impregnation of electric transmission cables.

CARBON BLACK. A product, essentially very finely divided carbon, prepared by the regulated, incomplete combustion of hydrocarbon gases, or of inflammable oils, or by the thermal or electrical decomposition of hydrocarbon gases.

CASING-HEAD GAS. Name applied to the gas which issues from the casing-head of oil-wells. *See* Natural Gas.

CASING-HEAD GASOLINE. *See* Natural Gasoline.

CERESINE. A white or yellow, opaque, wax-like solid, obtained from *Ozokerite* by suitable refining treatment. Ceresine is an amorphous mixture of solid hydrocarbons, related to paraffin wax, but usually of higher melting-point (70–80° C. e.g.).

CLEANERS' NAPHTHA, CLEANERS' SOLVENT. A refined petroleum fraction used in the dry cleaning of clothing, with a boiling range which normally lies between 100 and 200° C.

COAL OIL. Crude oil obtained by the distillation of coal. The term has, in the past, been incorrectly applied to kerosine.

COMPOUNDED OIL. A mineral oil compounded or blended with animal, vegetable, or similar oils.

CRACKED DISTILLATE. A distillate obtained from the cracking process, or from a distillation in which some cracking has occurred.

CRACKED GASOLINE, CRACKED NAPHTHA. Gasoline or naphtha obtained by the cracking process—a process involving molecular decomposition by which low-boiling products are obtained from higher boiling materials through thermal treatment.

CRACKING GAS, CRACKER GAS. Gas obtained as a by-product in the cracking process, and characterized by the presence of unsaturated hydrocarbons.

CRACKING STOCK. Any oil or similar product which is utilized as starting material for the cracking process.

CRUDE NAPHTHA. Naphtha in an unrefined state.

CRUDE OIL, CRUDE. A synonym for *Crude Petroleum*. Descriptive of any oil in an unrefined state.

CRUDE PETROLEUM. A synonym for *Petroleum* as obtained in the natural state, denoting the absence of any refining other than the possible removal of gas, water, and other extraneous material. *See* Petroleum.

The American Society for Testing Materials define crude petroleum as: A naturally occurring mixture, consisting predominantly of hydrocarbons, and/or sulphur, nitrogen, and/or oxygen derivatives of hydrocarbons, which is removed from the earth in liquid state or is capable of being so removed.

Note. Crude petroleum is commonly accompanied by varying quantities of extraneous substances such as water, inorganic matter, and gas. The removal of such extraneous substances alone does not change the status of the mixture as crude petroleum. If such removal appreciably affects the composition of the oil mixture, then the resulting product is no longer crude petroleum. (A.S.T.M. Designation D. 288-36T.)

CRUDE SHALE OIL. The oil obtained as a distillate by the destructive distillation of oil-shale. (A.S.T.M. Designation D. 288-36T.)

CUT. Term applied to any fraction obtained by distillation or other selective separatory process.

CUT-BACK PRODUCT. A residuum which has been 'cut back', 'fluxed', or diluted by blending with a distillate fraction. A heavy oil blended with a lighter oil to bring it to a desired specification. *See* Flux Oil.

CUTTING OIL. An oil used for the lubrication and cooling of metal cutting tools. Cutting oils may comprise straight or compounded lubricating oils, used as such, or soluble oils used in the form of an emulsion with water.

CYLINDER STOCK. Viscous residual oils obtained by the distillation of certain crude petroleums of low asphalt content, and used for steam-cylinder lubricating oils, and in the preparation of *Bright Stock*.

DEBUTANIZED GASOLINE. *See* Stabilized Gasoline.

DIESEL ENGINE OIL. A lubricating oil used for the lubrication of Diesel engines.

DIESEL OIL, DIESEL FUEL. A special grade of fuel oil for Diesel engines.

DRY GAS. A gas containing a relatively low proportion of

readily condensable constituents, e.g. a natural gas of low recoverable gasoline content. *See* Natural Gas.

DRYING OIL. An oil subject to ready oxidation which, on exposure in thin layers to the atmosphere, is converted to a relatively hard elastic film.

DUST-LAYING OILS. *See* Road Oils.

EDELEANU EXTRACT. That portion of an oil extracted by liquid sulphur dioxide in the Edeleanu refining process. Term usually refers to that from the refining of kerosines, comprising a highly aromatic oil, frequently of high sulphur content.

EMULSIFIABLE OIL. *See* Soluble Oil.

END-POINT. The highest temperature reading observed on the distillation thermometer during the distillation procedure conducted in accordance with the Standard Method of Test for Distillation of Gasoline, Naphtha, Kerosine, and Similar Petroleum Products (A.S.T.M. Designation D. 86) and the Standard Method of Test for Distillation of Natural Gasoline (A.S.T.M. Designation D. 216) of the American Society for Testing Materials (A.S.T.M. Designation D. 288–36T).

ENGINE DISTILLATE. A refined or unrefined petroleum distillate similar to naphtha, but often of higher distillation range. (A.S.T.M. Designation D. 288–36T.)

ENGINE OIL. Lubricating oil of moderate viscosity suitable for the lubrication of exposed bearings (not cylinder lubrication) of internal-combustion (gas) engines and steam engines.

ETHYL FLUID. A liquid product containing over 50% lead tetraethyl, used by the Ethyl Gasoline Corporation, for blending with motor spirits to improve their anti-knock characteristics.

ETHYL GASOLINE, ETHYLIZED FUEL. A gasoline or motor spirit containing a proportion of *Ethyl Fluid.*

EXTRACT. Term applied, in solvent-refining processes, to that portion of the oil which is dissolved in and removed by the selective solvent used.

FILTERED STOCK. A lubricating stock which has been filtered through fuller's earth or other filtering medium.

FLOTATION OIL. An oil used in the flotation process of concentrating mineral ores.

FLUX, FLUX OIL. (1) A liquid residuum from asphalt-base crude petroleums. (2) An oil for blending with asphaltic or bituminous materials for the purpose of softening or reducing their consistency. *See* Cut-back Product.

'FOOTS' OIL, 'SWEATS'. A mixture of oil and soft paraffin wax which separates during the sweating process, in the production of paraffin wax from slack wax. It is usually returned to the paraffin distillate for re-pressing.

FUEL OIL. A very general term which may be applied to any oil used for the production of power and heat.

In a more restricted sense it is applied to any oil or liquefiable product burned for the generation of heat in a domestic or industrial furnace or firebox, or for the generation of power in a Diesel engine, excluding oils burned in wick burners. Fuel oils in common use fall into one of four classes:

(1) residual fuel oils, which are topped crude oils or viscous residua obtained in refining operations;
(2) distillate fuel oils, which are distillates derived from crude petroleum, coal oil, or other suitable material;
(3) crude petroleums and weathered crude petroleums of relatively low commercial value;
(4) blended fuels, which are mixtures of two or more of the preceding classes.

Under A.S.T.M. Designation D. 288–36T, this definition is further restricted to petroleum products with a closed flash-point above 100° F.

GAS. Term commonly applied to gasoline, in the United States, by the motoring public.

GAS BLACK. A form of carbon black, prepared by the incomplete combustion of hydrocarbon gases.

GAS OIL. A liquid hydrocarbon distillate, generally from petroleum, of viscosity and boiling range intermediate between those of kerosine and lubricating oil. Suitable grades of gas oil are used for absorption oils, for Diesel oils, as cracking stock, and in the manufacture of oil gas by high-temperature cracking. Oils other than gas oil, as defined above, may be, and are, used for the manufacture of gas.

The following tentative definition is accepted by the American Society for Testing Materials: A liquid petroleum distillate having a viscosity intermediate between that of kerosine and lubricating oil. (A.S.T.M. Designation D. 288–36T.)

GASOLINE. Commercial name applied to a refined hydrocarbon distillate, usually restricted to that of petroleum origin, of characteristics suiting it for use as a carburetting fuel in internal-combustion engines. Originally prepared only from the first distillate cut of crude petroleum, gasoline now includes 'natural gasoline' recovered from natural gas, 'polymer gasoline' from the polymerization of hydrocarbon gases, and 'cracked gasoline' from the cracking of heavier oils. Commercially marketed gasolines are usually a blend of two or more of these products, and may in addition contain dopes such as lead tetraethyl, and other fuels such as benzole and alcohol. The boiling range of gasolines varies, but lies usually within the range 30–200° C. (85–390° F.).

The following definition is accepted by the American Society for Testing Materials: A refined petroleum naphtha which by its composition is suitable for use as a carburant in internal-combustion engines. (A.S.T.M. Designation D. 288–36T.) *See* Petrol, Motor Spirit.

GAS SPIRIT. Term applied, particularly in coal carbonization practice, to the mixture of volatile liquid hydrocarbons extracted from a gaseous mixture by the application of compression, absorption, or adsorption processes.

GREASE. *See* Lubricating Grease.

GUM. In the petroleum industry the term is descriptive of resin-like, insoluble deposits formed through the deterioration of petroleum and its products, particularly gasoline. The tendency of a gasoline to deposit gum, either on evaporation or during storage, is a factor of importance in its evaluation, and may be especially pronounced in cracked distillates. 'Existent Gum' or 'Preformed Gum' is the number of milligrams of residue from the evaporation of 100 ml. of a gasoline or motor spirit under specified conditions. 'Potential Gum' refers to the gum which is deposited by a gasoline or motor spirit, during storage, or under accelerated ageing conditions.

HARD PARAFFIN. *See* Paraffinum Durum.

HEAVY ENDS. The relatively high-boiling components of a distillate fraction.

HEAVY OILS. In the Excise Tariff of Great Britain, the term heavy oils refers to hydrocarbon oils other than light oils. *See* Light Oils.

HYDROSOLVENTS. Term applied to synthetic hydrocarbon solvents, of high aromatic content, obtained from petroleum oils by a combination of hydrogenation and cracking at relatively high temperatures and low pressures.

ICHTHYOL. An oily product of high sulphur content, used for pharmaceutical purposes, prepared by the sulphonation of shale oil and subsequent neutralization with ammonia.

ILLUMINATING OIL. An oil suitable for burning as an illuminant. *See* Burning Oil, Kerosine.

INHIBITOR. A substance which, when present in relatively small proportions, will arrest or suppress a chemical reaction. Inhibitors (notably amino and phenolic compounds) are used for suppressing gum formation in motor spirit.

INSULATING OILS, ELECTRICAL INSULATING OILS. Oils used in circuit-breakers, switches, transformers, and other electrical apparatus for the purpose of insulation, or cooling, or both. In general, insulating oils are well-refined petroleum distillates of low volatility, showing particularly high resistance to oxidation and sludging, which possess viscosities ranging from that of *Mineral Seal Oil* to those of light lubricants.

Iso-OCTANE. Commercial name for 2:2:4:trimethylpentane, C_8H_{18}, an iso-paraffin hydrocarbon used as a primary standard in the knock rating of motor fuels. It is prepared from the butylene fraction of cracking gas, by polymerization and hydrogenation.

KEROSINE, KEROSENE. A refined hydrocarbon distillate from petroleum, shale oil, or similar material, which is the intermediate product between gasoline and gas oil, and which normally distils within the range 150–300° C. Kerosines marketed in Great Britain and in the United States are required by legislation to have a closed flash-point not lower than 73° F. in the Abel Tester, and, in general, are oils suitable for use as illuminants when burned in wick lamps. Special kerosines (e.g. Power Kerosines) are also produced for other specific purposes.

The following tentative definition is accepted by the American Society for Testing Materials: A refined petroleum distillate having a flash-point not below 73° F. (23° C.), as determined by the Abel Tester (which is approximately equivalent to 73° F. (23° C.) as determined by the Tag Closed Tester, A.S.T.M. Standard Method D. 56) and suitable for use as an illuminant when burned in a wick lamp.

Note. In the United States of America local ordinances or insurance regulations require flash-points higher than 73° F. (23° C.), Tag Closed Tester. (A.S.T.M. Designation D. 288–36T.)

LAMP OIL. *See* Illuminating Oil, Burning Oil, Kerosine.

LEADED FUEL. A motor fuel containing lead tetraethyl. *See* Ethyl Gasoline.

LEAN GAS. A *Dry Gas*, or one which has been denuded of its more condensable constituents.

LIGHT DISTILLATE. Term applied to relatively low-boiling distillates, such as gasoline and kerosine fractions, usually boiling below 300° C. *See* Naphtha.

LIGHT OILS. In the Excise Tariff of Great Britain, the term light oils refers to hydrocarbon oils of which not less than 50% by volume distils at a temperature not exceeding 185° C., or of which not less than 95% by volume distils at a temperature not exceeding 240° C., or which give off an inflammable vapour at a temperature of less than 22·8° C. (73° F.), when tested in the manner prescribed by the Acts relating to petroleum.

LIGHT PETROLEUM. *See* Petroleum Leve.

LIQUID PARAFFIN. *See* Paraffinum Liquidum.

LIQUID PETROLATUM. *See* Petrolatum Liquidum.

LONG RESIDUUM. A residuum from a paraffin-base or mixed-base crude petroleum, of relatively low flash-point, containing all the lubricating-oil fractions, and frequently lighter fractions, of the original crude.

LONG-TIME BURNING OIL. A particularly high-grade burning oil for illuminating purposes, similar to *Mineral Seal Oil*, and used in signal lamps, &c.

LUBE OIL, LUBE. Abbreviated form of Lubricating Oil, Lubricant.

LUBRICATING GREASE. A solid or semi-solid oily material used for certain classes of lubrication. Petroleum lubricating greases are combinations of petroleum products, generally lubricants, with a soap or mixture of soaps. *See* Petroleum Grease.

LUBRICATING OIL. Any liquid oil used for the purpose of lubrication. Lubricating oils may be animal, vegetable, petroleum, or other products, or mixtures of these. Petroleum lubricating oils may be distillates or residues and may vary in viscosity from very mobile spindle oils to extremely viscous cylinder stocks.

MACHINE OIL, MACHINERY OIL. A lubricating oil suitable for the lubrication of the moving parts of machinery, not subject to extreme conditions of temperature, pressure, or rubbing speed.

MATCH WAX. A paraffin wax of low melting-point, usually 105–115° F., chiefly used for the impregnation of match splints.

MAZOUT. A term sometimes applied to crude petroleum residues after distillation and removal of the more volatile components. (Russian.)

MEDICINAL OIL. *See* Paraffinum Liquidum, Petrolatum Liquidum.

MEDICINAL PARAFFIN. *See* Paraffinum Liquidum.

MIDDLE OIL. A fraction distilling chiefly between 200 and 300° C. The term *Middle Oil Distillate* is sometimes applied in petroleum refining to the fraction known as gas oil.

MINERAL COLZA OIL. *See* Mineral Seal Oil.

MINERAL JELLY. *See* Petrolatum.

MINERAL OIL. Any oil obtained from a mineral source, including the liquid products and distillates from crude petroleum, shale oil, coal tar, &c.

MINERAL SEAL OIL. A refined petroleum distillate intermediate between kerosine and gas oil. *Mineral Colza* oil is a similar product.

MINERAL SPIRITS. *See under* Petroleum Spirits.

MIXED-BASE CRUDE PETROLEUM. *See under* Base of Crude Petroleum.

MONTAN WAX, MONTANIN WAX. A wax obtained by distillation or extraction of lignite.

MOTOR FUEL. Any material suitable for use as a fuel in an internal-combustion engine.

MOTOR SPIRIT. Generic name for volatile liquid fuels suitable for use as carburetting fuels in internal-combustion engines. The term is very general and includes petroleum and shale-oil products, low-temperature coal carbonization spirits, benzole, alcohols, mixtures of these, and other suitable volatile and combustible liquid mixtures, together with anti-detonation dopes such as lead tetraethyl.

The term *Gasoline* is preferred in the United States for motor spirits of predominantly petroleum origin, while in Great Britain the term *Petrol* is commonly accepted.

NAPHTHA. A general term applied to the lower boiling liquid fractions, or the first distillation cut, obtained from petroleum, shale oil, coal tar, and similar sources, and during such refining operations as cracking, poly-

merization, reforming, and stripping. It is usually confined to fractions which distil below 250 to 300° C., and may refer to the crude or refined product. *See* Petroleum Naphtha.

NAPHTHENE-BASE CRUDE PETROLEUM. *See under* Base of Crude Petroleum.

NAPHTHENIC OIL. Term applied to hydrocarbon oils of relatively high carbon/hydrogen ratio and of predominantly cyclic chemical structure, such as are obtained from naphthene- and asphalt-base crude petroleums. *See* Paraffinic Oil.

NATURAL GAS. A gaseous mixture, generally of predominantly hydrocarbon composition (but which may contain carbon dioxide, hydrogen sulphide, nitrogen, helium, &c.), found in nature. It is frequently associated directly with petroleum of which it may then be regarded as the gaseous component, and is a factor of considerable importance in its recovery and conservation. The hydrocarbon constituents of natural gas, chiefly methane, with varying proportions of its chemical homologues ethane, propane, butane, &c., are closely related to, or identical with, those present in petroleum and, in so far as both natural gas and petroleum are capable of existing in the liquid or gaseous state under suitable conditions of temperature and pressure, no strict distinction can therefore be made between them.

Natural gas may be classified as 'wet' or 'dry' according as it contains a relatively large or small proportion of gasoline constituents (propane, butanes, pentanes, &c.) recoverable by suitable means, the figure of 1 gal. of gasoline per 1,000 cu. ft. of gas being commonly accepted as the limiting amount.

NATURAL GASOLINE, CASING-HEAD GASOLINE. A low-boiling liquid petroleum product, consisting of the heavy hydrocarbons extracted from *Natural Gas* by the application of compression, absorption, adsorption, or other processes. Natural gasoline has a Reid vapour pressure of 10–34 lb. per sq. in. at 100° F., and should show 25–85% evaporated at 140° F. and not less than 90% at 275° F. (National Gasoline Association of America). In the unstabilized condition—Wild Gasoline—it contains a relatively high proportion of propane and butanes of high vapour pressure. By stabilization or debutanization the propane and part of the butanes are removed, yielding a stabilized gasoline, of relatively low vapour pressure, suitable for blending purposes.

NEUTRAL OILS, NEUTRALS. Lubricating oils, of low and medium viscosity, from the further treatment of the *Pressed Distillate*, or *Blue Oil*, produced in dewaxing practice. Neutral oils are chiefly used as lubricating-oil stocks for blending purposes.

The term is now commonly used to include any distillate lubricating oil of low or medium viscosity, whether from paraffinic or asphalt-base crudes.

NON-SLUDGING OIL. An oil resistant to the deposition of sludge during service. *See* Electric Insulating Oil.

NON-VISCOUS NEUTRAL OIL. A neutral oil of viscosity lower than 135 sec. Saybolt Universal at 100° F.

NORMAL BENZINE. A highly refined petroleum distillate used in Germany for the estimation of asphaltenes. It is free from unsaturated and aromatic hydrocarbons, has an aniline-point of approximately 60° C., and a boiling range of 65–95° C.

OCTANE. *See Iso*-OCTANE.

OILFIELD EMULSION. Emulsions of crude petroleum and water, with other material, obtained in oilfield production practice.

OIL FUEL. Term restricted to *Fuel Oils* burnt for steam-raising purposes.

OIL GAS. An inflammable gas, containing a high proportion of hydrocarbons, obtained by the destructive thermal decomposition of oils. *See* Blau Gas.

OIL SHALE. A naturally occurring rock, which may be petrographically classed as a shale, and which, upon destructive distillation, will yield an oil resembling crude petroleum.

The following tentative definition is accepted by the American Society for Testing Materials: A compact rock of sedimentary origin, with an ash content of more than 33% and containing organic matter that yields oil when destructively distilled, but not appreciably when extracted with the ordinary solvents for petroleum. (A.S.T.M. Designation D. 288–35T.)

OZOKERITE. A naturally occurring waxy mixture of hydrocarbons, related to petroleum, found in certain parts of eastern Europe, America, &c. *See* Ceresine.

PAINTERS' NAPHTHA. *See* Petroleum Spirits, White Spirit.

PAINT THINNERS. *See* Petroleum Spirits, White Spirit.

PALE OILS. General term applied to any low- or medium-viscosity petroleum lubricating oil of pale colour. Formerly restricted to the light-coloured *Neutral Oils* obtained as distillates from the treatment of pressed distillate or blue oil.

PARAFFIN. (1) Term applied to a member of the paraffin series of hydrocarbons of composition C_nH_{2n+2}.

(2) An alternative name used for paraffin wax. *See* Paraffinum.

(3) Paraffin, Paraffin Oil are names commonly applied by the public in Great Britain to kerosine.

PARAFFIN-BASE CRUDE PETROLEUM. *See under* Base of Crude Petroleum.

PARAFFIN DISTILLATE, WAX OIL. A lubricating-oil distillate fraction containing paraffin wax in a crystalline form, suitable for chilling and filter-pressing.

PARAFFINIC OIL. Term applied to hydrocarbon oils of relatively low carbon/hydrogen ratio and of predominantly open-chain (aliphatic) chemical structure, such as are obtained from paraffin-base crude petroleums. *See* Naphthenic Oil.

PARAFFIN OIL. A distillate lubricating oil from paraffinic or mixed-base crude petroleums.

The term is in common use in Great Britain to designate kerosine.

PARAFFIN SCALE. The residual crude paraffin wax obtained after the process of sweating the *Slack Wax*.

PARAFFIN SLACK WAX, SLACK WAX. The crude soft paraffin wax obtained by chilling and filter-pressing paraffin distillate or wax distillate.

PARAFFINUM. The 'Paraffin' of the United States Pharmacopoeia. A purified paraffin wax obtained from petroleum, of m.p. 50–57° C. and suitable for pharmaceutical purposes.

PARAFFINUM DURUM. The 'Hard Paraffin' of the British Pharmacopoeia. A purified paraffin wax obtained from petroleum or shale oil, of m.p. 50–60° C.

PARAFFINUM LIQUIDUM. The 'Liquid Paraffin' of the British Pharmacopoeia. A highly refined white petroleum oil used for medicinal purposes, of sp. gr. 0·880–0·895 and viscosity not less than 260 sec. Redwood at 37·8° C. (100° F.). 'Paraffinum Liquidum Leve', light liquid paraffin, or spray paraffin, is used as a vehicle for

oil-spraying solutions, and has a viscosity and specific gravity lower than those of liquid paraffin.

PARAFFINUM MOLLE. The 'Soft Paraffin' of the British Pharmacopoeia. A highly refined petrolatum available in two grades, yellow (flavum) and white (album), of melting-point between 38 and 46° C., and suitable for medicinal purposes.

PARAFFIN WAX. A mixture of solid hydrocarbons of the paraffin series, obtained from petroleum, from the distillation of shale, from the low-temperature distillation of coal, and from other sources. In the purified state, paraffin wax is a colourless, more or less translucent mass without taste or odour, crystalline when separating from solution, and slightly greasy to the touch. The melting-point of a paraffin wax may vary widely over a considerable range according to the source and mode of preparation of the wax. That of typical commercial varieties may vary from 40 to 60° C. (105–140° F.).

PEPPER SLUDGE. A fine suspension of acid sludge remaining dispersed in a sulphuric acid treated oil, after the main bulk of the acid sludge has settled out.

PETROL. Term commonly used in Great Britain for *Motor Spirit* or *Gasoline*.

PETROLATUM, PETROLEUM JELLY. A purified semi-solid mixture of hydrocarbons, of paste-like consistency, obtained from petroleum. Petrolatum is a naturally occurring mixture containing soft amorphous paraffin wax with viscous oil, obtained in the dewaxing of residual paraffin-base cylinder stocks.

PETROLATUM. The 'Petrolatum' of the United States Pharmacopoeia. A highly purified product of sp. gr. 0·820–0·865 at 60° C., melting between 38 and 54° C.

PETROLATUM LIQUIDUM. The 'Liquid Petrolatum' of the United States Pharmacopoeia. A highly refined white petroleum oil, known also as liquid paraffin or white mineral oil, used for medicinal and pharmaceutical purposes. Light liquid petrolatum (used for atomization) has a kinematic viscosity of not more than 0·370 at 37·8° C., while heavy liquid petrolatum has a viscosity not less than 0·381.

PETROLEUM. Petroleum, in its widest sense, may be considered to embrace all hydrocarbons, solid, liquid, and gaseous, occurring in nature. It is more precisely defined as a material, occurring naturally in the earth, which is predominantly composed of mixtures of chemical compounds of carbon and hydrogen with or without other non-metallic elements such as sulphur, oxygen, nitrogen, &c. Petroleum may contain, or be composed of, such compounds in the gaseous, liquid, and/or solid state, depending on the nature of these compounds and the existent conditions of temperature and pressure; it may, and frequently does, contain other extraneous material, including non-hydrocarbon gases, water, and earthy matter, in admixture. That portion of petroleum which, under normal conditions, is in the gaseous state, is commonly termed 'Natural Gas' (although the term 'Natural Gas' may not be restricted to this definition), but it should be understood that, in so far as all compounds are capable of existing in the solid, liquid, or gaseous states, depending upon the conditions of temperature and pressure, no strict distinction can rightly be drawn between gaseous, liquid, or solid components of petroleum. *See* Crude Petroleum; Natural Gas; Base of Crude Petroleum.

PETROLEUM ASPHALT. An asphalt (U.S. definition) obtained by suitable treatment from petroleum or its products. The distillation residue from an asphalt-base crude petroleum.

PETROLEUM COKE. The solid carbonaceous material obtained as a residue from the destructive distillation of petroleum, as in cracking and coking distillation practice.

PETROLEUM ETHER. A purified low-boiling petroleum fraction, usually with a boiling range below 120° C. 60–80 petroleum ether refers to a product distilling between 60 and 80° C.

PETROLEUM GREASE. A semi-solid or solid combination of a petroleum product and a soap or a mixture of soaps, with or without fillers, suitable for certain classes of lubrication. (A.S.T.M. Designation D. 288–36T.)

PETROLEUM JELLY. *See* Petrolatum.

PETROLEUM LEVE. The 'Light Petroleum' of the British Pharmaceutical Codex. A refined distillate from the lower boiling fractions of natural petroleum, shale oil, low-temperature tar, or products of hydrogenation of coal or cracking of oils; 95% distils between 40 and 60° C.

PETROLEUM NAPHTHA. A generic term applied to refined, partly refined, or unrefined petroleum products and liquid products of natural gas, not less than 10% of which distils below 464° F. (240° C.) when subjected to distillation in accordance with the standard method of test for distillation of gasoline, naphtha, kerosine, and similar petroleum products (A.S.T.M. Designation D. 86) of the American Society for Testing Materials.

Note. The 'naphthas' used for specific purposes, such as cleaning, manufacture of rubber, manufacture of paints and varnishes, &c., are made to conform to specifications which may require products of considerably greater volatility than that set by the limits of the generic definition.

(Tentative Definition, A.S.T.M. Designation D. 288–36T.)

PETROLEUM SPIRITS, WHITE SPIRITS. A refined petroleum distillate with a minimum flash-point of 70° F. (21° C.), determined by the Tag Closed Tester in accordance with the standard method of test for flash-point of volatile inflammable liquids (A.S.T.M. Designation D. 56) of the American Society for Testing Materials, or by the Abel Tester, with volatility and other properties making it suitable as a thinner and solvent in paints, varnishes, and similar products.

Note. The term 'turpentine substitute', as applied to petroleum spirits, is to be condemned as false and misleading. The term 'Mineral Spirits' is a misnomer, as it includes within its scope not only petroleum products, but other hydrocarbon mixtures such as coal tar distillates. In Great Britain the term 'Petroleum Spirits' is applied to a very light hydrocarbon mixture having a flash-point below 32° F. (0° C.).

(Tentative Definition, A.S.T.M. Designation D. 288–35T.)

PINTSCH GAS. *See* Oil Gas.

PITCH. The solid residue from the distillation of coal tar. The term should not be applied to petroleum products, unless qualified by the prefix 'petroleum'.

POLYMER GASOLINE. Gasoline obtained by the polymerization of gaseous hydrocarbons, by thermal, catalytic, or other means.

POWER KEROSINE. Kerosine of such characteristics suiting it for use as a carburetting fuel in internal-combustion engines. Power kerosines, known also as Tractor Oils and Power Vaporizing Oils, have relatively high overall

volatility and anti-knock rating in comparison with *Burning Oils*.

PRESSED DISTILLATE, BLUE OIL. The oil obtained by chilling and filter-pressing the paraffin distillate or wax distillate, prior to the finishing treatment for the production of *Neutral Oils*.

PRESSURE DISTILLATE. The crude distillate obtained from the cracking process prior to final fractionation and refining.

PROPANE. A gaseous paraffin hydrocarbon of formula C_3H_8 (b.p. $-44{\cdot}5^\circ$ C.), which may be separated from natural and refinery gases; used, in the compressed state, as a fuel gas.

QUENCHING OIL. An oil used for cooling metal components in hardening and tempering operations. Also termed Tempering Oil, Hardening Oil.

RAFFINATE. Term applied, in solvent-refining practice, to that portion of the oil which remains undissolved and is not removed by the selective solvent used.

RECOVERED ACID. Sulphuric acid which has been recovered, for subsequent re-utilization, from the acid sludge produced during the sulphuric acid refining of mineral oils.

RECOVERED OIL. Used lubricating oil which has been recovered and purified for subsequent re-utilization.

RED OIL. General term applied to transparent dark-coloured distillate lubricating oils. Formerly restricted to the darker coloured *Neutral Oils* obtained as residuals in the treatment of *Pressed Distillate* or *Blue Oil*.

REDUCED OIL. An oil from which the more volatile constituents have been removed by distillation.

REFERENCE FUEL. A fuel of accurately standardized characteristics used as a reference standard in the engine-testing of motor fuels, as, for example, in the routine determination of Octane Numbers and Cetane Numbers.

REFINERY GASES. Hydrocarbon gases produced during petroleum-refining operations, such as cracking, distillation, and stabilization.

REFORMED GASOLINE. A gasoline obtained by the reforming process, in which a material of low octane number (a straight-run gasoline for example) is subjected to cracking at relatively high temperatures and pressures to yield a product of substantially similar boiling range but of higher octane number.

RE-RUN OIL. An oil subjected to redistillation.

RESIDUAL ASPHALT. The untreated asphaltic residue from the distillation of an asphalt-base crude petroleum.

RESIDUUM. The residue obtained from the distillation of crude petroleum after gasoline, kerosine, and sometimes heavier distillates have been taken off.

RESINS. The term has been loosely applied to those constituents of an oil extracted by adsorbent earths such as fuller's earth, and which in turn can be extracted from the earth by benzene, chloroform, or similar solvent.

RICH GAS. A gas containing a relatively high proportion of readily condensable constituents. *See* Wet Gas.

ROAD OIL. An oil suitable for applying to earth roads to prevent dust and to consolidate and waterproof the surface.

ROD WAX. A pasty mass, composed chiefly of an emulsion of paraffin wax and oil, collecting about sucker rods and casing when pumping paraffinic crude oil wells.

SCALE WAX. *See* Paraffin Scale.

SHALE OIL. The crude oil obtained by the destructive distillation of oil shale.

SCRUBBING OIL. *See* Absorption Oil.

SLACK WAX. *See* Paraffin Slack Wax.

SLOP WAX FRACTION. A distillate fraction, from a paraffin- or mixed-base crude petroleum, taken off after the wax distillate, to give a residuum of suitable characteristics. It is usually unsuitable for the production of lubricating oil or wax and may be used for cracking stock or oil fuel.

SLUDGE. (1) *See* Acid Sludge.

(2) The sediment obtained during the deterioration of lubricating oils in use or in accelerated ageing tests.

SOFT PARAFFIN. *See* Paraffinum Molle.

SOLAR OIL. Term formerly applied to a light gas-oil distillate usually from Gulf Coast, Mid-Continent, and certain Russian petroleums.

SOLUBLE OILS. Term applied to oils which readily form stable emulsions or colloidal solutions on simple mixture with water. They usually contain metallic or ammonium soaps, or sulphonated oils, and may be used for cutting oils, detergents, insecticides, &c.

SOLVENT NAPHTHA. Term restricted to coal-tar naphtha and wood naphtha, excluding petroleum distillates.

SOUR OIL. (1) An acid-treated oil before neutralization with an alkali wash or clay treatment.

(2) An oil containing sulphur compounds (mercaptans) which does not pass the Doctor Test.

SPENT ACID. *See* Acid Sludge.

SPINDLE OIL. Low-viscosity lubricating oil, used in the lubrication of high-speed machinery, especially spindles and looms.

STABILIZED GASOLINE. Gasoline from which dissolved gaseous components of high vapour pressure, such as propane and a portion of the butane, have been removed by stabilization (fractionation under pressure).

STEAM-CYLINDER STOCK. *See* Cylinder Stock.

STEAM-REFINED OIL. A product which has been brought to a desired specification by continued distillation in steam. The process is applied to cylinder stocks and petroleum asphalts.

STEAM-TURBINE OIL. *See* Turbine Oil.

STILL COKE. *See* Petroleum Coke.

STRAIGHT-RUN GASOLINE. A gasoline obtained from a crude petroleum by direct distillation, with no cracking.

STRAW OIL. Commercial term applied to a high-grade gas oil, distilled under non-cracking conditions, and suited for use as an absorption oil.

STRIPPING OIL. *See* Absorption Oil.

SUCKER-ROD WAX. *See* Rod Wax.

SWEATS, SWEATS OIL. *See* Foots' Oil.

SWEET OIL. An oil having a negative reaction to the Doctor Test, indicating the absence of hydrogen sulphide and mercaptans.

SWITCH OIL. *See* Insulating Oils.

TAR. A viscous liquid obtained by the destructive distillation of wood, peat, coal, and similar organic or bituminous materials. The term should not be applied to petroleum products.

TECHNICAL WHITE OILS. *See* White Oils.

THICKENED OILS. Mineral oils, the viscosity of which has been raised by admixture of metallic soaps, rubber, or other suitable materials.

TOPPED CRUDE PETROLEUM. A residual product remaining after the removal, by distillation or other artificial means, of an appreciable quantity of the more volatile components of crude petroleum. (A.S.T.M. Designation D. 288–36 T.)

TOPS. The unrefined distillate obtained in topping a crude petroleum. (A.S.T.M. Designation D. 288–36 T.)

TRACTOR OIL, TRACTOR FUEL. *See* Power Kerosine.

TRANSFORMER OIL. A well-refined hydrocarbon oil, of low volatility and high resistance to sludging, used as a cooling and insulating medium in oil-filled electrical transformers. *See* Insulating Oils.

TURBINE OIL. A well-refined hydrocarbon oil, of high resistance to emulsification with water, used for the lubrication of steam turbines.

TURPENTINE SUBSTITUTE. *See* Petroleum Spirits, White Spirit.

VASELINE. A trade name for a variety of petrolatum.

VASELINE OIL. *See* Petrolatum Liquidum.

WASH OILS. *See* Absorption Oil.

WATER-SOLUBLE OILS. *See* Soluble Oils.

WAX. Term commonly used in the petroleum industry for paraffin wax.

WAX DISTILLATE. The lubricating-oil distillate from a paraffin- or mixed-base petroleum, containing a high proportion of solid paraffin hydrocarbons. It may be dewaxed directly for the production of wax and neutral oils, or may need a further cracking distillation to transform the wax into a crystallizable form for satisfactory pressing.

WAX OIL. *See* Paraffin Distillate.

WEATHERED CRUDE PETROLEUM. The product resulting from crude petroleum through loss due to natural causes, during storage and handling, of an appreciable quantity of the more volatile components. (A.S.T.M. Designation D. 288–36T.)

WET GAS. A gas containing a relatively high proportion of readily condensable constituents, e.g. a natural gas of high recoverable gasoline content. *See* Natural Gas.

WHITE OILS, TECHNICAL WHITE OILS. Generic name applied to highly refined, colourless, hydrocarbon oils, of low volatility, and covering a wide range of viscosities. They are widely used for medicinal and pharmaceutical purposes, and in the lubrication of food and textile machinery. *See* Paraffinum Liquidum, Petrolatum Liquidum.

WHITE SPIRIT. A refined petroleum distillate, intermediate between gasoline and kerosine, having volatility and other characteristics suiting it for use as a thinning medium for paints and varnishes. White spirit normally has a boiling range between 140 and 220° C., and a flash-point not lower than 78° F. *See* Petroleum Spirits.

WHITE SPIRITS. *See* Petroleum Spirits.

WILD GASOLINE. Natural gasolines, of high vapour pressure, prior to stabilization or debutanization. *See* Natural Gasoline.

NOMENCLATURE OF THE BITUM

By P. E. SPIELMANN, Ph.D., B.Sc., F.I.C., A.Inst.P., A.R.C.S., M

Consulting Chemist

G. SELL

THIS subject has for a long time been one of considerable complexity. Many schemes have been suggested, the chief of which are those of:

Clifford Richardson, *The Modern Asphalt Pavement* (1908) and elsewhere.

Holde, *Petroleum*, **7**, 713 (1912).

H. Abraham, *Asphalts and Allied Substances* (1913, onwards).

The American Society for Testing Materials (1918, onwards).

Le Gavrian and Ferret, *Chim. et Ind.* **9**, 837 (1923).

None has obtained wide acceptance, and only a few individual terms have survived.

Most troublesome of all has been the dissipation of the confusion of meaning of the words 'bitumen' and 'asphalt'. The final attempt to establish the signification of these two words has been part of a logical and coherent scheme that has gone [...] to obtain universal approval. This has very properly been undertaken by an organization of international character associated with road construction, because most of the bitumen and asphalt that is produced is used for this purpose all over the world.

Arising from the 5th International Road Congress, held at Milan in 1926, the first meeting of a Standardizing Committee took place in Paris in 1927 (*Roads and Road Construction*, **6**, 288 (1928)). Members representing the following countries were included in the committee: France, Belgium, Denmark, Great Britain, Holland, Italy, Spain, Switzerland, and the U.S.A. Complete unity of agreement was found impossible, in that the United States agreed only to the definition adopted for Bitumen—her own definition that had been adopted unaltered—but complete understanding was achieved as to the definite and clear meaning of the various words.

These definitions are the following:

BITUMEN. Mixtures of hydrocarbons of natural or pyrogeneous [*sic*] origin or combinations of both (frequently accompanied by their non-metallic derivatives) which can be gaseous, liquid, semi-solid or solid and which are completely soluble in carbon disulphide.

Whatever may be thought of the value of a definition that covers so enormous a range of materials under one name, experience has shown that it does take its place logically in the whole scheme.

It is to be noticed that the introduction of the word 'pyrogeneous' brings the CS_2-soluble substances of tar under the definition.

ASPHALTIC BITUMEN. Natural or naturally occurring bitumen, or bitumen prepared from natural hydrocarbons by distillation or oxidation or cracking; solid or viscous, containing a low percenta
possessing characteristic ag
and substantially soluble in car

This term is not used in the Unitec

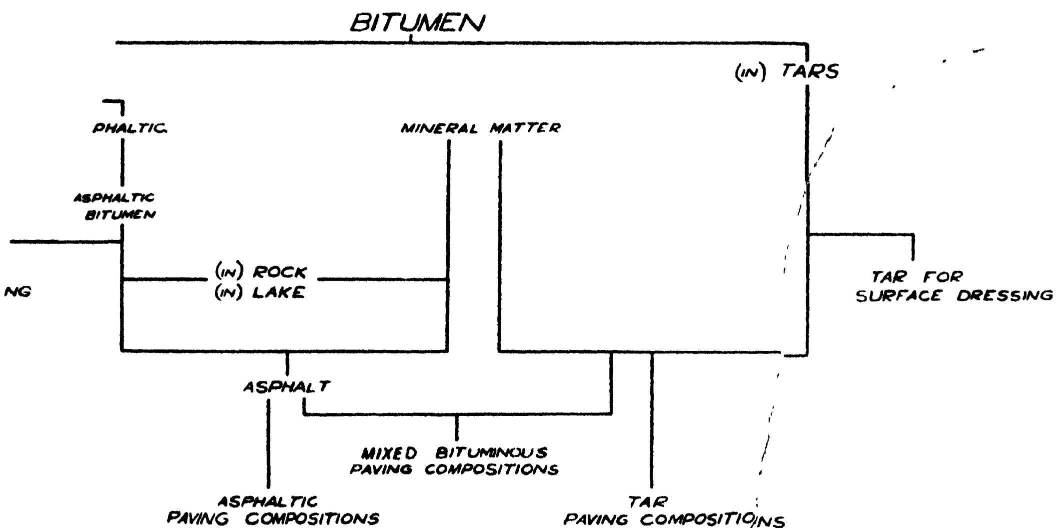
Acid tars of all kinds.

This was supplemented in discussion by Dr. Temme, representing the Arbeitsgemeinschaft der Bitumen-Industrie, E.V. Berlin, but he wished the word 'bitumen' to be added in brackets wherever the word 'asphalt' was given: this would indeed plunge the position back into the chaos of pre-1926.

There remain certain other terms which are not yet accepted officially. Some are included in *The Technical Dictionary of Road Terms in Six Languages*, which has been produced by the Paris Committee in tentative form (1931) and which is undergoing revision in the light of a number of years' experience. Two British committees are also sitting for the revision of the English words.

ASPHALTITE. A naturally occurring substance allied to asphaltic bitumen, soluble in carbon disulphide 40–100%, having a softening point (Ring and Ball) above 240° F.

Examples: Oxy-asphaltite, Thio-asphaltic, Grahamite, Gilsonite, Manjak



1. Classification of bituminous road materials. (*By the courtesy of the British Standards Institution.*)

/ soluble in carbon disulphide and mainly . *Example*: elaterite, peat, coal, oil shale.

ʻained directly or by further treat- ʻ*repared tars.*

2. Pitches

ʻstructive distillation of

ALBERTITE. A mixture of asphaltic bitumen with finely divided organic matter that is insoluble in carbon disulphide.

With regard to the *constituents of these bituminous substances*, the significance of the terms that were originally suggested have scarcely changed.

PETROLENES. Obsolescent, *see* Malthenes.

MALTHENES. Soluble in carbon disulphide, carbon tetrachloride, and standard petroleum naphtha.

ASPHALTENES (Hard Asphalt). Soluble in carbon·disulphide and carbon tetrachloride, but insoluble in standard petroleum naphtha.

rbon disulphide, but insoluble in ᴊe.

›halt). Soluble in carbon disulphide, ıixture of equal parts by volume of gr. 0·72°)—and ethyl alcohol (96%).

:se J. E. Hackford (*Mining and Metal-* ; *J.I.P.T.* **8**, 201 (1922)) introduced the

following terms, which have here been edited t
considerable degree.

KERITE. A naturally occurring bituminous substa
posed appreciably or wholly of kerotene.

Examples: Oxy-kerite Albertite, Elaterite
Thio-kerite Wurtzilite, Impsoni

KEROTENE. The component in kerite that is ins
carbon disulphide.

KEROL. The component in kerotene that is so
pyridine and in chloroform.

KEROLE. The component in kerotene that is sol
pyridine, but insoluble in chloroform.

There are a few unimportant exceptions to th
national scheme, resulting from terms being too
current use to be easily altered; but even these are
resistive:

SECTION 2

STATISTICS

STATISTICS OF PETROLEUM AND ALLIED SUBSTANCES

By GEORGE SELL, M.Inst.P.T.

Petroleum Times

Petroleum

THE first recorded production of crude petroleum was in 1857, when Rumania had an output of 275 metric tons. In 1859 the United States of America first produced petroleum on a commercial basis, the production for that year being 274 metric tons. The next country to yield petroleum in quantities sufficient to be recorded was Italy, which first produced in 1860, although the total quantity obtained from that year until 1890 was only about 6,000 metric tons. In 1862 Canada commenced to give a yield of crude petroleum, and in 1863 Russia entered the field.

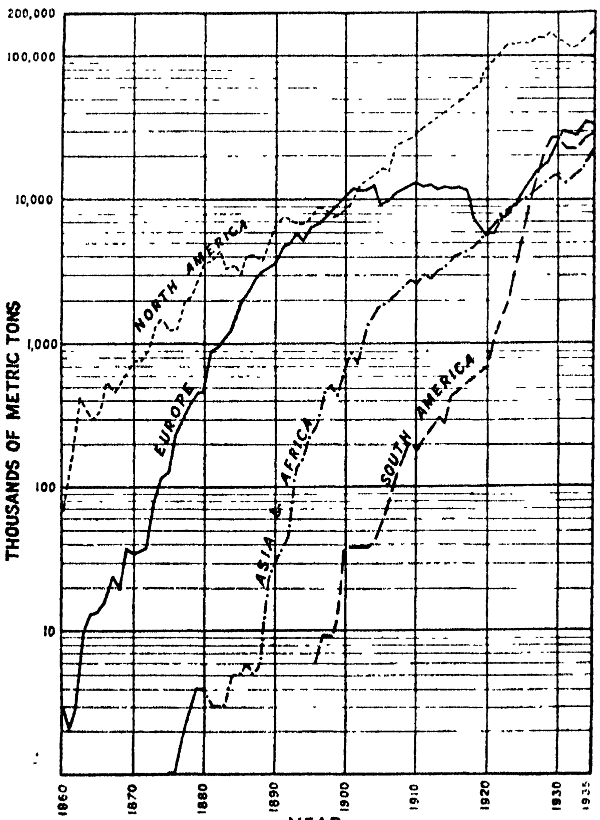

FIG. 1.

In Table I full details of the annual production in the various countries are given, the total to the end of 1935 being 3,776,227,000 metric tons. Of this quantity, 2,408,571,000 metric tons, or about 64%, has been obtained from the United States of America, while the U.S.S.R., second in order of total production, is responsible for 12·3% only. Garfias and Whetsel estimate the world's production in 1936 to have been 1,780,880,000 bbl., or approximately 247,000,000 metric tons [*Petr. Times*, 16 Jan. 1937].

In Fig. 1 the figures in Table I have been grouped under continents, Asia and Africa being included together for convenience. From this point of view the total world's production to the end of 1935 has been distributed as follows: North America, 72%; Europe, 16%; Asia and Africa, 6%; South America, 6%. From the graph it will be seen that, ignoring minor fluctuations, the curves of each continent show a general trend. In all cases there appears to be a flattening of the curves in recent years. During the period 1930 to 1935 all the continents showed a general decline followed by a rise tending to bring the curves back to normal. Even in the case of Europe, the curve for which shows a deep depression in the War and post-War years, it appears that the normal slope has been almost reached in 1935.

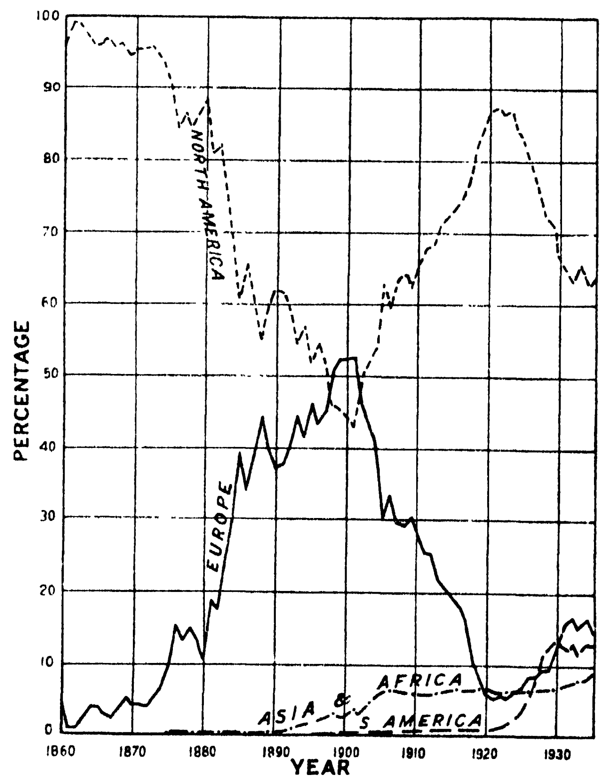

FIG. 2.

In Fig. 2 the production by continents has been plotted on the basis of the percentage of the world's total production, and the relationship of the four continents is clearly shown.

Petroleum Refining

In Table II such details as are available are given regarding the output of petroleum refineries in various countries, and, as is to be expected, the United States of America leads in this respect.

No information is available regarding the actual refinery capacity of these countries, except in the case of the United States, the details of which are given in Tables III, IV, and V.

In Table III the total number of refineries, their capacity and status for the years 1925 to 1935 are given, and in Table IV the refineries in existence on 1 January 1935 are listed in accordance with the type of process operated.

Table V deals with cracking operations in the United States during 1925 to 1935, and illustrates the rapid development which has taken place in this method of treatment. In less than 10 years the operating capacity of cracking plants in that country has nearly trebled.

Generally speaking, it can be said that the figures of refinery activity in the United States are indicative of the position throughout the world.

Consumption of Petroleum Products

In Table VI, which has been prepared by V. R. Garfias and R. V. Whetsel, the world's consumption of petroleum products is given for the years 1931 to 1935. From this it will be seen that, although there was a decrease in the demand in the year 1932, the figure for 1935 is about 13% higher than for 1931. The consumption in 1936, according to preliminary estimates, is 1,760,000,000 bbl. [*Petr. Times*, 16 Jan. 1937].

Natural Gas

Table VII sets out the production of natural gas in various countries since the year 1903. In many cases natural gas was produced in the countries mentioned prior to the first year for which a figure is given, but either no statistics are available or only a value is given in the official records with no information regarding the quantity. It is the custom in some countries to record only the quantity of natural gas actually consumed, and in some cases no statistics are available either for production or consumption.

Oil Shale

The annual production of oil shale in different countries since 1901 is given in Table VIII. This material is only actively exploited in those countries which are devoid, or practically devoid, of crude petroleum as such. The United Kingdom has produced the largest quantity of oil shale, practically the whole of which has been obtained from Scotland.

Natural Asphalt and Asphalt Rock

Natural asphalt and asphalt rock has been exploited in many countries, as shown in Table IX, where figures are given for the annual production since 1901.

Acknowledgements

Wherever possible the figures given in the tables have been compiled from official sources direct, and much information has been obtained from the annual publication of the United States Bureau of Mines (*Minerals Yearbook*) and from *Mineral Industry of the British Empire and Foreign Countries. Statistical Summary*, published yearly by the Imperial Institute, London.

* 1 metric ton = 1,000 kilograms = 2,204·6223 lb. av.

Where it has been necessary to convert from volumetric units, the following have been taken as equivalent to 1 metric ton: Mexico, 6·665 bbl.; India, 249 Imp. gal.; Peru, 7·3 bbl.; Colombia, 7·1 bbl.; Argentina, 1·113 cu. m.; Trinidad, 7·2 bbl.; Japan and Formosa, 6·498 koku; Canada, 7·776 bbl.; Ecuador 7·1 bbl.; Iraq, 7·6 bbl.

† The first recorded production in the U.S.A. was 274 metric tons in 1859.

‡ The production in Roumania in the years 1857 to 1860 was 275, 495, 605, and 1,188 metric tons respectively.
§ Includes the total production in Italy for the years 1860 to 1890.
|| The production in Argentina in 1907 was 14 metric tons.
¶ Including Bahrein Island, 41,000 metric tons in 1934 and 150,000 metric tons in 1935 (0·005% of grand total).

Outside the United States, refinery losses, crude for fuel, and consumption of by-products not included under *Miscellaneous* are yearly estimated as follows:

1931—17,100,000 bbl. making a grand total
1932—20,600,000 „ „ „ „
1933—23,700,000 „ „ „ „
1934—24,000,000 „ „ „ „

SECTION 3

ORIGIN OF PETROLEUM

THE ORIGIN OF PETROLEUM

By Professor V. C. ILLING, M.A., F.G.S., M.Inst. P.T.

Imperial College of Science and Technology

Introduction

FEW subjects of scientific interest have excited more speculation than the origin of petroleum, and few are burdened with a heavier load of literature. Geologist, chemist, biologist, and physicist have each their quota of evidence to contribute and their own particular viewpoint to perpetuate. Yet, as is so often the case where the sciences overlap, the progress of discovery has been slow, for research has lacked the co-operation between the sciences which is essential to success.

Yet it must not be imagined that this is only a subject of purely scientific interest. Its elucidation is of vital importance in the task of searching for new oilfields. The more obvious areas for drilling have now been tested, and the march of discovery renders the task of finding new oilfields ever more difficult. Untested areas have to be reviewed in the light of new ideas, and developed areas are drilled to greater depths to test deeper geological horizons. In this intensive search it is essential that the geologist should have a proper conception of the natural history of the substance for which he is searching. He must know in particular the environment in which petroleum is formed, so that he may utilize his stratigraphical studies to concentrate attention on areas which have been associated in the past with such conditions.

It must, however, be conceded that the origin of petroleum is a problem of unusual difficulty. Unlike coal, which can be examined in detail and its physical components differentiated under the microscope, oil gives no such evidence to the scientist. Furthermore, its fluidity enables it to pass from rock to rock so that often it is not even possible to state with any certainty the given rock type in which a particular petroleum was formed. This power of migration is one of the greatest difficulties with which the oil geologist has to contend, and there are only a few oilfields in which the source rocks can be identified with any certainty.

One further difficulty arises from the fact that the term petroleum is sometimes used vaguely to cover materials which, though chemically related, are not part of the same family. Thus natural gas is a true petroleum derivative and consists essentially of methane, but all natural occurrences of methane are not natural gas, and even a cursory study will show that methane has originated in several different ways in nature. Most of these have probably no significance from the point of view of the origin of petroleum, but all have been put forward at some time or other as significant evidence. Another instance may be given in the case of the so-called oil shales and bituminous sandstones. The former substance is not a shale containing oil and is probably not related to petroleum in any way; it is merely a material from which, like cannel coal, an oil can be formed by destructive distillation. The term 'bituminous' is also often used by the geologist as a synonym for 'carbonaceous', and may not therefore have any reference to petroleum. These examples of unfortunate terminology have added considerably to the confusion by their inclusion as evidence by the unwary.

There can be little doubt that hydrocarbons have originated in many different ways in the earth's crust, but this conclusion does not necessarily apply to the accumulations which are of commercial importance. The present problem is limited to the latter, and therefore the primary evidence must be sought in the conditions in which the large accumulations are developed. The chemist in particular is prone to regard the chemical nature of the substance as its primary characteristic and has complicated the issue by suggesting so many ways in which petroleum, or rather hydrocarbons, could be produced given an unrestricted choice as to the materials available and the conditions to which they had been subjected. Fortunately neither of these two factors are unrestricted, but as their study does not come within the province of the chemist, it can readily be understood that he has not always felt himself tied by their limitations. The so-called 'Inorganic Theories' all come within this category, and none of them would ever have been entertained if due weight had been given to the geological evidence. On the other hand, the geologist has often gone astray with unfortunate results when wandering beyond his own field of inquiry to a discussion of the processes by which petroleum could be formed.

It would seem logical to assume that the first steps in this inquiry should be taken by the geologist. It is he who has to study the conditions in which petroleum is found and must trace its history from the earliest stages to the condition of a large accumulation. The latter is contained within the rocks of the earth's crust, and it is the geologist's function to study these rocks and to consider the succession of events which brought them into being and their history after formation. The history of the oil formed a part of this broader history, and among the important questions which the geologist must decide are the following:

(*a*) The conditions of sedimentation which have given rise to oil-bearing rocks.

(*b*) The basic material from which it may be presumed the oil has originated.

(*c*) The limiting conditions of temperature and pressure to which these rocks have been subjected since their formation.

These will act as limiting factors to all chemical and physical theories of oil formation.

The answers to these questions do not give a complete theory of the origin of petroleum, but they narrow the field of inquiry. There is still the important question of the precise processes by which the petroleum is produced and the time needed for the transformation. On these matters the chemist and the biochemist can claim their right to enter the discussion, and the geologist's contribution can only be based on such studies as may condemn or support chemical reasoning.

It is not the purpose of the present article to deal in detail with the geological evidence on the origin of petroleum. It will be sufficient to give the broad conclusions which can be drawn from this mass of evidence and deal only in detail with such matters as are still in doubt.

The following are some of the general conclusions with

regard to the geological occurrence of oil with which practically all oil geologists will concur.

1. Petroleum as a solid, liquid, or gas is of widespread occurrence in the earth's crust, particularly in sediments. As an accumulation of commercial importance it is much less common and is restricted to areas of considerable sedimentation.

2. The oil and gas are found in porous rocks such as sands, dolomites, or limestones. These rocks usually form part of a thicker sedimentary series in which clays, marls, or limestones predominate. It must be assumed that the oil and gas have been formed from organic matter in these sedimentary suites, and the clays and limestones are the probable source rocks.

3. Porous rocks such as sands constitute the reservoir rocks because it is only from such permeable formations that the oil can be extracted in commercial quantities. In most cases the clays and limestones also contain oil, but it is too diffuse or too tightly held to be extracted profitably.

4. In particular oilfield regions the commercial oil-pools are clearly restricted to certain geological formations. Within these formations there are certain clays or limestones which have been claimed with good reason to be the source rocks. This identification is not always possible because of the migratory powers of petroleum, but where the evidence is clear the identification can be accepted with considerable confidence.

5. The oil-bearing rocks of most oilfields are marine, and the oil usually rests on salt-water which is believed to be derived from the original sea-water in which the sediments were laid down. There are, however, some oilfields in terrestrial formations in which the oil may have been produced in such rocks or may have migrated from other sources. The great preponderance of marine rocks in the known oilfields leaves no doubt that the source rocks from which the oil has been produced were normally laid down in a marine environment. The foregoing is a statement of fact and is not meant to assert that oil could not be formed in fresh-water sediments. The exceptions referred to above may represent such cases, though many of them seem to be migratory oils.

6. The sediments in which the oils occur show very little evidence of having been subjected to either abnormal heat or pressure. Some of them are folded, occasionally even highly folded, but there are other regions of prolific oil-pools which have not been subjected to any folding movements whatsoever, whilst nearly all oilfields have escaped any type of regional or local metamorphism. Occasionally an individual pool has suffered local effects from igneous activity, but the only thermal influences on the sediments that can be ascribed to the majority of the oilfield strata is the increase in temperature due to the overlying load of sediments. In most cases this rise in temperature could not have been more than 100° C., for the temperature gradients in such rocks are low and the cover was usually not greater than 20,000 ft., though there are cases of exceptional overburden.

General Theories of the Origin of Petroleum

Inorganic Theories.

So many theories have been put forward for the origin of petroleum that it would be invidious to select any particular ones as representative. More particularly is this true of the so-called inorganic theories which visualize the origin of oil and natural gas as a large-scale, simple laboratory reaction within the earth's crust. Mendeléeff, for instance, considered that it was essentially a reaction between descending waters and subterranean metallic carbides [14], whilst Berthelot thought that it might be due to water charged with carbon dioxide coming into contact with metallic sodium [5, 1866]. Apart altogether from the intrinsic merits or interest of such theories they all fail to satisfy the fundamental requirement that the origin of petroleum in large quantities is bound up with the history of particular sediments.

The same reasoning may be applied to the so-called volcanic theory, which is a modification of the normal inorganic theories. This visualizes petroleum as one further example of the ultimate phase of vulcanicity. It is true that in certain oilfields, as, for instance, Mexico, there are some incompletely explained examples of association between igneous rocks and oil deposits, but these appear to be cases of favourable conditions for accumulation rather than of origin, and they are so exceptional that they have attracted more than their share of attention. Furthermore, the argument that there is parallelism between the world's oilfields and the distribution of volcanoes is true only in part and is completely falsified by the Palaeozoic oilfields of the United States. This parallelism is more true of the Tertiary fields, and is undoubtedly due to the fact that vulcanism and the occurrence of petroleum are both independently related to the zones of Tertiary marine sedimentation which were later affected by crustal disturbances. Taken as a whole, the study of oilfield regions indicates clearly that they are not normally associated with any phase of igneous activity.

Organic Theories.

The synopsis of the geological factors connected with the origin of oil which was given above leaves no doubt that it must be formed from organic matter deposited in the sediments with which it is associated. Although there may be general agreement on this point, there are considerable divergences of opinion on other matters which are of equal importance. It must not be forgotten that the source of the organic matter is but the first stage in the process. Other considerations include the environment in which such source sediments are laid down; the factors which have changed the organic material into petroleum, and the time at which such changes have taken place, i.e. whether oil originates in the sediments or is produced at a later stage when the sediments have become rocks. All of these questions must be considered in a complete theory, and there is clearly room for diversity of opinion among authors who may be in complete agreement on the question of the original source material.

Source Material.

There has been a tendency for a division of thought into two broad groups: those who believe in the origin of petroleum from terrestrial vegetation, and those who consider animal matter of marine origin to be the probable source. Such a grouping does not cover the whole field, for in such vegetal substances as marine algae and diatoms we have obvious contributing elements which may be of great importance. It would perhaps have been to better purpose had the battle been fought on the question whether oil originated from terrestrial or marine matter, for that would have thrown light on the environment in which source sediments are laid down, a much more important question. Furthermore, it may be questioned whether nature's processes are particularly concerned with whether

a material be animal or vegetable, though the question whether it consists of cellulose, fat, or protein may be of fundamental importance. It is the chemical nature of the materials, and in particular their decomposition products after partial putrefaction, which are of primary importance. This and the environment of deposition are clearly the two main considerations.

There has been one field in which controversy was bound to occur, the fundamental relationship between coal and oil. Are these two substances in any way related? Have they been produced from analogous materials, and are their differences due to variations in treatment of the original materials? Or, on the other hand, are they related in the sense that they are produced from different materials, but have undergone a parallel series of changes after entombment? Both points of view have been championed vigorously, the first by E. H. Cunningham Craig [6, 1912] and the second by David White [26, 1935].

The arguments for the supposed relationship between coal and oil may be briefly summarized as follows:

(*a*) There is a general geographical and geological relationship between coal and oil.

(*b*) In certain instances it has been claimed that coal or lignite can be proved to pass laterally into oil-bearing strata.

(*c*) The decomposition of vegetable matter in water produces methane which is chemically identical with the basic constituent of natural gas.

(*d*) The destructive distillation of coal, lignite, and peat gives substances closely akin to petroleum. The hydrogenation of coal would be a further instance.

(*e*) Coal and oil have been claimed to have undergone parallel changes in certain regions, particularly in the Appalachian oilfields.

All of these comparisons, save the last, bear directly on the source material of petroleum, so they may be considered in detail. The last point is of greater importance when it comes to the consideration of the forces which produce petroleum and will be considered in that section.

(*a*) The geographical relationships of coal and oil can have little bearing upon the problem, but a geological association would be of fundamental importance. A review of the world's oilfields, however, shows very little evidence to support this view when due allowance is made for the fact that both materials occur in sediments, and oil, being of migratory habit, can readily pass into neighbouring strata. Coal and oil are found in the same formations in Kansas, Venezuela, Assam, Borneo, and Roumania, but the majority of oilfield measures do not contain coal. Indeed, oilfield strata are normally marine in contrast to the brackish or fresh-water conditions associated with most coals.

Two examples have been freely cited to support the contention of a close geological association of coal and oil, Pennsylvania and Trinidad. Both are unfortunate examples, for in each the coal and oil occur in different strata and the line of demarcation is clear cut. In Pennsylvania an upper coal-bearing series lies disconformably on an underlying oil-bearing formation. The break between the two formations is clearly defined, and there was a considerable period of erosion between them. There are no coals in the underlying series and no oil in the overlying beds. A little gas has migrated above the plane of unconformity, but this is hardly to be wondered at; indeed, the outstanding feature is the sharpness of the break between the oil and the coal series in spite of the migratory habits of oil. It has been argued that in this case the lower series under a greater cover has changed to oil, whereas the upper formations have retained their organic matter as coal. This argument is, however, not tenable, for the line of demarcation follows the plane of unconformity and not the zone of equal cover.

In Trinidad the lignitic strata of the Upper Miocene occur as a fresh-water formation which is clearly separated from the underlying marine oil-bearing series except for a few cases in which migration has occurred. The source of the oil in the lower series is not satisfactorily settled, but there can be no doubt that it did not originate in the upper lignitic series.

The problem must also be looked at from the point of view of the regional and stratigraphical distribution of coal as well as that of oil. Such studies leave no doubt that the two substances are completely independent of each other.

(*b*) The cases of a supposed lateral variation of coal or lignite into oil within a limited distance are few. Wall described tree-trunks submerged in the pitch of the Pitch Lake in Trinidad in which he claimed that the bitumen was derived from the decomposed cell structure of the wood [22, 1860]. There can, however, be no doubt that he was merely dealing with cases of semi-decomposed wood tissue which had become impregnated with bitumen from the surrounding pitch. E. H. Cunningham Craig describes an example on the coast of Trinidad between Point Fortin and Cedros [7, 1912]. The formations he was considering belong entirely to the lignitic series, and he was mistaken in his view that the porcellanite, which he claimed was the lateral equivalent of a lignite, had been an oil-bearing clay. It is, of course, freely admitted that a coal-bearing series can pass laterally into an oil-bearing series with a change in facies from deltaic to marine, but such regional changes do not bear on the question at issue, for the source of the organic material may be quite different.

(*c*) The decomposition of vegetable material to form marsh gas is the strongest material link between oil and coal. It must, however, not be pressed too far. The gas associated with vegetable material and coal contains only methane and none of the higher molecular weight hydrocarbons, whereas 'natural gas' often contains ethane, propane, butane, &c., in considerable quantities.

(*d*) The destructive distillation of coal, peat, &c., gives liquid oils and gas which, while differing from petroleum particularly in the percentage of their unsaturated constituents, are probably no more distinct than are the variations to be noted between different types of petroleum. Such differences also cannot be stressed unduly, for the heat treatment to which these oils have been subjected may be a partial cause of these unsaturated hydrocarbons. Apart altogether from such questions, the real point is how far such comparisons affect the issue. In this case the significance of such distillation products can be very little, for it was shown long ago by Warren and Storrer [23, 1867], and later by Engler [8, 1888–9], that animal fats could produce oils on destructive distillation which were much more akin to petroleum products.

Hydrogenation as practised in the formation of petrol from coal requires high temperatures and pressures and a supply of hydrogen. It is very doubtful indeed whether these conditions occur in nature in oilfield strata, and though some suggestion of alterations in oils due to hydrogenation have been put forward, they are quite unsubstantiated.

The results of the foregoing considerations leave little

positive evidence in favour of a genetic connexion between oil and coal. The geological environment favourable to the formation of each is shown to be completely different: coal is essentially a terrestrial deposit, whilst oil is normally produced in rocks formed in a marine environment. This does not prove that each may not have been produced from the same organic matter, but it makes it exceedingly unlikely, and though both materials are of organic origin it seems probable that this is about the full extent of their connexion.

Owing to the migratory habits of petroleum it is not always possible to assert conclusively that a particular formation is the source rock from which the oil was obtained in a particular region. There are, however, some areas where the source rock can be identified with considerable probability. Sterry Hunt [11] identified the Trenton Limestone as the source rock for the oils which were found in it, basing his argument on the compactness of this formation and the impossibility of oil moving for any considerable distance through it.

Arnold and Anderson claimed that the Monterey Shales of California were the source rocks of most of the oil in that area [2, 1910]. They drew attention to the abundance of diatoms in that formation, and suggested that the oil had been derived from these organisms. The oil in California has perhaps several zones of origin, but the consensus of opinion still supports the Monterey Shales as the most important source rock. Taff has suggested that both diatoms and Foraminifera contributed to the source material and that the chemical nature of the oil so produced varied with the type of organic matter [17, 1934]. In Poland the main oil sands are so closely associated with the Menelite Shales that it was inevitable that these shales would be considered as the rocks from which the oil had been derived. Such cases can be considered as representative, and in each case the source rock is marine. It is composed of clay, marl, or limestone, and in some cases the rocks are obviously rich in organic remains, but in others, particularly the dark clays, the evidence of organisms is not by any means striking.

It might be argued that if oil is formed in marine sediments, a study of the latter ought to bring to light examples of oil in process of formation. This, of course, assumes that the oil is formed immediately the deposit is laid down and not as a later process when the sediment becomes a rock. Various claims have been made of oil or hydrocarbons being produced on the sea floor, but none of these can be accepted without reserve. One of the main difficulties is that it is almost impossible to eliminate the chances of contamination by seepage of oil from the basement of the sea floor, and the cases cited by the Hungarian expedition to the Levant [15, 1901], and by Wade in the Red Sea [21, 1914], are all suspect on this account. Krämer and Spilker described the formation of a wax in the sediments of the Gulf of Stettin which they compared with ozokerite, the hydrocarbon wax of the Boryslaw oilfield [12, 1900, 1902]. This identification has, however, been challenged by Potonié, who considers that their material was merely semi-decomposed organic matter analogous to sapropel [16, 1904].

Trask and Wu have undertaken an extensive examination of marine sediments both to study their organic content and also to see if there is any evidence of oil formation contemporaneous with deposition. So far as the latter question is concerned they conclude that there is no evidence to support such contemporaneous oil formation [20, 1930]. Trask's studies of organic matter in marine deposits need not be referred to in detail here, for they form the subject of a separate contribution. It is sufficient to point out that he finds appreciable quantities of organic matter in sediments, particularly along the flanks of submarine basins. These organic mixtures contain little of the original fats, protein, and carbohydrates of the organic matter, but correspond rather to complex residual substances, the ultimate result of bacteriological decay.

This conception of a preliminary stage of decomposition or putrefaction is by no means new. It was postulated by Engler in his theory of oil formation, first as a means of eliminating nitrogen, and secondly as a preparatory stage of the break-down of the fatty matter [9, 1909].

It is agreed that some initial putrefactive process is incidental to the deposition of all organic matter, and such a conception seems eminently reasonable. We are not concerned so much with the original composition of the organic matter as with its composition after such decomposition has taken place. The general tendency of Trask's investigations appears to prove that all such organic matter tends to become enriched in carbon and hydrogen by the preferential elimination of oxygen and nitrogen. This subject is treated fully in Trask's contribution on 'Petroleum Source Beds', and the reader is referred for further details to this contribution.

Environment of Deposition.

It is sometimes claimed as an inherent weakness in the marine origin theory that the examination of modern sediments has failed to discover any which are sufficiently rich to enable them to become the sources of petroleum. This claim is, however, based on a misconception. The petroleum found in a reservoir rock forms only a small percentage of the total volume of the reservoir, for most oil reservoirs contain large water-saturated sections. Furthermore, the reservoir rock is usually but a small percentage of the total volume of source rock, so that the volume of oil to be accounted for is only a small percentage of the total source rock. There is no need, therefore, to consider that petroleum source sediments need be abnormally rich in organic matter, and the quantities of such material that have been discovered in sediments of suitable environment are adequate for our purpose. There are, it is true, some instances of abnormally rich marine sediments such as those which have been studied in the Black Sea by Archangelski [1, 1927]. Here the conditions for preservation of organic matter appear to be particularly favourable, and the organic content rises to as much as 18%. The writer is, however, inclined to the view that sediments of such abnormal richness are probably unnecessary. Petroleum formation is a normal, not an abnormal, process in the history of marine sediments, and it is therefore more likely that it requires an environment which, while it involves certain essentials, does not involve features which are only rarely attained.

That rapid oxidation is the normal accompaniment of shallow-water marine deposition is well known, and organic matter laid down in such conditions will be rapidly oxidized and lost. There are, however, certain cases in shallow-water sediments where the sediments contain no free oxygen, and in the deeper parts of the sea this is the normal condition. McKenzie Taylor has shown that some clays, when subjected to base exchange, can become so impervious that even in shallow water they produce an anaerobic environment [18, 1928]. In the basal areas of

the sea floor it is probable that the lack of convection currents and the resultant stagnation of the water leads to the bottom waters being exhausted of their oxygen and the environment becoming anaerobic. Furthermore, the broad areas of the sea floor which are covered with blue muds, a type of deposit typical of an anaerobic environment, indicate how commonly the conditions of the sea floor are of this type.

It is not, however, sufficient that the conditions of deposition be anaerobic to satisfy all the requirements for a source sediment. There must be an adequate supply of organic matter to form the basis of the material from which the petroleum will ultimately be derived. The conditions must be favourable to the continued development of organic matter in the water, and probably imply favourable conditions for the growth of phytoplankton. The marine areas adjoining the main continents or close to the zones of oceanic islands provide such an environment, but in parts of these zones the conditions for the preservation of the organic matter would be unfavourable. However, on the edges of the main basins and in the dominant basins of the submarine platforms there would be conditions favourable to the development of life and to the preservation of the organic matter in the sediments. It therefore seems probable that petroleum-source sediments were laid down in marine basins and at no great distance from land, a condition which is in agreement with the palaeogeography of oil-bearing rocks in most of our oilfields. It is also probable that the sedimentation of the organic matter is greatly helped by the muddy sediments in the water, but the incidence of such conditions has not been specially studied.

The importance of bacteria in the special decomposition processes has been emphasized in the case of other substances [4, 1926]. The formation of iron sulphide in the black muds is apparently due to the decomposition of the sulphates in the sea-water—the formation of free hydrogen sulphide which reacts with iron hydroxide in the sediments to form iron sulphide. This seems to be but one instance of the importance of bacterial control of the conditions in such sedimentary environments, and under such conditions the decay of the organic matter is probably mainly controlled by bacteria and it is converted into organic acids or their derived salts. The large volume of salt-water present would probably inhibit the production of toxic conditions in the sea-bottom, so that bacterial decay would go on. A further preventive to such toxic conditions would be the decomposition of protein to form alkaline solutions [24, 1937], and the inwelling of waters of slightly different salinity which would cause base exchange in the sediments in which the organic decomposition was taking place.

The Transformation of Organic Matter into Petroleum.

The ultimate formation of petroleum from the decomposition products of organic matter in the sediments is the most elusive problem in the origin of oil. There are two broad schools of thought into which the various theories can be divided. These two schools postulate, on the one hand, a process of temperature or pressure metamorphism, and, on the other, decomposition by bacteria. Whatever compromises may be made regarding the type of organic matter involved, there can be no compromise between these two mutually antagonistic ideas.

The theory of metamorphism may be regarded perhaps as the orthodox school in so far as it has been held ever since the origin of petroleum has been discussed, and is based on a wealth of chemical data. The fundamental idea is that the organic matter, after an initial process of putrefaction, to eliminate the nitrogenous material, is entombed in the sediment, and that the rise in temperature involved in such burial produces a slow process of chemical distillation involving long geological periods. It is claimed that high temperatures will not be needed; the same processes which take only a few hours in a retort will take place at much lower temperatures if given sufficient time. Thus Maier and Zimmerly claim there would be a 1% conversion of the organic matter in $8{\cdot}4\times10^5$ years at a temperature of 100° C. [13].

It is, however, not necessarily true that a reaction which takes place in the laboratory at 275–325° C. will take place, though at a much slower rate, at temperatures around 100° C. Before such claims can be made the rate of the reaction must be studied, particularly at the lower end of the temperature scale, for most reactions of this nature tend to occur only within a certain range of temperatures. Obviously the results will vary with the substance used, but in some experiments on a typical torbanitic cannel which the author has investigated it was clearly shown that the reaction velocities did not diminish with temperatures below 250° C. in accordance with theoretical calculations, but at a rapidly increasing rate showing an approach to virtual stagnation at about 220° C. This would be in accordance with many other similar endothermic chemical reactions which only occur within a certain limited range. It is therefore doubtful whether these reactions take place at low temperatures, and that this doubt is justified is supported by the occurrence of large deposits of typical oil shales in pre-Cambrian rocks which would have been destroyed long ago had such processes been possible at temperatures of 100° C. It is beyond doubt that such rocks have been subjected to as great a temperature for far longer periods than have most of the oil-source rocks. Unless, therefore, special catalysts are invoked or the original organic material is unlike anything which has yet been investigated, it is difficult to see why the process is so selective.

The geological evidence makes it exceedingly unlikely that the oil-source rocks have been heated to temperatures more than 100° C. above normal atmospheric temperature. Some of them may have been loaded with an exceptional cover, but the majority have not. Furthermore, there is also a considerable amount of chemical evidence which indicates that many crude oils have not been subjected to temperatures above 100° C. (See Brook's contribution on 'The Origins of Petroleums'.)

A further difficulty is that all destructive distillation at whatever temperature must leave behind a residue or 'spent'. Such a material is readily identifiable, and it is unlikely that material of this type would have escaped recognition in all the oilfields which have been investigated.

For these very substantial reasons it appears very doubtful indeed whether this theory of thermal decomposition can be accepted in spite of its apparent simplicity. The arguments against it are very strong indeed, and when coupled to these arguments there arises the conviction from many aspects of geological reasoning that oil formation is not an indefinitely postponed reaction, but takes place within a reasonable period of deposition, it becomes necessary to look for some other explanation of petroleum formation.

There has been some suggestion that whereas tempera-

ture alone could not have caused the destructive distillation, it might have achieved it with the aid of catalysts or by pressure.

The first is an interesting suggestion, particularly in view of the presence of nickel and vanadium in most petroleum ashes, but it is purely a hypothesis and does not remove the other substantial objections to destructive distillation. The suggestion of pressure as the other controlling factor is, however, based on a misconception. High pressures have been used in cracking processes and in some destructive distillation in order to achieve the high temperatures required, but not as an end in themselves. It is difficult to conceive that pressure would induce a reaction which automatically involved an increase in total volume owing to the large amount of gas produced.

Another possible cause of the genesis of hydrocarbons has been suggested in the effects of α-radiation on organic matter. A difficulty incidental to this explanation is the associated formation of hydrogen which ought, on this principle, to occur with petroleum deposits. The fact that hydrogen is rarely present in petroleum gases tends to negative this possibility, though the hydrogen may have been used up in the alteration of unsaturated to saturated hydrocarbons which is considered by Barton and others to take place with time and deep burial [3, 1934]. A more serious objection to the influence of radioactivity in the formation of oil is that there is no obvious reason why it should have occurred in oil-bearing strata and not in other organic deposits.

Biochemical Formation of Petroleum.

In discussing the conditions of deposition of organic matter in marine sediments it has been postulated that all such material would be rapidly oxidized and lost unless it were deposited in an anaerobic environment. During the accumulation of this organic matter it may be assumed that it will have undergone considerable alteration. Apart altogether from the changes which arise by virtue of the consumption of the phytoplankton by marine organisms and the resultant change in the material, it must be realized that the organic constituents which fall into the sediment will be only such faecal and dead matter as can be entrained by the falling sediment. According to Trask this material will consist of complex residual ring and chain compounds which represent the final residuum after bacteriological and enzyme decay [19, 1932]. It might also contain considerable quantities of metallic soaps which would have escaped detection as such in the methods of chemical investigation adopted by Trask. The question now arises whether bacteriological decay, having reduced the nitrogen and oxygen content of the organic matter during deposition, ceases to play any further part in the transformation of the organic matter once the material has been covered by other sediments on the sea floor. Trask maintains that this is the case, and adduces as evidence his failure to find any appreciable quantity of petroleum in modern sediments. It must be realized that the materials so examined were only the uppermost layers of the marine sediments and would therefore represent only the earliest stage of bacteriological decay. This lack of success is therefore not conclusive evidence against the bacterial theory. Of more weight is the fact that all studies of such decay have tended to confirm the impression that the ultimate end product of all such decomposition tends to be methane, and until it has been proved conclusively that bacteriological decay can produce the higher molecular weight hydrocarbons, the bacterial theory can only be regarded as a tentative solution [10, 1934]. Its main basis lies in the fact that it is in agreement with the view, supported by many independent lines of approach, that the formation of petroleum, if not contemporaneous with sedimentation, takes place not long after the sediment has been laid down. The processes of biological decomposition are discussed by G. D. Hobson in 'Biochemical Aspects of the Origin of Oil' and need no further reference here.

Conclusions

Hydrocarbons may originate in many different ways in the earth's crust, but the geological conditions in which petroleum and natural gas occur in commercial quantities point overwhelmingly to the conclusion that these materials are of organic origin and they are intimately bound up with the history of sedimentation. The most favourable environment for the accumulation of oil-producing sediments is a marine one. The sediments which ultimately produce the oil are in the main clays, marls, and limestones, and the oil must have been formed from the organic matter which was enclosed in these sediments. The richness in organic matter need not have been abnormally high, for the oil and gas have been segregated and concentrated by the processes of migration. Furthermore, oil-source rocks are sufficiently widespread to indicate that they represent a normal and not an abnormal phase in marine sedimentation.

Three main essentials appear to be called for in the development of a source rock: an ample supply of sediment, a favourable environment for organic life, and anaerobic conditions of sedimentation on the sea floor. Such conditions are supplied by basinal areas on the continental shelf marginal to the land masses or to large oceanic islands.

The residual organic matter becomes enriched in carbon and hydrogen at the expense of nitrogen and oxygen as a result of the various processes of decomposition, but it is not by any means a group of hydrocarbons when it is deposited. The transformation of this material into petroleum is still a matter for discussion. One school of thought believes that it is a gradual process of thermal metamorphism taking place as a result of blanketing of the source material over long geological periods and at relatively low temperatures. The other believes that the processes occur in the body of the sediment by an extension of the processes of bacterial decay coupled with associated chemical alterations. Both of these theories involve difficulties which have not yet been overcome. The first seems to be inadmissible on various geological grounds unless it can be shown that the final residual organic material can be altered into hydrocarbons at lower temperatures and at a much faster rate than is at present conceded. The theory of biochemical decay is at present unsubstantiated by direct evidence that the higher molecular weight hydrocarbons can be produced by such action.

ON THE ORIGIN OF PETROLEUM

By Professor SAMUEL C. LIND

Director, School of Chemistry, University of Minnesota

A SATISFACTORY theory of the origin of petroleum must explain its two most outstanding characteristics, abundance and great chemical complexity. An organic origin which seems to be the one most favoured at present by geologists does not appear to throw any light on its surprising degree of chemical heterogeneity.

One is confronted with the choice between admitting that the mixture of hydrocarbons which constitute petroleum had this degree of complexity from its origin or that it has become complex through subsequent chemical changes. On *a priori* grounds it has always appeared to the writer highly improbable that such a variety of molecular species should originate from a single source by any natural process in one step either chemical or biological.

The recent spectroscopic discovery that the atmospheres of our largest planets [1, 1934] which have probably never sustained life in any form consist almost exclusively of hydrocarbons, principally methane, together with Russell's [9, 1935] very plausible interpretation of this fact, may throw an entirely different light on the question, and merits consideration along with the discarded theory of the origin of petroleum through the action of water on deep-lying carbides.

It is the object of this chapter to review some of the chemical and physical factors which have a bearing on the origin and nature of petroleum.

Before examining this question further, the properties of hydrocarbons occurring in nature should be considered. The series appears to be unbroken from methane, the principal constituent of combustible natural gas up through the higher gaseous members into liquid petroleum and over into the naturally occurring solid materials such as asphalt, gilsonite, &c. Never is one hydrocarbon found alone, but always in a mixture of higher and lower members spreading out with decreasing occurrence in both directions from the centre of greatest abundance.

The possibility of such complexity statically considered, arises from the unique property of hydrocarbons and of their derivatives to form long chain compounds through the linkage of carbon atoms one to another. So long and multiple-branched are their chains that the number of theoretically possible compounds is enormous and most of them seem to be contained in petroleum, though no one of them to any large extent. The carbon to hydrogen ratio changes from compound to compound by such small steps as to be almost a continuous variable as it approaches its limiting value of 1:2 in the higher saturates. Certainly the law of definite multiple proportions would never have been arrived at, had the compounds of petroleum been the subject of study.

It is not only remarkable that such a large number of chemical compounds can be obtained from two light elements with simple valencies, but so numerous and closely spaced (chemically) are they that their separation has been and still is one of the major problems of petroleum research. Distillation is the principal method, but even this fails for final separation and can be supplemented by fractional crystallization from solvents at low temperatures. Washburn [12, 1929] and his co-workers found that fractionation is still proceeding when difference of boiling-point no longer serves as a guide, the continued fractionation being shown by changes in refractive index. The hydrocarbons contained in petroleum are not limited, however, to the saturated series, but also include naphthenes and benzenes.

On examining the general thermodynamic relationships in reactions between saturated hydrocarbons, generally one finds that they involve but small free chemical energy. For this reason, there is no driving force to cause interaction, and under ordinary conditions they are quite inactive towards each other. On the other hand, since there is no driving force in any direction, there is no large opposing force to be overcome; in other words, the heats of reaction are low. Furthermore, if suitable conditions are found to produce reaction, and since there are no large directing forces, one may expect reaction to take place in any direction and to proceed by successive steps in all directions, hence leading to great complexity of product, without having to assume such variety in the original source.

A thermodynamic treatment of possible reactions between hydrocarbons has been given by Professor H. A. Wilson [13, 1927, 1928] of the Rice Institute. Between successive members of the paraffin series in the region of temperatures of several hundred degrees and pressures from a few to several hundred atmospheres, he assumes equilibria of the type:

$$2C_nH_{2n+2} \rightleftharpoons C_{n+1}H_{2(n+1)+2}+C_{n-1}H_{2(n-1)+2}.$$

Thus there exists an equilibrium, dependent on pressure and temperature, between any member of the paraffin series and the members next above and next below in the series in point of number of carbon atoms. Since the relationship is perfectly general, it will extend in both directions: to methane and ethane at the lower, gaseous end of the series, and to solid members at the upper end. The light gases will be either trapped, and thus furnish the gas pressure associated with petroleum, or, if liberated, will allow the dynamic equilibrium to cause a chemical drift of the hydrocarbons continuously from higher towards lower members.

Wilson has pointed out that so far as his calculations are concerned, the equilibria might be purely physical ones among pre-existing members of the series, but it seems quite justifiable to make the step, as he does in his later paper, 'Theory of Cracking [14, 1930] of applying the same considerations to equilibria arrived at by chemical action. To the writer, it appears entirely logical to extend the reasoning to the processes of petroleum generation, regarding cracking and petroleum formation as entirely similar processes from the chemical standpoint, after making due allowances for such differences of physical conditions as would be necessary.

With this kind of mechanism it would be possible under influence of such temperatures and pressures as may quite reasonably exist in the earth's upper crust, to start with any member of the paraffin series and arrive at liquid

mixtures like petroleums. [This assumes that petroleums consist solely of hydrocarbons, which is not the case. Ed.]. The olefine series has been given similar thermodynamic treatment by Wilson and offers no new difficulties. Equilibria similar to those among the paraffins may be set up. Transition from paraffins to olefines could be effected by the elimination of methane. The treatment promised by Wilson for benzene and the other ring series has not yet been given. It is an interesting question whether a transition from chain to ring members could be accomplished by inorganic processes in nature, or whether the ring members originated in life processes in the primary source. While there is some evidence of the generation of benzene derivatives from paraffins by some of the vigorous agents to be next discussed, it is by no means conclusive as yet.

Besides the reactivity of hydrocarbons under the influence of heat and pressure just discussed, other more vigorous agents such as electrical discharge [7, 1928–30], alpha radiation [6, 1926], and ultra-violet light [11, 1927; 10, 1929; 4, 1930], have been found effective in causing them to interact. While all of the characteristics of these various types of agents are not as yet understood, they have one property in common which is rather surprising. In spite of the large quantum amounts of energy applied, the hydrocarbons are not generally broken down but exhibit the striking property of condensation to form liquids or solids, with only so much elimination of lower gaseous members as is necessary to avoid chemical supersaturation.

Even when spectrographic evidence indicates an intermediate dissociation of high degree, as in the work of Harkins and Gans [3, 1930] with benzene, subsequent action leads to additional products in solid and extremely inert states.

The precision of the results obtained in the action of alpha rays on gaseous hydrocarbons has permitted the development of a theory of the reaction mechanism. Whether it be direct action between ions and molecules or interaction of free radicals does not concern the present discussion vitally. The predominant result is condensation of lower to higher members on up into the region of liquids and solids [8, 1927]. The theory gained from the alpha-ray studies also predicts a great variety of products both in the paraffin and olefine series. Starting from a single member either high or low should lead to all other members above and below, distributed according to some form of probability curve with its maximum at the member having double the number of carbon atoms of that in the original molecule. The theory is confirmed among gaseous members, but owing to the scant quantity of liquid obtained under alpha radiation, fractionation of the liquid products has not been attempted. However, the same theory has been found applicable to liquids obtained by electrical discharge in single hydrocarbons [7, 1930]. The quantities of liquid thus obtained have been sufficient to permit of some fractionation. Great complexity is revealed, as expected, and the most abundant molecular species has double the number of carbon atoms of the original species; for example, octane from butane.

The application of some of these processes to the origin of petroleum may appear remote. Indeed it is so, except as the general principle may apply that when a certain type of reactions or a set of products is demonstrated to be possible through the employment of some special agent such as ultra-violet light or alpha radiation, the probability becomes greater that some conditions of temperature, pressure, or catalysis exist which render the same reactions possible with a lower quantum expense of energy.

Although electrical discharge and ultra-violet radiation are abundant in the earth's atmosphere, they are unknown in the crust and hence can play no role in the synthesis of petroleum. But, not so with alpha radiation, which, due to the universal radioactivity of the crust, is everywhere present, though in very low intensity. In their original consideration of the chemical behaviour of hydrocarbons under alpha rays, Lind and Bardwell pointed out [6, 1926] that feeble intensity of radiation might be so compensated by prolonged action through geological periods of time as to suggest a theory of the origin of petroleum from gaseous hydrocarbons under the influence of alpha radiation, provided two apparent obstacles could be overcome.

First, are there conditions in the crust under which an appreciable fraction of the alpha radiation could be absorbed by hydrocarbons? Since the 'porosity' of gas and oil sands reaches the value of 20%, it seemed probable that the fraction of alpha radiation effectively absorbed in the petroleum structure might approach that degree of efficiency.

The second obstacle appears more formidable. The action of alpha rays on all members of the paraffin and olefine series was found to result in the liberation of much hydrogen; whereas in all natural gases occurring in the United States, hydrogen is notably absent. The dilemma exists, though possibly in a milder form, whether we consider the action of alpha radiation in the earth's crust on hydrocarbons to have any connexion with the origin of or changes in petroleum or not. The absence of hydrogen in natural gases is still anomalous, since we know it must be liberated in the earth's crust by the action of alpha particles on any hydrogen-containing compounds—including water. It must then be removed from earth gases by some reaction which again fixes it, possibly assisted by contact catalysis. It might be, for example, the reduction of a metallic oxide to give water and the free metal or a lower oxide. But in the case of unsaturated hydrocarbons, the writer [5, 1931] has suggested that hydrogenation of these may be an important factor. This, of course, could not be expected to account for all the hydrogen from an original saturated hydrocarbon without the assistance of some other hydrogen-removing agent.

In the purely thermal processes of Wilson, liberation of hydrogen is not assumed. This alone would appear to make his mechanism the more probable. But neglecting this hydrogen difficulty, if we calculate the amount of petroleum in the earth's crust that would correspond to the present total of helium content of the atmosphere, on the basis that each atom originated in the crust as an alpha particle, a large total is obtained. This calculation has been made by Farr and Rogers [2, 1928, 1930] on the basis of the alpha-ray energy in producing petroleum and assuming the same yield per ion pair as found by Lind and Bardwell experimentally. The estimated total of two billion tons of potential petroleum for the Petrolia Field of Texas is so great that even after making large allowances for overestimation of energy utilization, yield, &c., the balance could still exceed the actual production. It is also to be remembered that only about 20% of the oil contained in a structure is actually recovered. Corrections in the opposite direction, such as possible loss of helium from the atmosphere leaving the present total content too low, and helium in natural gases still remaining in the earth would raise the total possible. The calculations of Farr and

Rogers also have the advantage of being independent of any time factor. It may be mentioned incidentally that some recent analyses of natural gases in New Zealand by the same authors report as much as 4 to 20% of hydrogen in 10 out of 82 samples, though the helium content in none of them exceeded 0·02%.

To sum up, it may be said that we now know processes either thermal or ionic by which progression both up and down the hydrocarbon series is effected, starting from any member in the series. This leads directly to the complexity found in natural petroleums, and also found in the electrically synthesized ones. Consequently, the starting material, whether of vegetable, animal, or mineral source, does not need to be a complex mixture, but may be a single chemical species, from which a high degree of complexity is obtained by steps which appear simple and natural when the chemical and thermodynamic properties of hydrocarbons are taken into account. The simplicity of such a mechanism may lend indirect support to the old idea of an inorganic origin from one or a few hydrocarbon gases such as might be produced by the action of water on metallic carbides in the earth's interior. On the other hand, it does not preclude animal or vegetable origin, but strongly suggests that the primary material, whether gaseous, liquid, or solid, is later subjected to thermal (or ionic) agents (or both) which produce the complexity found in nature.

PETROLEUM SOURCE BEDS

By PARKER D. TRASK, M.A., Ph.D.

Associate Geologist, United States Geological Survey, Director, American Petroleum Institute Research Project on Source Beds

Published by permission of the Director, U.S. Geological Survey.

SOURCE beds are sediments that are or have been capable of generating petroleum. The subject of source beds is intimately associated with the problems of origin and migration of oil. As these problems are discussed fully in other articles in this treatise, only brief mention will be made of them in this report.

According to the prevailing opinion of geologists, as amply discussed by White [25, 1926; 26, 1934; 27, 1935], Snider [17, 1934], Kelly [10, 1933], and Krecji-Graf [11, 1935], the chief mother substances of petroleum are organic compounds that accumulate in near-shore marine sediments in an environment deficient in oxygen. Though most oilfields are associated with marine sediments, the possibility is not excluded that continental deposits may be source beds. In fact the gas in some fields may be derived from remains of land plants (Torrey [20, 1934]). Oil shales, which commonly are of terrestrial origin, because of their large organic content, have been postulated as sources of oil (Pratt [15, 1934] and Stadnichenko [18, 1931]). The scarcity of oilfields associated with rich oil-shale deposits of continental origin, notably the Green River shale in Wyoming, suggests that continental oil shales may not be good source beds (McCoy and Keyte [13, 1934]). Brooks [5, 1934] comes to a similar conclusion as he observes that waxes, resins, and similar substances (kerogen) such as characterize continental oil shales are so stable that once formed and preserved in the rocks they 'undergo no further chemical change whatever under the conditions of temperature and pressure existing in sedimentary rocks even of great geologic age and depth'.

Coals similarly have been suggested as a source of oil (Cunningham-Craig [6, 1923]), but the prevalence of oilfields in areas devoid of coal, such as California, argues strongly against such a hypothesis. Coal, however, may yield gas and thus be a source of gas in some gasfields. The scarcity of igneous deposits in many oil areas and the presence of barren sands beneath productive zones in numerous fields has for many years convinced most geologists that petroleum is not of inorganic origin, but Krusch [12, 1931] still believes that in some fields it is derived from magmatic emanations. Stadnikoff [19, 1930] also postulates an igneous source for the hydrogen necessary to saturate the unsaturated compounds that he regards as mother substances of petroleum.

Petroleum, presumably, is derived from special types of organic matter under particular conditions. The relative scarcity of oilfields indicates that not every type of organic matter will yield oil, and the localization of fields in certain areas, such as the Gulf Coast Province, suggests strongly that it forms under special conditions. The factors that act upon the mother substances after they have been deposited may be influential in the formation of oil. As pointed out by White [25, 1926; 26, 1934; 27, 1935], the chemical nature of the organic constituents of sediments is influenced by time, temperature, and pressure; and such factors as degree, duration, and date of folding, and also depth of burial may affect the generation of oil. Moreover, it is conceivable that under some conditions source material might generate oil, but not under other conditions. For example, in a series of alternating beds of sandstone and shale the oil might be able to migrate from the shale where it originates to the reservoir where it accumulates, but in a shale body containing a similar amount of source material but no interbedded sand the oil might not be able to reach the reservoir.

Very little is known as to the particular types of organic matter that give rise to petroleum. Oily substances may be produced by distillation of many types of organic material, but as Brooks [5, 1934] points out, these oily substances are highly unsaturated and are rich in aromatic compounds, and though mainly of a hydrocarbon nature, are distinct in composition from petroleum, which is composed of saturated substances and ordinarily contains a small quantity of aromatic compounds. However, whatever the particular substances that give rise to petroleum may be, they presumably accumulate in sediments according to the laws governing the deposition of the organic constituents in general.

The organic content of sediments depends upon the supply of organic matter in the overlying water, though it does not follow that given an equal proportion of organic matter in the water in different areas, an equal quantity will accumulate in the sediments in those areas. Currents may transport the particles of organic matter, and organisms may destroy them before or after they reach the sediments. Organic constituents, being buoyant, are easily moved by currents and are likely to be deposited with fine detrital particles that ultimately give rise to shaly deposits. The conditions under which fine sediments are laid down also favour the preservation of organic matter, because fine sediments are commonly deposited in relatively quiet water, which generally contains less oxygen than moving water and thus favours the preservation of the organic constituents (Hecht [9, 1933]).

The organic content of sediments, therefore, is definitely related to the texture. In fact, in the Channel Islands region of California, the clayey sediments on the average contain twice as much organic matter as the silty deposits, and the silty deposits contain twice as much organic matter as the fine sands. The same ratios hold throughout 5,000 ft. of Pliocene sediments in the Los Angeles basin and 30,000 ft. of strata in the Lower Cretaceous of northern California (Trask [22, 1937]). Whether or not similar ratios hold for all types of sediments has not yet been established, but the available data indicate that these ratios are of the proper order of magnitude, and that given a constant supply of organic matter in the overlying water the clays will contain more organic matter than the silts, and the silts more than the sands, but the clays in one area may contain a different amount of organic matter from the clays in another area.

In other words, shales should be the best source beds,

but sands, particularly poorly sorted sands, such as are present in the Santa Fe Springs field in California, under some conditions might be source beds (Snider [17, 1934]). Limestones deposited under conditions similar to those under which shale accumulates likewise could have a large organic content and might be source beds (Potonie [14, 1928]). The prevalence of limestones in the oilfields of West Texas supports the concept of generation of oil in limestone.

Irregularities on the sea floor, because of their effect on currents, also influence the accumulation of organic debris. Sediments deposited on submarine ridges or open slopes contain relatively little organic matter, and deposits that accumulate in basins or protected embayments have a relatively high organic content (Trask [21, 1932]). Diastrophism, because of its effect on the configuration of the sea bottom, therefore, influences the deposition of source beds. In areas of relatively pronounced earth movements, such as the Channel Islands region off the coast of southern California, or those in which the Pliocene sediments in the Los Angeles basin were laid down, the organic content of the deposits may double within 10 or 15 miles, but in quieter areas, such as those in which the Upper Cretaceous sediments in the East Texas basin and in Central Wyoming were deposited, the organic content may be remarkably constant over areas as much as 200 miles in diameter (Trask [22, 1937]). Thus, in regions of active diastrophism at the time of deposition, the organic content may vary greatly within a short distance, and inferentially the capacity of the sediments as source beds may similarly vary considerably within a few miles. Diastrophism also favours the deposition of alternating beds of sandstone and shale, and thus indirectly facilitates the accumulation of oil.

Organic matter, once it has been formed by the plankton or some other form of life, tends to decrease in quantity with time. Sooner or later it serves as food for other types of life, with the result that some of it is incorporated into the tissues of the organisms that devoured it, some of it is unassimilated, and the rest is used to create energy and is transformed to waste products, such as carbon dioxide and water. The organisms that fed upon the original matter or the unassimilated products in turn serve as food for other organisms, with the result that the original quantity is still further decreased. As long as organic matter can serve as a source of energy it will be acted upon by organisms. In the presence of oxygen it may be totally destroyed, but once it has been buried in sediment it is in an environment of little or no oxygen and ordinarily is not decomposed completely.

It is estimated that on the average at least 90% of the original organic matter is destroyed and no more than 10% is trapped in sediments (Trask [22, 1937]). This estimate is not based on sufficient data to be very reliable, but nevertheless, it is evident that under ordinary conditions a very large proportion of the original planktonic organic matter fails to accumulate in sediments. After the organic matter has been deposited, it still continues to be destroyed, presumably mainly in the upper layers of the sediments where bacteria can live. However, owing to the scarcity of available oxygen, it seems probable that bacteria, though perhaps being able to exist, do not destroy much organic matter after the sediments have been buried to some depth (White [25, 1926]). The rapid decrease in quantity of bacteria from the surface of deposits downwards is in accord with such a concept (Zobell and Feltham [28, 1934]). The presence of significant quantities of organic matter in nearly all ancient sediments likewise supports this inference.

The average quantity of organic matter in recent sediments is about 2·5% by weight (Trask [22, 1937]). This average is a median based on 1,600 samples from 150 environments of deposition from many parts of the world. The quantity, of course, varies greatly among different types of deposits. In near-shore marine sediments it ranges mainly from 1 to 7%, being large in areas characterized by plentiful plankton. In some lakes it may be as high as 40% (Potonié, 1935, see reference 8), and in some deposits in the Black Sea it is 35% (Krejci-Graf [11, 1935]). Typical oceanic sediments far from land contain 1% organic matter or less (Trask [21, 1932]).

The average organic content of several thousand samples of ancient sediments ranging in age from Cambrian to Pliocene and located in many areas in the United States west of the Mississippi River, as indicated by the analyses thus far made, is 1·5% (Trask [22, 1937]). Very few ancient sediments in existing oilfields contain less than 0·5% or more than 5% organic matter.

The analyses upon which these averages are based represent many types of sediment, and are sufficiently large in number to indicate at least the proper order of magnitude of the organic content. The difference in the average organic content of the recent and ancient sediments is 2·5 less 1·5 or 1·0%; that is, the average loss during burial is 1·0/2·5 or 40%. Individual sediments, including some or perhaps many source beds, may lose more, or less, organic matter than the average, but as a general rule it seems that the loss should be about 40%. In other words, nearly all recent marine sediments contain a significant quantity of organic matter, most of which does not seem to be destroyed in the course of time; that is, the organic constituents of sediments, in general, are composed of resistant substances.

The decrease in quantity of organic matter is accompanied by a progressive loss of oxygen and nitrogen and possibly hydrogen with respect to carbon (White [27, 1935]). According to some geologists, notably Krejci-Graf [11, 1935], sediments characterized by the greatest amount of deoxidation are the most likely to be source beds. In fact Krejci-Graf [11, 1935] argues that in order for a sediment to be a source bed, it must be deposited in a reducing environment in which practically no oxygen is present. Such conditions favour the formation of dark sediments, and many American geologists, as reported by Snider [17, 1934], regard a dark colour as a favourable indication of source beds. For want of definite evidence as to what types of sediments are source beds, one cannot say that colour is not an index of the ability of the rock to generate oil, but many light coloured sediments, some of which are associated with oil zones, such as parts of the Niobrara formation in the Rocky Mountain region, contain much organic matter, and on the contrary some dark sediments contain little organic matter. Colour, therefore, should not be regarded as an infallible index of source beds.

Some geologists believe that sediments must be extremely rich in organic matter in order to be source beds. Krejci-Graf [11, 1935] leans to this view because he holds that oil cannot migrate until an excess is produced over that which is adsorbed by clay particles which it may encounter in the process of migration, and that as clay particles have considerable powers of adsorption, a sediment must be very rich in organic matter in order to be a source bed.

However, as mentioned above, very few ancient sediments in many oilfields in the western United States now contain more than 5% organic matter. The organic content at the time of deposition was of course larger than it is now. As indicated above, the initial content probably was about 70% greater than the present content of the sediments in the oilfields. That is, these sediments in general probably contained less than 10% organic matter at time of deposition. The samples that were examined represent such great thicknesses of sediments from so many areas that it is probable that a considerable number of them are analogous to rocks that have generated petroleum. Consequently it would seem as if a very large organic content at the time of deposition is not an essential requisite of source beds, and it is almost certain that sediments that have already generated oil do not necessarily contain much organic matter. This is particularly exemplified by the Santa Fe Springs field in California, where the average organic content of some 4,000 ft. of lower Pliocene sediments which are intimately associated with the oil zones is less than 2% throughout the drainage area of the field (Trask [22*a*, 1936]).

On the other hand, though extreme richness does not seem essential, moderate richness very likely is a common characteristic of source beds. Numerous formations which contain from 2 to 5% organic matter, such as the Eagle Ford shale of Texas, the Mowry shale of Wyoming, and the Pliocene and Miocene sediments in the Los Angeles area of California, are intimately associated with oil zones. However, some sediments that contain equally as much organic matter, such as parts of the Pierre shale in Wyoming, are not contiguous with oil horizons, and some sediments that contain very little organic matter, such as some of the Carboniferous formations in Wyoming, are associated with oil zones. In other words, moderate richness, though perhaps a favourable indication of source beds, is by no means a certain guide.

Knowledge of the proportion of the organic matter that has to be converted into petroleum in order for a commercial pool to form would aid the solution of the problem of what is a source bed. In the Santa Fe Springs field of California, the proportion of organic matter that had to be transformed to oil probably is more than 2% and less than 40%, and the most plausible figure, according to Trask [22*a*, 1936], is between 5 and 10%. Other fields, especially those complicated by faults, might require different percentages of conversion.

This estimate of conversion of organic matter to oil affords a line of attack on the problem of what particular organic substances may be mother substances of petroleum. Simple proteins seem to be decomposed more or less completely before they reach the sediments (Hecht [9, 1933]), and hence probably are present in sediments in too small quantities to be main sources of petroleum. However, all sediments, both recent and ancient, contain considerable quantities of nitrogenous substances. Nitrogenous compounds ordinarily constitute 30 to 50% of the organic constituents in recent sediments, and from 15 to 30% in ancient sediments (Trask [22, 1937]). The magnitude of these quantities makes it difficult for one to maintain that oil cannot come from compounds containing nitrogen.

Cellulose has been regarded as a source of oil (Berl [2, 1934]). The quantity of cellulose in the upper layers of marine sediments at the time of deposition in general seems to be less than 1% of the organic content and even less in deeper layers of the sediments (Trask [21, 1932]). This small quantity hardly seems adequate for cellulose to be a major source of petroleum, especially since it seems as if at least 2% and probably as much as 5% of the organic matter has to be converted into oil to make a commercial pool. However, some of the organic constituents of sediments may be derived from cellulosic matter in the protoplasm of the microscopic plants in the overlying water. Brandt [4, 1898] and Waksman [23, 1934] point out that the peridineans, which constitute one of the main groups of marine organisms which form organic matter from inorganic constituents with the aid of sunlight, when dried, contain 40% cellulose. It is therefore possible that the basic organic source of petroleum might be cellulose, but if so, it almost certainly has lost its cellulosic character by the time it reaches the sediments.

Fats, also, generally are present among the organic constituents of sediments at the time of deposition in quantities of less than 1% (Trask [21, 1932]). Accordingly, it seems unlikely that fats are present in sufficient quantity to generate enough oil for a field. However, so many people, notably Engler and Höfer [7, 1909], have postulated fatty substances as the main source of petroleum that the origin of oil from fats should receive serious consideration. It is possible that such fatty substances, though originating as fats in some particular organisms in the water, may not be present as fats in sediments, but instead may be in some other form, such as metal salts of fatty acids—that is, as soaps (Wasmund [24, 1935]). As the quantity of such soaps in sediments is not yet known, it is an unsettled question as to whether they are present in a sufficient quantity to produce source beds. Even if they should be found to occur in significant amounts, it does not necessarily follow that they would be the main source of oil. The chief reason fatty substances have been regarded as sources of petroleum seems to be their low oxygen content. Most fatty acids contain two atoms of oxygen and if by some process these were removed a chain hydrocarbon would be produced. Petroleum contains a considerable quantity of chain hydrocarbons, which are almost all members of the paraffin series, but according to the data on the composition of petroleum, compiled by Brooks [5, 1934], cyclic compounds of naphthenic and benzenoid nature are commonly more plentiful in petroleum than paraffin compounds. Furthermore, as pointed out by Barton [1, 1934], petroleum as first formed may be largely naphthenic in nature and acquire its content of paraffins as it grows older. Thus, since cyclic or ring compounds form such a large part of petroleum, and since fats are chain compounds, there is at least a fair presumption that oil may in part, or even to a large degree, be formed from non-fatty constituents of sediments that contain as little oxygen as do fatty substances.

The oxygen content of the fatty acid radicals, such as palmitic acid ($C_{16}H_{32}O_2$), which might be expected to be present in sediments, is about 12%. The average oxygen content of the organic constituents of one-fourth the sediments examined by Trask [22, 1937] is calculated by him to be 16% or less. Many of these samples low in oxygen, such as those from the Eagle Ford shale, are associated with oil zones and may be source beds. It therefore seems possible that compounds which are low in oxygen, but which are not of a fatty nature, may be present in sediments in sufficient quantity to be a source of oil. The whole question is complicated by lack of knowledge of the chemical nature of the organic components of sediments, and the problem of what kind of a rock is a source bed cannot be solved until more quantitative data are obtained.

THE CHEMICAL AND GEOCHEMICAL ASPECTS OF THE ORIGIN OF PETROLEUM

By BENJAMIN T. BROOKS, Ph.D., A.I.Chem.E., M.Inst.P.T.

Consulting Chemical Engineer

THE earlier theories of the origin of petroleum were proposed when little was known of the chemical character of petroleum and other organic minerals: coal, lignites, kerogen, asphalts, fossil resins, and waxes. Geological knowledge relating to these organic materials was equally fragmentary when the theory of the thermal decomposition of fatty oils of marine sources, or, as it is often called, the destructive distillation theory of petroleum origin, was suggested by Warren and Storrer [47, 1865] in 1863, and later (1888) by Engler [10]. Though this theory is still widely held it has become increasingly difficult for geologists to reconcile it with the evidence of geology. Thus on geological grounds alone Illing [18, 1926] has stated that the geological evidence demands a theory of petroleum origin contemporaneous with the sediments and 'not, as the distillation theory would suppose, as a later process of metamorphism'. Beeby Thompson [39, 1925] also states: 'In seeking the origin of petroleum one must not introduce extraordinary theories for its occasional occurrence amongst unusual surroundings, but consider only such views as will account for its *extensive production and wide distribution by common processes of nature*.' The current ideas regarding source beds for petroleum have been well reviewed by Snider [31]. (See also the articles in this section by P. D. Trask and V. C. Illing.)

As the physical conditions, particularly low temperatures, have become more widely recognized, the thermal-decomposition theory has been modified. It is generally believed that the organic material originally deposited in the source sediments must have been solid or semi-solid in order to be held in the original muds and that the conversion to oil came later by the slow action of mild degrees of heat. This view was held by the late David White [50, 1935], who believed that the change of coal to higher fixed carbon ratios was evidence of a thermal effect and that the same conditions producing these changes in coals were factors in the production and alteration of petroleums. From a study of the Appalachian coal and oilfields White believed that in regions where the fixed carbon of the coal deposits exceeded 60–4% no oil would be found, and outlined so-called extinction zones where conditions of metamorphism were believed to preclude the finding of oil. The present status of the carbon-ratio theory has been reviewed recently by Thom [38]. Some support for the alteration of petroleum with age and depth, by thermal influence, is to be found in the recent studies of Barton [2, 1934] of the oils in the Gulf Coast region, who showed that in this area most of the oils become lighter and more paraffinic with age and depth. However, this relationship has been shown not to hold in Wyoming [3] and Californian fields [34]. Although petroleums may have been altered in certain instances by regional metamorphism, it is doubtful, in view of the evidence submitted in the following discussion, if heat has been the primary factor in the formation of petroleums [6, 1934].

Consideration of petroleums alone, excluding other organic minerals, would be inadequate, as much of the evidence as to petroleum origin, source materials, and physical conditions prevailing in sedimentary strata is furnished by other organic material deposited in strata of widely varying geological age.

Common Organic Minerals

In Cambrian and pre-Cambrian rocks graphite occurs occasionally in the form of small flakes. The pre-Carboniferous coals sometimes approach pure carbon in composition (ash-free basis) and sometimes contain small quantities of graphitic carbon. Graphite deposits fall into two classes: (1) bedded and disseminated deposits derived from organic matter in sediments by contact or regional metamorphism, and (2) vein deposits formed by igneous intrusions [7, 1921; 8, 1923; 25, 1912; 44, 1911].

The formation of petroleum by the thermal decomposition of the kerogen of oil shale or of coal would presumably leave a carbonized residue, possibly graphitic, assuming the gas and oil to be removed in some way to cooler absorbent strata. However disseminated, graphitic material is geologically far removed and geographically usually very remote from oil-producing strata. Mention is made of the occurrence of disseminated graphite only because the theory that petroleum has been formed by the thermal decomposition of something requires an association within reasonable distances of petroleum or natural gas, and graphite or highly carbonized residues.

The relative abundance of petroleum through the geological scale runs roughly parallel with the abundance of the other organic material and fossil remains. Although the Lima-Indiana petroleum and certain of the deeper Mid-Continent and Texas oils are derived from the Middle Ordovician, organic material does not become abundant until much later, in the thick beds of the black shale of the Devonian period. In the more recent Carboniferous period both coal and oil are still abundant, and oil is found scattered through the more recent periods down to and including the Tertiary. It is noteworthy that many oil shales, containing kerogen but little or no oil, are geologically much older than many petroleums. Probably the oldest of these shales is the New Brunswick shale which Ells [9, 1925] places at the bottom of the Cambrian series. The oil shales of Esthonia, Ontario, and Ohio are Devonian, and those of Scotland, Nova Scotia, New South Wales, and one in Brazil date from the Carboniferous period. The geological antiquity of many of the oil shales is a striking proof of the chemical stability of the organic material contained in them under conditions of temperatures and pressures prevailing in these beds during their long history. Or, in other words, the survival of such organic material, often without the formation of oil, is very satisfactory evidence against the assumption that petroleums have been formed by the thermal decomposition of organic material, at least of the kerogen type.

Perhaps the most convincing evidence of the low-temperature history of oil shale, as well as petroleum, is furnished by the recent discovery of Treibs [41, 1934–5]

that many shales, asphalts, and asphaltic petroleums contain chlorophyll porphyrins. In a discussion of the origin of oil shales George [13, 1925] states that in some of the oil shales fossil plant remains predominate and others are relatively rich in fish or animal fossil remains. Treibs found evidence of meso-porphyrin, derived from haemin, in several oil shales, which agrees with the mixed character of the fossil remains. However, in the series of oil shales, asphalts, and petroleums investigated by Treibs chlorophyll porphyrins predominated and were the only porphyrins detected in the majority of cases.

Very little is known of the chemical nature of kerogen [24, 1924]. Extraction of oil shales with solvents usually yields very little oil; for example, New Brunswick shale yields 1·36% of the shale, or about 4% of the kerogen, by extraction with various solvents [12]. Only traces of the extracted material distil below 200° C., showing the complete absence of oils of the nature of gasoline. The carbon-hydrogen ratio of kerogen in various oil shales varies from about 7·42 to 8·92. The nitrogen appears largely as ammonia, on destructive distillation, and the sulphur content is often high, forming hydrogen sulphide and a series of complex organic derivatives.

The kerogen of oil shales, in its insolubility in solvents and in the character of the products obtained on destructive distillation, closely resembles the cannel or boghead coals. Stadnikoff [32, 1930] has recently published a great deal of evidence to show that the organic material in cannel and boghead coals consists almost wholly of products of polymerization and anhydride formation of fatty acids. The oils obtained by destructive distillation contain only very little phenols, are rich in olefines, the lighter distillates contain free fatty acids and the higher-boiling fractions contain small proportions of saponifiable material, yielding fatty acids after saponification, which Stadnikoff regards as fatty acid anhydrides. The oxygen content of these oils also indicates the presence of neutral oxygen derivatives, probably ketones. The gas formed is mainly methane.

Stadnikoff gives the composition of the oil distillates of several cannel-type coals as follows:

TABLE I

Constituents of Cannel Coal Distillates

	Carbonic acids %	*Phenols* %	*Organic bases* %
1	0·04	1·70	2·02
2	0·20	1·30	1·30
3	0·14	2·35	1·68
4	0·20	3·42	1·85
5	0·50	2·00	2·00
6	0·44	1·70	0·30

Brown coals, though chemically quite different from cannel coals and oil shales, commonly contain resin and wax, the survival of which through long geological periods is striking proof of the low-temperature conditions prevailing since their deposition. Resin inclusions, resembling kauri gum, have been found in New Zealand brown coal [19, 1925]. The resin was found to consist almost completely of a carboxylic acid. Still more striking is the survival of organic esters of the higher alcohols, as in montan wax of German brown coals. This wax contains the acids [42, 1934] carboceric, $C_{27}H_{54}O_2$, and montanic, $C_{29}H_{58}O_2$, and as esters the alcohols tetracosanol, $C_{24}H_{50}O$, ceryl alcohol, $C_{26}H_{54}O$, and myricil alcohol, $C_{30}H_{62}O$. The amorphous, rather indefinite, mineral pyropissite occurring in Tertiary brown coals begins to give off gas and decomposition products on heating to 120–50° C., and on destructive distillation yields a mixture of crystalline paraffins, saturated and olefinic oils.

It has long been believed that the progressive carbonization of coals has been primarily due to heat, or to heat and pressure. Thom [38] concludes that the fixed carbon ratios of coals appear to provide a fair qualitative index of local metamorphic intensity. Regions containing anthracitic coals are apparently completely barren of commercial oil-pools. Thom also states that carbon ratios do not afford sufficiently accurate or critical evidence to warrant the drawing of 'dead-line' limits to possible oil and gas occurrence. He regards coals as 'particularly sensitive' to the influence of heat and pressure. The fact that petroleums often contain complex labile substances easily decomposed by heat may indicate that cellulose, peats, and coals are progressively carbonized under pressure and during geological time at temperatures much lower than has heretofore been assumed. Thom states: 'The assumption that oil is generated *only* by dynamo-chemical alteration of organic source materials is contradicted by what is now known of the occurrence of oil in relatively young formations.—A great proportion of the world's known oil fields of importance occur in sedimentary rocks which are entirely or almost wholly unconsolidated, and the remaining fields occur in formations which are unmetamorphosed and only partially filled with cementing materials.' In other words, the carbonization of coal, serving as a 'qualitative index of local metamorphic intensity', may indicate conditions severe enough to have *destroyed* petroleum, but cannot be accepted as evidence for the manner of petroleum formation under the very different conditions of the normal occurrences of petroleum.

It has often been assumed that the hardening of sedimentary strata, or lithification, has been mainly due to pressure and temperature. Compaction by pressure is evident and is generally progressive with the depth [26]. But in view of the very low-temperature history of petroleum which the chemical evidence indicates, it is much more probable that cementation by deposition of the cementing material from solution, together with compaction, are the primary factors.

Ozokerite is generally believed to occur as a mechanical concentration or separation of the higher melting-point, less soluble paraffins of petroleum. It is of interest in this connexion only as indicating that the conditions of temperature and pressure of the deposits in which it is found have not been sufficient to change it to mixtures resembling petroleum. The occurrence of ozokerite is an indication that petroleums are not so-called equilibrium mixtures of hydrocarbons produced by heat and that such hydrocarbons, once formed, may be separated, filtered, and absorbed and concentrated but not chemically changed by natural conditions.

Natural Gas

Methane, though now known to be a major constituent of the atmosphere of some of the planets [29, 1935], and known to be formed from certain metallic carbides by the action of water, is also formed by the common anaerobic fermentation of cellulose. The composition of natural gas accompanying petroleum has a definite bearing on the genesis of petroleum. Natural gas contains no trace of hydrogen, carbon monoxide, or ethylene; gas formed by

the pyrolysis of fatty acids or natural fats, as in Engler's experiments, contains all three of these substances. Although ethylene and carbon monoxide can be hydrogenated under suitable conditions and in the presence of specially prepared catalysts, it is not reasonable to assume that these three substances would always be produced by pyrolysis in exactly the proportions required for their subsequent complete elimination by hydrogenation. The absence of hydrogen in natural gas accompanying petroleum is also very strong evidence against the theory, suggested by S. C. Lind [21, 1931], that petroleum has been formed by the action of alpha radiation from radio-active minerals on methane, since hydrogen is formed in large proportions from methane in the process.

The occurrence of helium in small proportions in natural gas in certain localities, in the light of the evidence of organic origin, is to be regarded as an adventitious constituent probably derived from primitive granites beneath the sedimentaries, as in the case of the old buried granite ridges in the Mid-Continent area of the United States, or from secondary radio-active minerals in certain sedimentaries, as in the Shinarump conglomerate of Colorado.

Natural Occurrences of Hydrocarbons

Recalling Beeby Thompson's [39, 1925] statement regarding 'common processes of nature', it should be noted that saturated paraffins and olefinic hydrocarbons of widely varying types are found in nature, produced by biochemical processes at ordinary temperatures. At least 15 normal paraffin waxes occur in the essential oils of about 25 plant species, as in the oil of roses, the buds of the sweet birch, tobacco, &c. The source of pure normal heptane, used as a standard reference fuel in the determination of knock rating, is two pines in the western United States, *P. sabiniana* and *P. jeffreyi*, and also a prune-like fruit in the Philippine Islands. The chemical mechanism by which such paraffins are formed in growing plants is quite unknown, and while it is obvious that petroleum has not been formed by accumulations of hydrocarbons from such sources, their natural occurrence is important as showing that 'the processes of nature' can produce them, at normal temperatures. The natural paraffins are not associated with fatty acids of the same or C_{n+1} carbon atoms, and many contain more carbon atoms than any known fatty acid.

The terpenes, $C_{10}H_{16}$, the sesquiterpenes, $C_{15}H_{24}$, and the rubber hydrocarbons, rather widely distributed in nature, appear to be related to the C_5 group of the pentoses and the pentosans, from which they may be derived by biochemical processes of dehydration and reduction (or biochemical hydrogenation).

It is not at all necessary to assume that a high energy-input is necessary to accomplish such reductions. Such changes are observed to occur with very little net energy-change by the conversion of part of the original material to an oxidized state and part to a reduction product, as in the conversion of sugar or glucose to carbon dioxide and ethyl alcohol, and the fermentation of cellulose to methane, carbon dioxide, and small proportions of other products. One of the significant corollaries of the discovery of chlorophyll porphyrins in petroleums, asphalts, and oil shales is that the original organic material associated with these porphyrins passed rather quickly into an anaerobic environment, since chlorophyll is rapidly destroyed in aerobic fermentations. It is possible that anaerobic fermentations will be discovered which will produce ethane, propane, and other hydrocarbons.

The Composition of Petroleums

Our knowledge of the composition of petroleums is now much more extensive than when the theory of thermal decomposition was first suggested. The facts as to composition which have a bearing on the question of petroleum origin may be stated briefly.

The relative proportions of paraffins, naphthenes, and benzenoid hydrocarbons, wax, and asphalt in petroleums are summarized by Stadnikoff [32, 1930] as follows:

TABLE II

Average Composition of Typical Petroleums

Type of crude	Wax %	Asphalt %	Composition of 250–300° C. fraction: Paraffins	Naphthenes	Benzenes	Specific gravity of residue over 300° C.
Light paraffinic	1·5–10	0–6	46–61	22–32	12–25	0·897–0·929
Paraffin-naphthene	1–6	0–6	42–5	38–9	16–20	0·897–0·908
Naphthenic	trace	0–6	15–26	61–76	8–13	0·895–0·912
Benzenoid	0–0·5	0–20	0–8	57–78	20–35	0·950–0·970

The light, low-boiling fractions contain the largest proportion of paraffins. No petroleum has ever been found which contains unsaturated hydrocarbons of the olefine type, at least in the lighter distillates which can be separated by distillation without decomposition. The hydrocarbons of the C_nH_{2n} series are naphthenes and those of the higher carbon ratios C_nH_{2n-2} to C_nH_{2n-8}, &c., occurring in the lubricating-oil distillates, are evidently polycyclic hydrocarbons. According to Mabery [22, 1923] the distillable lubricating fractions of Cabin Creek petroleum are mainly of the series C_nH_{2n-4}; the distillable lubricating-oil fractions of Baku oil are mainly of the series C_nH_{2n-10}, and the corresponding fractions of Sour Lake, Texas, oil are of a series C_nH_{2n-12}. Mabery also showed that many of the hydrocarbon fractions separated from undistilled residuum by the action of solvents were sensitive to heat and could not be distilled under a good laboratory vacuum without decomposition.

Nitrogen Bases

J. R. Bailey [1, 1930] and his co-workers have shown that certain Californian petroleums, having a relatively high nitrogen-content, yield no bases on acid extraction, but that the distillates contain bases which are readily extracted by dilute acid. Their observations show that the crude petroleum contains complex nitrogen derivatives which are sensitive to heat and are rapidly decomposed at temperatures above 200° C., in the kerosine boiling range, to give nitrogen bases as decomposition products. A recent private communication from Treibs reports that the Californian petroleums which yield distillates containing nitrogen bases are also relatively rich in chlorophyll porphyrins and that a study of these oils is in progress.

The discovery of chlorophyll porphyrins in asphalt and asphaltic petroleums by Treibs [41, 1934–5] is probably the most significant discovery ever made with respect to the origin of petroleum. Its significance is in showing a complete history of temperatures so low as definitely to preclude the formation of petroleum by thermal decomposition of fatty oils or any other known likely raw material.

From the presence of aetio-porphyrins which are formed

by loss of CO_2 from the corresponding acid derivatives, Treibs concluded that the organic material may have been heated to a temperature as high as 200° C., but evidently overlooked the fact that decarboxylation of chlorophyll porphyrins takes place in a few hours in the digestive tract of animals.

Asphalts

All asphalts examined and all asphaltic petroleums contain chlorophyll porphyrins. Treibs considers that the clear asphalt-free oils had lost their porphyrin content by adsorption during filtration through absorbent material. These results also show that chlorophyll-bearing plants (algae) existed as early as Devonian and probably as early as Silurian time. Owing to the rapidity with which these chlorophyll derivatives are decomposed by oxidation, Treibs considers that their presence in oil shales, asphalts, and asphaltic oils indicates that in the original deposition of the organic material anaerobic conditions must have been brought about quickly, as by covering with sediment. The same consideration definitely excludes the assumption that asphalts have been formed by the oxidation, by air or evaporation, of petroleum. As Treibs states: 'In oils of medium viscosity, with considerable asphalt content, one has a more original oil, while the thinner, lighter colored oils represent natural raffinates.' He further suggests that one can expect that certain classes of substances will be found very little changed in petroleums and bitumens.

In the case of a Triassic oil shale from near Meride in Croatia, Treibs found 0·4% of porphyrins, corresponding to more than half as much as the chlorophyll content of dried green leaves. In contrast with the porphyrin content of oil shales and asphalts and asphaltic petroleums, lignites and cannel coals showed only traces of porphyrins. This indicates that the source material of coal was very different from that of petroleum or that the prevailing biochemical conditions were very different.

The discovery of chlorophyll porphyrins in oil shales, asphalts, and petroleums suggests that green algae may have contributed largely as source material for petroleums [15, 1932]. Few chemical studies of algae have been made. Some algae contain much fatty oil, but Stadnikoff [32, 1930] has pointed out two instances where abundant growths of algae result in semi-solid materials consisting largely of products derived from the fatty oil content. In a shallow brackish lake in southern Russia an abundant growth of green algae, *Bobriococcus braunii*, forms masses of rapidly fermenting materials, evolving hydrogen sulphide, and when air dried yields a material 'balchaschite' which is semi-solid and which consists largely of polymerization products of unsaturated fatty acids. Stadnikoff and others, however, consider this material as probably related to cannel coal or boghead coals. In a lagoon in southern Australia Thiessen [37, 1925] observed the formation of masses of semi-solid fatty material from the algae *Elaeophyton coorongiana*. A sample of the material, called coorongite, gave 5·7% of oil consisting in part of non-saponifiable oil. These results, together with the findings of Treibs, suggest that oil-bearing algae may have been an important source material of petroleum. Certainly we can no longer confine our speculations to fatty oils of fish, foraminifera, or diatoms.

The fatty material from algae, such as coorongite, forming first a waxy or semi-solid substance fulfils the condition advanced by many geologists (that the original source material of petroleum must be solid or semi-solid in order to be deposited and preserved in the forming sediments. Trask and Hammer [40, 1932], in a thorough study of contemporary sediments, found practically no organic matter in the form of extractable oil.

Naphthenic Acids

Petroleum naphthenic acids are usually separated from the distillates or from the alkali soaps formed in the still residues when the oil is distilled in the presence of caustic alkali. Pyhälä [28, 1933] found in the case of two Russian petroleums that the distillates contained 11 to 12 times as much naphthenic acids as the undistilled crude oils, indicating that, like the nitrogen bases, the naphthenic acids are mainly decomposition products of more complex materials which are readily decomposed on heating. Von Braun [45] has shown that petroleum naphthenic acids are of three general types, aliphatic $C_nH_{2n}O_2$, monocyclic $C_nH_{2n-2}O_2$, or bicyclic $C_nH_{2n-4}O_2$. Some of them are optically active. Petroleum from north Germany, Roumania, California, and Texas all contain the same monocyclic and bicyclic types of acids. The monocyclic acids are derivatives of cyclopentane $C_5H_9\cdot(CH_2)_xCO_2H$. The only similar acids found in nature are the chaulmoogric and hydnocarpic acids of chaulmoogra oil, which acids contain the cyclopentene group. Acids of this type are so rare in nature that the structure of the petroleum naphthenic acids appears to be evidence of their formation by decomposition of polymers of unsaturated fatty acids originally present in the petroleum source material.

Sulphur Derivatives

Practically all the sulphur derivatives so far investigated have been those found in the distillates, and particularly cracked distillates produced by cracking processes. Thiophenes have been found in the latter, and in shale oils, but it is doubtful if they occur in undecomposed petroleum. Kewley [20, 1934] has stated that certain crudes yield sweet distillates, free from mercaptans, if distilled under vacuum below 140° C., but at this temperature decomposition of complex labile sulphur compounds takes place with the formation of mercaptans. It has been pointed out by Gruse [14, 1928] that the sulphur and nitrogen compounds in crude petroleums, prior to distillation, are for the most part unknown.

Optical Activity

The fact that the higher-boiling fractions of petroleum show optical activity has long been regarded as disposing of the theory of the origin of petroleum from carbides. It is equally of importance as evidence against the more recent suggestion of Lind [21, 1931] that petroleum may have been formed from methane by the action of alpha radiation. In the light of other evidence as to low-temperature history it should be recalled that Walden [46, 1906] regarded this fact alone as proving a relatively low-temperature history. The optical activity of oils derived from cholesterol has been noted by Zelinsky and Steinkopf [33, 1927].

The above facts show clearly that we now know petroleum to contain many complex substances which are unstable even to moderate temperatures. Many of them are decomposed by heat much more readily than are the fatty acids or the hydrocarbons.

Complexity of the Hydrocarbon Mixture

Probably one of the reasons for the persistence of the thermal decomposition theory is the large number of hydrocarbons present in most petroleums. Petroleums contain the normally gaseous hydrocarbons, methane and ethane, dissolved under pressure, and also contain the normal paraffins and some of the branched-chain paraffins, from propane up to those of more than 25 carbon atoms. They also contain a large number of cyclic, polycyclic, and benzenoid hydrocarbons. The range of composition with respect to types of the major constituents is shown in Table II.

Wilson [51, 1927–8, 1930] has pointed out that in both the paraffin and olefine series the change from one or a few hydrocarbons to a great many of the same series involves no great amount of net energy change or reaction heat. However, one of the puzzling facts is the universal presence of small proportions of benzenoid hydrocarbons. Francis [11, 1928] has also treated this subject from the thermodynamic standpoint, and states that the formation of aromatic hydrocarbons from paraffins requires temperatures within the range of 550–900° C. This evidently assumes the splitting off of hydrogen. According to Francis, the reactions possible below 550° C. are quite *different in kind.* It is therefore wrong to assume that the formation of benzenes which is characteristic of the results obtained experimentally above 550° C. may also proceed at the much lower temperature associated with petroleum deposits at much slower rates during geological time.

The extremes of petroleum composition, as shown in Table II, should also be noted. If what may be termed the hydrocarbon dispersion and isomerization has been due to heat, even at relatively low temperatures over long periods of time, then petroleums would be much more alike in composition, would, in fact, be *equilibrium mixtures.* However, the differences in the chemical character of petroleums is much greater than can be reasonably explained by different intensity or duration of thermal action.

Barton [2, 1934] has observed certain general consistencies between the A.P.I. gravity and composition as related to depth and age of petroleum in the Gulf Coast area which if borne out in other fields, or if the exceptions could be satisfactorily explained, would at least show that petroleums are progressively altered with depth (temperature and pressure) and age. In this connexion it is of interest to note, as pointed out by Barton, that the naphthenes and *benzene* hydrocarbons occur in the largest proportions in the youngest and shallowest Gulf Coast oils. The older and deeper oils in this area are lighter and more paraffinic. Washburne [48, 1919] has argued, from general theoretical principles, that if altered by heat and pressure the older oils should be the heavier and contain the largest proportions of naphthenes and benzenes. Pratt [27] states: 'Whatever may be the exact sequence and nature of events in petroleum genesis, a theory of uniform and progressive cracking does not explain the observed facts.' These considerations led Pratt to suggest that petroleums were progressively hydrogenated, the hydrogen being derived from methane. The experimental conditions for decomposing methane and hydrogenating heavy oils are more extreme than for cracking alone. It should be noted, however, that Healdton, Texas, oil and many of the Wyoming and Californian oils do not follow the general relations shown by the oils of the Gulf Coast area.

The temperatures observed in the producing strata are significant. Some of our most prolific fields yield their oil from geologically recent sands whose bottom-hole temperatures do not exceed 100° F. and whose strata are only slightly arched or otherwise disturbed. It has often been assumed that even slow uplifts and bending of the strata could produce temperatures sufficient for the decomposition of organic material. Mere compaction is no doubt often mistaken for thermal metamorphism. Heald [17, 1930] states, 'Not enough measurements are available to permit any conclusion as to the possible influence of a great, gentle uplift like the Bend arch on earth temperatures', and that in wells thus far measured the depth of the granite basement has had no relation to the temperature. At Oklahoma City a temperature of 100° F. is encountered at 4,100 ft. In south-west Texas a rise of 1° F. for each 50 to 60 ft. is noted, while in the Permian Basin of West Texas and the Panhandle area the temperature rise is 1° F. for about 100 ft. of increasing depth. It may reasonably be assumed that the present bottom-hole temperatures are much higher than the temperatures of the original sediments when laid down, and that the present temperatures may be at or near the maximum for the entire period. The temperatures observed at the bottom of wells about 8,000 ft. in depth vary from about 150° F. to 170° F. [43, 1928]. McCoy and Keyte [23] state, 'Most of the known oilfields surely were formed at temperatures lower than 140° F.', which is far below the temperature required to decompose or isomerize oils such as paraffins, naphthenes, and benzenoid hydrocarbons at any measurable rate. Seyer [30, 1933] has employed the velocity constants for cracking, determined by others, and calculated that at 212° F. the higher paraffins have a stability greater than the element potassium, and the 'one-half life period' is about $3{\cdot}68 \times 10^{14}$ years and that 'any buried waxy material must have been at a temperature of at least 302° F. to allow for its transportation into petroleum within the limits of geological time'. In fact, the one-half life period for the decomposition of wax at 302° F. (150° C.) is $1{\cdot}15 \times 10^{10}$ years. Study of the lead-uranium ratio of the mineral cyrtolite, found in a pegmatite intrusion at Bedford, New York, which intrusion geologists place as dating from the Early Ordovician, shows the age of the Early Ordovician to be about $3{\cdot}8 \times 10^{8}$ years. Then, according to the reaction velocities calculated from measured cracking rates, about 20 times the *whole* of geological time since the Ordovician and a temperature of 300° F. for the whole of this time would be necessary to decompose half of a quantity of buried wax to oil or other products.

Using the temperature gradient observed in the Permian Basin of West Texas, no petroleum should be formed by heat decomposition in geological time short of a depth of about 28,000 ft.

In making his calculations, Seyer was seeking evidence for the formation of petroleum by heat decomposition. He was led like Washburne to reason that dense saturated molecules with a low hydrogen-carbon ratio, such as the polycyclic naphthenes, should be produced to a greater and greater extent with increasing time, temperature, and pressure. Exactly the opposite is strikingly shown by many light, highly paraffinic but geologically old oils and the wax-free, heavy naphthenic oils of many of the Gulf Coast and Californian pools of much more recent origin as already noted.

No entirely consistent relationship has been discovered

between the composition of petroleums and their age or depth of occurrence. The question is evidently complicated by alterations in composition due to selective adsorption of asphaltic and other material of high molecular weights during migration of oil through the rocks, to chemical reaction with sulphur and perhaps other causes. It appears to be more probable, and also more consonant with the evidence of low-temperature history, that the wide variations in chemical character of different petroleums have their origin chiefly in the character of the original material deposited in the submarine sediments, or possibly in differences in the biochemical influences in the early stages of their history [6, 1934].

Pressure may conceivably have had a marked effect in the formation of petroleum, although the hydrostatic pressures even in our deeper wells seldom exceeds 150 atm. Pressure, in general, favours polymerization of olefinic materials, but the ease with which many unsaturated substances polymerize spontaneously indicates that the effect of the rather moderate pressures, particularly at shallow depths, may have been important. The formation of coorongite and balchaschite from the fatty oils in the algae, noted above, indicate that polymerization of unsaturated fatty oils to solid or semi-solid material is one of the first changes to take place, as suggested by Stadnikoff [32, 1930]. The highly insoluble character of the kerogen of oil shales and most of the organic material in cannel coals indicates that it is highly polymerized. Evidence that such material contains cyclic or naphthenic groups is furnished by Stadnikoff, who found bicyclic hydrocarbons of the series C_nH_{2n-2} as major constituents of the oil produced on hydrogenating a Siberian boghead coal by the method of Bergius. A lower degree of polymerization, or less unsaturated character of the original material, may account for the lubricating oil fractions of petroleum. Engler suggested that polymerization of olefines possibly accounted for the presence of naphthenic hydrocarbons in petroleums. The polymerization of the more reactive olefines by fuller's earth is well known, and it has recently been shown that this property is by no means confined to fuller's earth, but is a property of a wide variety of sedimentary rocks, particularly the clays and shales and to a lesser degree the sandstones [5, 1931].

In view of the evidence given in the preceding pages, the conclusion may be warranted that organic materials as stable as the paraffins, waxes such as the Montan waxes and the kerogen of oil shale, once formed and sealed in the sedimentary rocks *normally undergo no further changes due to the influence of heat*. If this view is correct, then the problem of how a few paraffins may be chemically 'dispersed' and rearranged to a great number of hydrocarbons does not exist. Rather, the hydrocarbons found in petroleum must mainly have been formed as such in the gradual biochemical anaerobic degradation of the organic materials buried in the sediments.

Possible Source Materials for the Biochemical Production of Petroleum

Students of petroleum geology have differed widely as to the source material and source beds of petroleum. Probably very few believe that petroleums have been derived entirely from one type of material. However, the present discussion has to do with the chemical types of raw materials; and indirectly with physical or geological conditions which are indicated by the chemical evidence. The work of Treibs showing the derivation or association of petroleum source material with chlorophyll-bearing algae or plant life implies a shallow water plankton. There is much geological evidence for such conditions of deposition which cannot be reviewed here.

The principal types of organic substances which have to be considered as the main source material for petroleum are as follows:

(1) **Cellulose.** Cellulose readily yields methane under anaerobic conditions. The fact that methane is formed in peat and remains in certain coals, entirely unaccompanied by oil, is evidence that cellulose alone does not produce the higher paraffins, or oil, by any anaerobic fermentation, with which we are familiar. The fact that the reduction of carbon monoxide, by hydrogen in the presence of cobalt catalyst, as in the Fischer process, or that cellulose can be converted by hydrogenation under relatively high temperatures and pressures with caustic soda as carried out by Berl [4, 1934], to a series of paraffins, may be significant although no result of this nature has been observed as a result of biochemical reduction. The conditions of Berl's and Fischer's processes are far removed from natural conditions.

(2) **Starches and Sugars.** Water-soluble sugars would, of course, quickly be lost. However, Taylor [36, 1928] has shown that sugars and starches undergo anaerobic fermentation in the slightly alkaline conditions under a layer of sodium-clay yielding products which are entirely gaseous, the gas consisting principally of methane.

(3) **Proteins.** These are rapidly and almost completely destroyed by putrefaction. Small proportions of protein degradation products may be preserved under anaerobic conditions and may account for the nitrogenous material in petroleum which yields nitrogen bases. Sulphur, as free sulphur, hydrogen sulphide, and complex sulphur derivatives are so abundant in many crude petroleums that the reduction of sulphates would appear to be more plausible as an original source. Clays such as fuller's earth have been shown experimentally to catalyse the formation of mercaptans by the addition of hydrogen sulphide to olefines. Hydrogen sulphide has been observed in abundance in the fermentation of the masses of algae incident to the formation of balchaschite. Simple amines of the type of ptomaines have not been found in petroleums.

(4) **Lignins.** Lignins are very resistant to microorganisms, and are converted to humic acids. However, they may be broken down under conditions not yet observed or studied. Taylor [36, 1928] states that by anaerobic fermentation under the alkaline conditions resulting from base exchange under sodium-clay lignin was attacked. Lignin is the only natural organic material occurring in abundance which may have furnished the benzene derivatives found in petroleums without assuming high-temperature conditions.

(5) **Oleo-resins.** These generally lose their volatile oils, as in amber, the fossil copals, resinous inclusions in coal, but the resins are preserved through long periods of geological time.

(6) **Waxes.** The natural waxes, consisting mainly of esters of the higher, solid alcohols, and complex organic acids, are also exceedingly resistant under natural conditions. They do not appear to be attacked by microorganisms. The waxes in peat show no appreciable change in composition with increasing age.

(7) **Fatty Oils.** It has long been known that fatty oils are hydrolysed in a few years, losing their glycerine. Wells and Erickson [49, 1933] found that a solid material,

obtained from the wreck of a small ship which had carried a cargo of herring, consisted chiefly of the calcium and magnesium salts of the fatty acids of herring oil, and suggested that in the presence of sea-water the formation of such insoluble fatty salts may be one of the early processes involved in the formation of petroleum.

That the putrefactive decomposition of the organic matter deposited in the sediments is an initial step in the formation of petroleum has long been generally recognized. Engler [10, 1888–9, 1897, 1912] suggested that fatty acids probably lose CO_2 at an early stage. The prevailing opinion, however, seems to be that bacterial action soon ceases altogether. Probably few subjects have been the object of so much speculation and so few attempts to obtain experimental evidence as the question of the role of bacteria in the formation of petroleum. There is no published evidence of the actual formation of liquid hydrocarbons by bacteria. McCoy and Keyte [23] note that following initial putrefaction the decomposition by anaerobic forms must proceed at a very slow rate, a condition necessary for the retention and later accumulation of the material. That many species of bacteria found in soil waters are able to utilize petroleum or the more complex hydrocarbons under aerobic conditions appears to be well substantiated. Tausz and Donath [35, 1930] found that in general the ease with which a hydrocarbon is attacked increases with the length of the chain. However, very few anaerobic studies have been carried out. The work of Taylor on the slow anaerobic degradation of fatty oils and fatty acids under sodium-clay appears to be the only experimental study of such changes thus far published. Triacetin formed methane and tributyrin formed 'gaseous paraffins'. Stearic and palmitic acids were slowly attacked, but the products formed were not determined. At present the depth in the sediments at which bacterial action ceases is much in dispute. Unfortunately the poorer the experimental technique the deeper bacteria are likely to be reported.

Petroleum in Transition Stages

Entirely aside from chemical considerations, geologists have stated that the organic source material from which petroleum has been formed must originally have been deposited in the sediments as solid or semi-solid material, the oil and gas now found being sealed from escape by overlying impervious clays or shales. This is consistent with the findings of Trask, whose samples were collected at or near the surface of the sediments.

Engler recognized the differences between his unsaturated distillates, made by the pyrolysis of fats, and petroleum, and suggested the term protopetroleum for the undiscovered transition stage of petroleum, assuming such a material to be derived from fats by thermal decomposition. No material resembling Engler's distillates has been found in nature. The findings of Trask, the solid mixtures of coorongite and balchaschite formed from algae, the discoveries of Treibs, and the observations of Taylor all harmonize with the primary physical requirement postulated by geologists. Accordingly it might be expected that protopetroleums in transition stages will be found in geologically recent strata, in the form of solid or semi-solid material. Such material might be expected to be a mixture of hydrocarbon oils together with polymerized fatty or naphthenic acids. The writer suggested several years ago (Rochester, New York, 1931) that asphalts might repay investigation from this point of view. Certainly asphalts are not oxidation products of petroleum, but rather their oxygen content has survived from the original source material. The findings of Treibs are certainly strong evidence for this point of view. Asphalts would appear to be either petroleum in transition or 'near-petroleums' formed coincident with petroleum. It has often been suggested that the source material of petroleum has been laid down in estuarine sediments. The anaerobic conditions which Treibs's findings require and which Taylor's work suggests demand rather rapid or frequently intermittent sedimentation. The study of the organic material, probably still well disseminated, in Tertiary and Recent deposits which fulfil these conditions may fill in some of the gaps in the chemical history of petroleum.

Conclusions

1. The geological antiquity of organic minerals other than petroleum, particularly the kerogen of oil shale, indicates a low-temperature history.
2. The temperatures of our deeper wells, about 170° F., are not sufficient to decompose or 'crack' paraffin hydrocarbons within geological time, according to the calculations of Seyer, without assuming some now unknown catalytic agencies.
3. Petroleums contain several types of constituents which are more easily decomposed by heat than the hydrocarbons or fatty acids. These labile constituents are complex substances which yield nitrogen bases, naphthenic acids, and sulphur derivatives. The presence of optically active constituents is also evidence of low-temperature history.
4. The presence of chlorophyll porphyrins is evidence of (*a*) low-temperature origin and history; (*b*) derivation of petroleums or association of the original organic source material with chlorophyll-bearing plant life, probably marine algae; (*c*) anaerobic conditions during or intermittently during the deposition of the original source material.
5. The chemical evidence agrees with the maximum temperature of petroleum formation, 140° F., suggested by McCoy and Keyte. The chemical evidence is consistent with the general conditions of deposition and oil formation postulated by geologists.
6. Petroleums are not equilibrium mixtures.
7. The wide differences in the compositions of petroleums probably relate to the differences in original source materials or to biochemical history.
8. Asphalt is a primary product, not a derivative or oxidation product of oil.
9. Fatty oils are still to be regarded as the principal source material of petroleums.
10. The indicated low-temperature history of petroleum favours the view that the hardening or so-called lithification of sedimentary rocks is due entirely to compaction and the deposition of cementing material from solution.

BIOCHEMICAL ASPECTS OF THE ORIGIN OF OIL

By G. D. HOBSON, Ph.D., D.I.C.
Imperial College of Science and Technology

I

CERTAIN features of crude petroleum point to its having had a low-temperature history, and to the unlikelihood of its ever having attained a temperature such that purely thermal cracking could have transformed organic matter to petroleum in the period of time available. Seyer's [14, 1933] computations from the known data regarding cracking velocity constants and heats of activation, put the half-period for Rangoon wax, which he considers as a possible proto-petroleum, at $3{\cdot}68 \times 10^{14}$ years at 100° C., and $3{\cdot}2 \times 10^{6}$ years at 200° C. Yet Barton [1, 1934] states that the Gulf Coast crudes now produced cannot have attained temperatures even as high as 100° C. Some of the deeper ones may have reached 70° C. or a little more, but many cannot have been above 50° C. The mere presence of optical activity is said to be sufficient evidence of a low-temperature history. Many of the hydrocarbons present in petroleum are sensitive to heat and not distillable without decomposition, even under good vacuum. Certain of the nitrogen bases, sulphur and oxygen compounds are similarly decomposed. Treibs claims to have found chlorophyll compounds, which cannot have been at temperatures as high as 200° C., in many crude oils. Furthermore, it seems probable that primary migration of the oil from the source to the reservoir rock must occur before depth of burial, with consequent compaction, can have raised the temperature sufficiently to bring about thermal decomposition of the source material. Therefore, the agent capable of transforming organic matter to crude petroleum must be active at temperatures well below 100° C. Biochemical processes seem to fulfil this condition.

Many relatively stable compounds are easy prey to fermentation. Simultaneous oxidation and reduction of different parts or components of the source material permit the transformations to be carried out with little net energy change. Micro-organisms are known to effect reactions of this type. Clark [4, 1926] records that fossil bacteria have been found in oil rocks and that petroleum has been found in recent bacterial deposits. Living bacteria have been obtained from the oil-water mixtures produced from rocks of various ages, but absolute assurance of non-contamination by more recent percolating-surface waters seems to be lacking. In Lake Mendota, wet mud from 2 ft. below the surface of the deposits contained 60,000 bacteria per g.; 6 ft. below, 2,000 per g., and 8 ft. below, 5,000 per g. With increase in depth there was an apparent disappearance of carbonaceous matter from the deposits. Kuhr (Bastin [2, 1926]), found sulphur bacteria in sand and intercalated dark clay layers at depths of 10 to 37 m., and sulphate-reducing bacteria have been found in the deposits of the Black Sea at depths of 2,118 m. Zobell and Anderson [20, 1936] have observed as many as 420,000,000 bacteria per g. in marine sediments, and rarely less than 10,000 per g. The numbers fell off after the first few centimetres in the sediment. About 25% of the forms isolated were proteolytic. Most samples had 5 to 15% capable of reducing nitrates and nitrites, lipolytic species, and generally sulphate reducers, cellulose decomposers, and methane organisms.

As a rule, micro-organisms and the enzymes by which they work are seriously damaged or destroyed by temperatures of 60 to 100° C., depending on the conditions, but low temperatures, say, 0 to 10° C., are not harmful. At times there are more bacteria in deep water with temperatures of 3 to 7° C. than in shallower water with higher bottom temperatures. Marine bacteria multiply and are physiologically active at temperatures below zero, and while low temperatures retard their multiplication, they favour their prolonged survival. The temperature coefficients of biochemical reactions are fairly high. In addition, bacteria and enzymes have a temperature of optimum activity which is not independent of the time factor considered. Since bacterial decompositions on complex media with a variety of organisms present are usually a chain of reactions, at temperatures removed from that which gives a maximum yield of a given end-product in a set time, other intermediate compounds may become apparent and accumulate, owing to the succeeding reactions not being able to utilize them as quickly as they are formed. In January 1927, Trask [17, 1932] found the surface temperature of the deposits in Pamlico Sound to be 3·4 to 5·5° C., and 10 to 14·5° C. at a depth of about 130 cm. in the sediment. In May 1927 the temperature of the surface of the sediments in the Potomac estuary was 16° C.; at a depth of 210 cm. it was 11·5° C., and at 430 cm. 13·5° C. Laboratory incubations are often carried out at 30° C., which is considerably higher than the temperatures under which natural decompositions may begin.

In trying to obtain hydrocarbons by biological processes in the laboratory, it must be remembered that bacterial forms and activities vary under different external and chemical conditions. Fermentation may not take place or may follow a rather different course when using relatively pure materials. Some of the forms produced may be abnormal and incapable of reproduction, whilst others may persist only so long as the special conditions obtain, and may develop properties which are latent, absent, or masked in the original strain. These variations can become more or less stabilized and continue under a variety of conditions. Waksman [18, 1927] found that some cellulose-decomposing organisms, if kept under laboratory conditions for any length of time, especially on nutrient agar media, undergo marked physiological changes which may include loss of cellulose-decomposing power. Similarly, Ginsburg-Karagitscheva [5, 1933] observed that the presence of oxygen caused bacteria from Grozni wells to change from rods to cocci-shape and simultaneously become incapable of causing fermentation. It is not impossible that under moderately high pressures micro-organisms may form rather different compounds from a given substrate from those produced under atmospheric pressure, for pressure aids the polymerization of unsaturated substances in particular.

II

Organic matter, whether animal or vegetable, is a protein-carbohydrate-fat complex, often containing unsaturated compounds, whereas petroleum is dominantly hydro-

carbon, saturated and with relatively small amounts of sulphur, nitrogen, and oxygen in combination. What, then, are the transformations which have been shown to be produced by micro-organisms?

Proteins and Amino Acids.

It has been generally accepted that proteins are decomposed rapidly and almost completely, leaving sulphur in the muds. Thus Ruttan and Marshall [13, 1917] found only 0·665% of protein in adipocere from a pig which had been buried 45 years. Proteins are first hydrolysed by bacteria and fungi to the constituent amino acids. Further action leads to a variety of changes, dependent on the materials and the conditions. Under anaerobic conditions, which are most likely to occur in oil-source beds, the amino acids may undergo deamination and reduction to form saturated acids:

$$R\text{—}CH(NH_2)COOH + H_2 = R\text{—}CH_2COOH + NH_3.$$

But deamination can take place without reduction, to form an unsaturated acid. A third change is decarboxylation with the production of an amine:

$$R\text{—}CH(NH_2)COOH = R\text{—}CH_2\text{—}NH_2 + CO_2 \text{ or}$$

$$R\text{—}CH(NH_2)COOH + H_2 = R\text{—}CH_2\text{—}NH_2 + H\cdot COOH.$$

Both amine and acid production may proceed simultaneously, the preponderance of one or the other reaction being dependent on the type of organism involved.

Aerobic organisms, especially fungi, can carry out oxidative deamination:

$$R\text{—}CH(NH_2)COOH + O_2 = R\cdot COOH + NH_3 + CO_2.$$

The products formed by biochemical decomposition of proteins include ammonia, carbon dioxide, amines, fatty acids, alcohols, aldehydes, phenol, indole, skatole, methane, and sulphuretted hydrogen.

Other Nitrogenous Compounds.

Non-protein nitrogenous compounds are also subject to biochemical action. Hecht [9, 1935] believes that the resistant nitrogenous substances such as faecal matter, of bottom organisms especially, may constitute a main source of petroleum. Trask [17, 1932] concludes that most of the loss of nitrogen does not take place until after the burial of the sediments, and there is a tendency for the relative amount of the resistant nitrogenous complexes to increase with age. *B. cellulosae dissolvens* decomposes cellulose very quickly in the presence of faecal matter as a source of nitrogen, giving ethyl alcohol, carbon dioxide, hydrogen, acetic and butyric acids (Waksman [18, 1927]).

Fats and Fatty Acids.

Fats are hydrolysed by micro-organisms to the fatty acids and glycerol, the latter then being used to form methane. Some believe that fatty acids resist subaquatic anaerobic decay, but Neave and Buswell [12, 1930] observe that anaerobic bacteria capable of decomposing fatty acids are widely distributed in nature. The adipocere examined by Ruttan and Marshall [13, 1917] was found to consist mainly of saturated acids, being constituted as follows:

Palmitic acid 67·52%, stearic acid 3·3%, oleic acid 5·24%, *i*-hydroxystearic acid 9·48%, θ-hydroxystearic acid 6·32%, stearin and palmitin 1·21%, olein 0·16%, unsaponifiable matter 0·87%, calcium soaps 4·41%, protein 0·665%, ash 0·578%, humus and undetermined matter 0·25%.

Free fatty acids may combine with metallic ions to form soaps in the sediments. The insoluble soaps in sediments are recovered only with difficulty, and little is known of the quantity present. Much of the inflammable gas from sewage arises from greases and soaps. McKenzie Taylor [11, 1928] has shown the anaerobic biochemical degradation of stearic and palmitic acids under a sodium-clay cover, and Thayer [16, 1931] carried out bacterial decompositions on the sodium salts of a series of organic acids: propionic, *n*-butyric, *i*-butyric, *n*-valeric, *i*-valeric, *n*-caproic, *i*-caproic, heptylic, lauric, palmitic, margaric, and stearic, with the production of carbon dioxide, hydrogen, and methane (within the limits of experimental error) only, and no determinable amount of unsaponifiable matter was left in the liquid.

Brooks [3, 1934] suggests that coorongite seems to be a product resulting from two different changes in fatty acids; one takes place in the presence of excess of air giving oxidation and polymerization of the unsaturated fatty acid. The other involves the loss of the carboxyl group of the acids and their polymers under anaerobic conditions.

The main fatty acids found in sediments by Trask [17, 1932] were cerotic ($C_{26}H_{52}O_2$), montanic ($C_{28}H_{56}O_2$), melissic ($C_{30}H_{60}O_2$), and caproic ($C_6H_{12}O_2$).

Carbohydrates.

According to Hackford [7, 1932] protobitumen is a partially reduced carbohydrate, which on further or total reduction yields oils. Fucosan, a polymer of fucose, is a constituent of the cell wall of marine algae. Acid hydrolysis of *Laminaria digitata* extracts gave fucose, which formed algarite (pure protobitumen), and a series of unstable polyhydric fatty acids which readily lost part or all of their oxygen to give hydrocarbons. At the same time the ethereal sulphonic esters broke down, yielding sulphuric acid which accelerated the hydrolytic process, and the unstable tertiary amines formed decomposed to give oil. In support of this mechanism he has found tertiary amines in oils, and the decomposition products of algae in natural oils and seepages. Bitumens from seepages have been hydrolysed to sugars, and sugars have been found in the water accompanying oil. Trask reports pentoses, pentosans, and glucose from the Lake Maracaibo deposits. In parenthesis, it is noteworthy that the prolonged boiling of sugars with dilute acids leads to the formation of a somewhat ill-defined substance known as humus; cf. hasemanite, coorongite, and phlobaphenes. Humus bodies are generally of an acid character, dissolving in alkalis to form brown solutions.

The action of acids on pentoses produces furfural (Gortner [6, 1929]). Hydrogen and methane seem to be produced directly from sugars by anaerobes (Waksman [18, 1927]), and Tarvin and Buswell [15, 1934] found the fermentation of dextrose to give methane and carbon dioxide with intermediate butyric, propionic, formic, acetic, and lactic acids, the last two acids also having been obtained from pentoses and pentosans by Fred.

Anaerobic decomposition of cellulosic matter gives carbon dioxide and fatty acids through methane or hydrogen fermentation. The evolution of gas ceases unless the acid products are neutralized. Many bacteria can live on cellulose, and such forms have been found in Grozni oil-well waters. Hackford suggests that decomposition of the cellulosic constituents of algae may give furfural and phenols. The peridineans have 40% of cellulose in their bodies, and with diatoms form the two main groups of

marine plants which, aided by sunlight, are able to produce organic from inorganic matter.

Both cellulose and hemi-cellulose can undergo enzymatic hydrolysis to sugars.

Lignins.

Lignins are fairly resistant to bacterial attack and may be slowly transformed to humus substances. It is necessary to distinguish the bacterial destruction of lignin from that of the contained pentosans and probably proteins. Trask found that the relative amounts of lignin-humus complexes showed an increase in 4 metres' depth of burial. Soil humus or 'humic acid' may contain 10% of material soluble in ether and alcohol (dihydroxystearic, oxystearic, lignoceric, and other acids).

Hasemanite, asphaltic though not a true fossil asphalt, occurs in some swamps close to the sea, and Haseman [8, 1921] believes it to be formed in the sediments from percolating ulmo-humic acids which are precipitated by sea-water. It is said to be found surrounding asphalt and contains tannic, ulmic, lignitic, humic, azo-humic, and azo-silico-humic acids.

Tannin.

Tannin is hydrolysed by acids to a variety of products, one of which is nearly always a sugar and another a hydroxy derivative of the aromatic series (usually an acid) (Gortner [6, 1929]). Heating with dilute acid gives solid, amorphous, insoluble 'phlobaphenes', as well as sugars, gallic and ellagic acids. These phlobaphenes are formed by any process tending to cause the tannin to lose water. Chemically they are relatively inert, and occur in nature only in association with tannins.

Waxes.

These, the esters of mono- (or in some cases di-) hydroxy alcohols or sterols with certain of the higher fatty acids, are more difficult to saponify than oils and fats which are esters of glycerol, and are very resistant to alteration, showing little change with age.

III

Conditions of Biochemical Action.

Trask finds that the absence of oxygen from the overlying waters is not absolutely essential for the preservation of organic matter in sediments, and it is not certain that completely anaerobic conditions are necessary for the production of methane.

Protein-splitting enzymes are most often active in an alkaline medium (Zinsser and Bayne-Jones [19, 1934]), and McKenzie Taylor used an alkaline medium, obtained by hydrolysing sodium-clay which gave an impermeable cover with consequent anaerobic conditions, and also neutralized the toxic acid products of the bacteria. Thayer's attempts to accelerate biochemical decompositions by varying the *pH* value were inconclusive, but nearly all his cultures were found to be alkaline, the more active having the lower *pH* values. Increasing the *pH* value inhibited the action. On the other hand, Hackford found his extracts of *Laminaria* to develop *Cladothrix dichotoma* and become acid due to free sulphuric acid, and carried out acid hydrolysis to form oil.

IV

Biochemical destruction of petroleum can occur, for there are certain bacteria capable of utilizing petroleum, paraffin, vaseline, benzene, naphthenes, phenols, cresols, &c. Lipman and Greenberg [10, 1932] have obtained a coccus or cocco-bacillus from petroleum from a depth of 8,700 ft. which can decompose petroleum completely to carbon dioxide. The action only seems to take place at the oil-salt-water contact, so it is unlikely to be of importance as far as large bodies of oil are concerned, but for oil globules disseminated in water, biochemical destruction may be extensive. Hence, if oil originates as scattered globules in water, there may be serious losses from the time of origin until it is accumulated into large bodies with relatively small areas of oil-salt-water contact, or until all the salts or other active constituents essential to the destructive reaction have been removed from the vicinity.

V

Thus it appears that methane is formed commonly by bacterial decomposition of organic matter, and is often accompanied by carbon dioxide. Hydrogen is sometimes produced. McKenzie Taylor records 'gaseous paraffins' from tributyrin under anaerobic conditions, but does not identify them. Ginsburg-Karagitscheva, using bacteria from oil-wells, reports the production of unsaturated gaseous hydrocarbons with methane from egg white, and from gum, acetate, and lactic acid the gases evolved had a flame indicative of unsaturateds. In discussing fats, Waksman states that Bach and Sierp have shown that under anaerobic conditions, carbon dioxide is split off and fatty acids change to hydrocarbons. Hence, omitting Hackford's work involving acid hydrolysis though with initial bacterial action, although there are hints about the formation of higher hydrocarbons, methane seems to be the only hydrocarbon proved to be produced in quantity by biochemical activity in the laboratory.

SECTION 4

DISTRIBUTION OF PETROLEUM

THE STRATIGRAPHICAL DISTRIBUTION OF PETROLEUM

By W. A. J. M. VAN WATERSCHOOT VAN DER GRACHT, M.E., D.Sc., F.G.S.

Netherlands Bureau of Mines. Holland

I

Origin

DEPOSITS of oil or natural gas occur in practically all geological formations from Quaternary to Cambrian. In many more localities indications exist that the sediments at one time contained hydrocarbons which have become dispersed but have left their traces. This even holds true for pre-Cambrian and other crystalline rocks, in so far as they are sedimentary, but were changed by metamorphism (graphitic slates and schists, as occur in New Brunswick and in the Skelleftefjeld, in northern Sweden, and notably veins of graphite, which originally were veins of asphalt, such as are known from Ceylon).

There is a fundamental difference between primary deposits, in which the bitumen originated, and secondary deposits, where oil or gas accumulated after migration. Nearly all commercial oil deposits are in this latter class. No secondary accumulation, naturally, is possible unless primary bitumen is present in appropriate vicinity, in 'source rocks'.

Unfortunately much disagreement still exists concerning the most fundamental problem, namely *the origin of petroleum and natural gas.* Two main questions are involved: (I) the nature of the source material, and (II) the time and method of conversion and accumulation of this material into pools of liquid or gaseous hydrocarbons.

Most petroleum geologists believe that our commercial deposits of **oil and gas are exclusively of organic origin,** but again, unfortunately, there is a wide divergence of opinion both as to the types of organisms which have contributed the organic matter, and as to the nature and time of the transformation of this primary organic matter into petroleum. The existence of nitrogen derivatives and the optical activity of petroleum are strong indications of organic origin. Observation, moreover, shows that oil is practically always associated in some manner with sediments which contain abundant organic carbonaceous material. Differences of opinion exist as to the original organisms, some advocating vegetable, others animal material; some consider macro-organisms, like fishes and molluscs, dying occasionally in vast quantities, as the main contributors; others believe micro-forms, notably the plankton, to be the chief source. Much confusion has been caused by the concentration of research on kerosine shales and bogheads, which, although they may contain up to 70% in volatile matter, have never been known to be a source rock for commercial deposits of liquid oils in nature, however rich they may be in *fixed* bituminous matter. This can only be expelled by distillation. Some have thought that there exists a relationship between petroleum and coals, but modern views strongly hold that the coal-measure facies is adverse to the formation of free liquid bitumen. Evidently we must distinguish fundamentally between adsorptively *fixed* 'polybitumen', and *free* 'kerogen' (Mrazec, Krejci-Graf). The first is stable, the other, under certain conditions, is able to migrate. Some oil shales (for instance the Esthonian Ordovician kukersite) contain both kinds of bitumen, others, 'coal-oil shales', bogheads (Utah), only contain fixed polybitumen. In the earlier literature this important distinction is not made; in Germany *both* substances are referred to as 'Polybitumen', in English treatises, however, as 'Kerogen'.

The writer's own view has been arrived at after consideration of worldwide research work on modern marine sediments, executed, in part under his guidance, by P. D. Trask, and the recent independent work of K. Krejci-Graf and others. He has formed the opinion that the source rocks of commercially important accumulations of petroleum belong exclusively to two related classes of sediments: (1) those of the more or less '*Euxinic*' *facies*, typically present to-day in the Black Sea, which has clearly occurred locally in the sea throughout all geological time, and (2) sediments of a moderately *saline facies*, where the sea bottom was covered by water of a strong saline concentration. Both facies have this in common, that organic life (which may be exceptionally prolific under these circumstances) is confined to the upper horizons of more normal water, whilst the deeper and notably the bottom layers of water are more or less devoid of oxygen and in the extreme phase contain poisonous admixtures which exclude life on the bottom ('benthos'). In consequence all organic sediment (chiefly derived from plankton) is preserved from attack by the numerous scavengers which abound on all normal sea-bottoms, and becomes fossilized. In the present Black Sea, with a depth exceeding 2,000 metres in places, we have an extreme case. Here only the upper 50 metres of water contain sufficient oxygen to support life; in addition, all the deeper water, below 100–200 metres, is poisoned by sulphuretted hydrogen, liberated by sulphur bacteria. The black sediment contains from 23 to 35% of organic matter, and is devoid of any living thing, except anaerobic bacteria and ciliates. In the muds of normal seas, in the most favourable places for the accumulation and preservation of organic matter, Trask has never been able to find more than 7% of organic matter, and this was very exceptional (in deep sheltered troughs in the Channel Islands region off the coast of California). The average quantity of organic matter among recent sediments, as indicated by Trask's study of nearly 2,000 samples from many parts of the world, is 2·5%. Pelagic sediments were found to contain very little organic matter, not in excess of 1·5% (diatomaceous ooze of the Antarctic Sea; in the Atlantic and Pacific Oceans it is only half this amount). It is the exceptional, relatively rare circumstance that bottom life is sufficiently reduced or even excluded, which permits the formation of rocks sufficiently rich in organic material to be considered as source rocks of petroleum.

It would not seem necessary that such a high concentration of organic matter is reached as now exists at the bottom of the Black Sea. We know prolific oilfields where no source rocks of similar concentration can be identified (cf. P. D. Trask: Proportion of Organic Matter converted into Oil in Santa Fe Springs Oilfield, California, *Bull. Amer. Assoc. Petr. Geol.* 245–57 (1936)). The true Euxinic facies, however, is to be distinguished from the sometimes still more highly organic, often also marine, but mostly

coastal, Gyttja facies, also a sediment deposited under a restricted, but not excluded, oxygen supply. Here bottom life, although in a restricted number of species, is still actively present. True shallow-water Gyttja-sediments, however, never seem to cause petroleum deposits, but oil shales (algal gyttjas) and, in their highest organic concentration, boghead or cannel coals. The evolution is different. The presence of oxygen has prevented the preservation of porphyrins, notably from algal chlorophyll; gyttjas are richer in nitrogen and also in bromine. A modern occurrence of this facies exists prominently in the embayments along the coasts of Denmark.

True Euxinic sediments are exclusively marine, and generally a deep-water facies. There is no bottom life; chlorophyll porphyrins are preserved; they are poorer in nitrogen and bromine, but are distinguished by a concentration of such elements as Va and Cu (respectively 0·05 and 0·01%). At the present geological epoch the Euxinic facies is restricted to few secluded deep-sea basins, like the Black Sea. Because we still live in a moderately glacial period, when the earth's poles carry ice caps, there is active circulation of cold, oxygen-bearing polar water in the depths of all open oceans. There have been periods, for instance the Ordovician-Silurian, when this was not the case, and convection currents of oxygen supply in oceans were much reduced. As a consequence Euxinic environment was much more prevalent, even in widespread oceanic seas.

We find undeniable evidence of a more or less complete Euxinic facies in many geological formations. Well-established instances are: the black, sulphurous pre-Cambrian slates of northern Sweden; the widespread, dark graptolite-shales (a Palaeozoic planktonic organism) of the European and American Ordovician and Silurian; the black bituminous shales and limestones of the Upper Devonian and Lower Carboniferous (Culm) in the geosynclines and foredeeps of the chains of the Variscan orogenic cycle of North America and Europe; the Kupferschiefer of the west European Permian; several horizons of the Mesozoic and the Tertiary in the outer zones of the Alpide chains all over the world (for instance, the Oligocene and Cornu beds of Roumania). A very notable instance is the Late Tertiary of the Caucasian region, when the Black Sea extended much farther, with the same Euxinic environment as we find now; the oil deposits of Baku, &c., are derived from these source rocks. As stated, a present-day example is the now much-reduced Black Sea. These rocks are black sulphurous, pyrite-containing muds; if the facies is very pronounced, fossils are rare and confined exclusively to siliceous or chitinous remains of floating organisms, mostly small plankton forms, which are largely devoid of any shell or skeleton, fish scales, brachiopods which float attached to seaweed (Lingula, &c.), or buoyant shells of cephalopods. Lime shells are absent: calcareous matter is dissolved under these conditions. Source rocks of the saline class are found in deposits of concentration basins, before (or after) deposition of actual rock salt, at a time when strong salt solutions prevailed at the bottom, but the less salty upper layers of the water supported life. It is not necessary that the stage of precipitation of actual salt was ever reached; the cycle may have been interrupted. Concentrated brines are not only adverse to life, but they also prevent convection currents and access of oxygen to the deeper layers of water. The latter is the real cause of the preservation of organic matter, much more than concentrated salinity. These saline source rocks are generally dark bituminous dolomites and gypsiferous shales (*Stinksteine*). They are known especially from the Permian and Triassic salt basins of the American Mid-Continent and of Europe.

II

A. Conversion

The time and method of the conversion of the primary organic material to oil and gas is still obscure. It is evident that some fatty material may be deposited contemporaneously with source sediments, but it is very uncertain that any of this has the properties of petroleum. The conversion may be effected in various ways. Bacteria probably play an initial role; however, it has not yet been demonstrated that bacteria, either aerobic or anaerobic, can produce liquid hydrocarbons, except by their action on amino acids, in which case the resulting product is a small amount of benzene. The influence of elevated temperatures and pressures induced by deep burial or mountain folding, or both may be important. Experiments have indicated that the conversion of organic matter into free, soluble bitumen is a reaction not solely dependent upon temperature, but is also a function of time. However, there may be a critical temperature (under 150° C.?) below which no distillation will occur, no matter how long the time involved. The presence of chlorophyll porphyrins in many bitumina is an indication of a low-temperature history of petroleum. Petroleums contain several other types of constituents which are more easily decomposed by heat than the hydrocarbons or fatty acids. The presence of optically active constituents is also evidence of a low-temperature history. Shearing-pressure and high radial axial pressure experiments on supposed source rocks have yielded conflicting results, possibly because many of these experiments were made on oil shales and even coals, materials containing only fixed polybitumen, which is never known to be associated with commercial oil-deposits in nature. Experiments at the Colorado School of Mines, applying pressures as high as 200,000 lb. per sq. in. for 68 days, and even 250,000 lb. per sq. in. for 20 days, to Esthonian and Colorado oil shales, failed to produce any free oil. It would be interesting to continue similar experiments, not with oil shales, but with black marine bituminous shales of Euxinic facies. Even in bituminous marine shales the remains of higher plants are always preserved as coal, but lower vegetable forms, like algae, are in part converted into free kerogen. Hydrogenation stimulated by natural catalysis and even alpha radiation have also been suggested to play a part in conversion, but this is still unproven. It appears, however, that there is a general absence of free hydrogen in rocks of the earth's crust. The fact, however, that hydrogen is so easily migratory, still much more than the also very rare helium, may explain why it has never been preserved. That alpha radiation affects gaseous hydrocarbons and produces a condensation of lower into higher members, up into the region of liquids and solids, has been demonstrated.

The fact that oil, and especially gas, are so readily susceptible to dispersion would suggest that present-day accumulation in old rocks, notably in the Early Palaeozoics, closely overlain by old land surfaces, does not date from such very remote time, but is of comparatively recent formation. There may be periodically recurring events which induce the liberation of liquid petroleum from still unspent source rocks, which would thus be able to generate successive crops of oil or gas. These events, probably, are complex, but must generally be in the nature of a slow 'cracking' of

primary bitumen resulting from biochemical processes; especially when the beds have become supersaturated, beyond the amounts which can be fixed by adsorption, free bitumen may be induced to migrate either by compaction or by orogenic stresses. It seems highly probable that the very saline water, with excess of calcium, iodine, and bromine, sometimes also potassium, which is regularly found associated with oil-pools, is no fossil sea-water, but a segregation product of the original organic material: organisms which have concentrated these rare constituents of sea-water. Pollution by waters of another origin may, of course, frequently have happened.

That diagenetic processes are involved in the conversion seems indicated by the Ordovician kukersite of Esthonia, which may contain from 30 to 50% of free kerogen. In this region pressure by overburden has never been considerable, high temperatures caused by deep burial have not occurred, and orogenetic stresses have been absent. As a result of these same conditions Palaeozoic coals are still in the lignite stage, and we find plastic, entirely recent-looking clays even of Lower Cambrian age; evidently nothing has occurred here that could convert kerogen into freely migrating petroleum.

B. Migration and Accumulation

Traces of bitumen and oil are of very frequent occurrence in sediments; commercial accumulations, however, are rare and restricted to relatively very small areas, which are determined by favourable structure. The three products of the original organic source material evidently segregate, and migrate according to their specific gravities, oil and gas seeking the higher levels in a reservoir stratum, water the lower ones. Beds containing commercial oil can be of every petrographic description or geological age, provided they possess porosity. They may be marine or continental sediments, sands or sandstones, gravels or conglomerates, oolitic or otherwise permeable beds, even porous igneous rocks or their derivatives (Texas). Evidently these petroliferous strata are only secondary reservoirs into which free bitumen has migrated. In many cases typical source rocks are known to underlie oil-pools at greater or lesser depth; in most other cases there is reason to assume their presence, whilst reservoir beds are mostly of a nature which excludes primary (autogenous) petroleum.

Where a stratigraphical sequence contains numerous porous strata a structural oilfield will generally contain a number of superimposed 'oil sands'. The general section of the pool will present a more or less conical platform of petroliferous horizons, narrower towards the top and laterally wider towards the base. The productivity in each individual 'sand' is dependent on its petrographic aptitude as a reservoir, but in general those nearer to the source beds will be richer. The oils will differ vertically, in a manner that can be explained either as a consequence of filtration or through oxidation in contact with surface waters, or otherwise. Gas not associated with or dissolved in oil will mostly be characteristic for the upper 'sands'. Many Californian oil-pools, and also those in the Baku region, on account of the great thickness of the local petroliferous section, offer perfect examples of typical infiltrated oil-platforms (for instance, Ventura, Signal Hill, Apscheron Peninsula); the same rules, however, with more or less perfection, apply to practically all major oilfields.

In the writer's opinion, migration, in consequence, must be assumed to occur chiefly in a vertical direction, towards the surface, in accordance with density and the gradient of pressure. That downward migration may also occur, at least over a short vertical distance, is proved by the lower zone of the Playa del Rey oilfield in California. This zone rests directly on metamorphic (Franciscan) schist, having no possibilities as a source for oil, but is overlain by a 100–200-ft. bed composed of the most highly bituminous shale found in any oil section in the United States (Trask). The successive 'oil sands' of a petroleum deposit may be separated by major unconformities (Oklahoma City, &c.), or even by great overthrust faults (Borislaw), in consequence of which petroleum impregnation affects beds which originally have been deposited many miles apart, and vertically traverses two or more overthrust slices (cf. the article on Oilfields in Folded Rocks). Sometimes the supply of oil appears to have stopped at an unconformity and not to have extended to younger beds. There are cases where displacement of beds along faults or even by folding have not, or not yet, been followed by a readjustment of the oil deposits along the new structural lines, but where oil and gas still remain concentrated in accordance with older structure. This suggests that conversion and migration of petroleum is sometimes almost contemporaneous with sedimentation, or that in other instances it may start at some time considerably later than the deposition of the source sediments; that it is not induced or even influenced by every orogenic displacement of beds, and that it may, or may not, be renewed, and may occur in different successive crops which are widely separated in time.

Many geologists have accepted lateral migration over considerable distances, from regional synclines or depressed basins towards structural highs, or from areas of intense compression towards such as are less affected by orogenic forces. The writer is willing to concede lateral migration over relatively moderate distances, notably from the flanks towards the crest of individual anticlinal or monoclinal structures, but denies the possibility of long-distance regional migration, because resistance would be excessive and observations prove that it has not actually occurred, except to a very limited extent. The main paths of migrating petroleum must be small partings and fissures, which abound in all rocks and sections and are generally directed more or less vertically upward. Even impervious clays and rock-salt have been observed to contain fissures, actually carrying oil, asphalt, ozokerite, and other derivatives of petroleum. Sandstone dykes, as we know them from Roumania, Baku, California, Burma, and even from Huronian shales near Cleveland (Ohio), also bear witness of ascending water, carrying fine sand and mud, even erratics. These materials were probably driven by natural gas, as escaping to-day from mud volcanoes. Aptly these phenomena have been called 'sedimentary volcanism'. It is by no means necessary to consider only faults and wider fissures, although tnese also may play a role. Considerable faults are mostly impervious, because plastered by clay produced by friction they cannot act as conduits, and have a sealing effect.

In accordance with the prevailing upward direction of migration we find that, in general, asphaltic oils decrease in density with depth (Roumania, Gulf Coast); paraffin oils, however, increase in density with depth (Roumania). Often asphaltic oils (oxybitumina) overlie deeper paraffin oils. There are, however, exceptions to this scheme. Oxidation must be assumed to induce polymerization, but the latter appears the major factor in the formation of asphalts. Filtration and the adsorption of the larger molecules, which will also occur in narrow fissures, explains the decrease in density

of paraffin oils towards the surface. Asphaltic deposits and inspissated oil of a previous cycle of migration may occur at or near old buried land surfaces along unconformities, and be overlain by paraffin oils in younger strata, filled by a later cycle of continued or renewed migration of petroleum (Oklahoma City and Lucien oilfields, Okla., where these asphalts (grahamite) occur in the top of the Ordovician). There is no relation between asphaltic or paraffin oils and absolute depth, and both kinds of crude may occur in reservoir rocks of any age; only access of oxygen (now or at some earlier period) seems to count, but there is some indication of the influence of calcium-salts on the formation of asphaltic products low in oxygen. The writer is aware that this conclusion is contested by B. T. Brooks and A. Treibs on account of the presence of chlorophyll porphyrins in many asphalts, derivatives which are decomposed by oxidation. There are asphalts low in oxygen, which may have another history.

Although migration may in some oilfields (California, Baku) be a relatively recent event, it remains nevertheless a slow process. At Ceptura (Roumania) we know an instance of recent folding, to which the oil accumulation has not yet adjusted itself, still occupying locations evidently previous to the latest displacement of the strata. Water, however, migrates more rapidly than the oil and precedes it (as is observed in the flooding practice for the revival of oilfields). This explains the prevalence of salt-water sands, intercalated between oil sands in a petroleum deposit.

For further details regarding the very important, though yet far from fully cleared subject of migration, reference should be made to the several papers contained in the symposium *Problems of Petroleum Geology* (Amer. Assoc. of Petroleum Geologists, 1934) and the recent publications by F. M. Van Tuyl, B. T. Brooks, K. Krejci-Graf, St. Zuber, and O. Stutzer. They contain a critical discussion of many conflicting views which have been expressed, and in several cases an extensive bibliography of references.

III

The actual stratigraphic distribution of petroleum reservoirs in the various oilfields of the world is, as already described, a very wide one; these reservoirs are not the autogenous source rocks, but secondary accumulations. The source rocks may sometimes be almost contemporary deposits (Los Angeles, Baku), at other times they are of widely different age.

A. Palaeozoic Oilfields

These are widespread in North America, but this is possibly only a consequence of more extensive exploration. In the Appalachian oilfields of the eastern States, in Michigan, in Indiana and Illinois, over the entire Mid-Continent, as far south as central Texas, also in the Rocky Mountain region, in Alberta and in Ontario in Canada, petroleum occurs, sometimes very prolifically, in well-consolidated sandstones, and often in limestones of Palaeozoic age, ranging from the Permian down even into the Upper Cambrian.

1. In the **Cambrian** a little gas occurs in New York State; some notable quantities of asphalt are reported from Upper Cambrian rocks of western Australia.

2. **Ordovician** petroleum is produced in Ohio and eastern Indiana (Trenton dolomite), in Illinois (Middle Champlainian), in Kentucky and Tennessee, in Michigan (Ordovician and also Devonian), in Kansas, Oklahoma, and central Texas (Ordovician 'Wilcox sands', and Cambro-Ordovician Arbuckle limestone). Ordovician petroleum now constitutes the major supply and reserves for the production in the States of Oklahoma and Kansas.

3. **Lower Silurian oil** is found in the Medina and Guelph dolomites of Ontario.

4. **Middle and Upper Devonian and Lower Carboniferous** petroleum is produced from sandstones and some limestones in a number of oilfields along the western foothills of the Appalachian Mountains, the bulk in the Lower Mississippian and Upper Devonian, at or near the unconformable contact between these strata: in New York, Pennsylvania, West Virginia, Ohio, Kentucky, Tennessee, and then again from limestones in the Rocky Mountain region, in Alberta and Montana, Wyoming (Lower Mississippian Madison limestone); in Michigan there is also production from Mississippian rocks (Berea).

On the Eurasian continent the oil of the Timan Range (Ukhta) occurs in Upper Devonian strata.

5. **Upper Carboniferous to Lower Permian** petroleum is produced in America from the upper horizons of the Appalachian oilfields, but notably all over the mid-continent: in Illinois, Missouri, Kansas, Oklahoma, north-central Texas, in the Rocky Mountain region, in Utah, Colorado, and Wyoming (Tensleep formation).

In Europe: from the western flank and the foreland of the Ural Mountains (Tschussovaija, &c.)., possibilities exist in north central Europe (Westfalia, Holland, &c.) and in England (Hardstoft).

Several indications are reported from central Asia which are probably Upper Palaeozoic.

6. **Upper Permian** petroleum is produced abundantly in North America from dolomites and limestones in the Great Salt Basin of west Texas and eastern New Mexico.

In Europe, to a limited extent in Germany (south of the Harz Mountains in Thuringia; Volkenroda, &c.).

B. Mesozoic Oilfields

These again are common and prolific in North and Central America: in the Cretaceous of the Rocky Mountains region from Alberta to Mexico, and in east Texas and northern Louisiana–southern Arkansas; in California Cretaceous production is insignificant.

7. **Jurassic** petroleum is produced in small quantities in North America: in Alberta and Montana (Ellis formation), and in Wyoming and Colorado (Sundance formation).

In Europe: in several Jurassic horizons on flanks of the north German salt-domes.

In Asia: in Middle and Upper Jurassic strata of the Emba region, north-east of the Caspian Sea (some oil has also been found there in Permian and Lower Cretaceous horizons).

8. **Cretaceous** petroleum is produced abundantly in North America along the eastern foothills and in intramontane basins of the Rocky Mountain system in Alberta, Montana, Wyoming, and Colorado; in the Cretaceous oilfields of the Gulf Basin in southern Arkansas, Louisiana (Sabine Uplift), and east Texas (Balcones Fault zone and monoclinal structures along the western flank of the Sabine Uplift; east Texas oilfield, Rodessa, and other Woodbine sand and Trinity (basal Cretaceous) oil-pools); in the State of Mississippi the Jackson field is producing from Cretaceous chalk.

In Central America the prolific oil-pools of Mexico produce from the Cretaceous along the eastern foreland of the Sierra Madre Oriental.

In South America: in Bolivia and the Argentine, along the eastern flank of the main Cordillera.

In Europe: in the Wealden formation of northern Germany, on the flank of some salt-domes; some of the Carpathian oil of Galicia is produced from Cretaceous reservoir rocks. Indications of petroleum exist in the Lower Cretaceous and Jurassic of southern England.

C. Tertiary Oilfields

Tertiary oil is still much more common all over the world in many, not infrequently extremely prolific, oilfields.

In North America may be cited: California, producing abundantly from Miocene and Pliocene sands of great thickness, and in minor quantities from Oligocene and Eocene; the Lower Rio Grande Basin of south Texas and northern Mexico (Eocene: Fayette, Yegua, and Cook Mountain formations); the salt-domes in the coastal zone of the Gulf Coast Basin of Texas and Louisiana (from Miocene to Eocene horizons).

In South America: the oilfields of Venezuela, Columbia, and Trinidad; the eastern Argentine, and Peru.

In Africa: the oilfields of Egypt (saline Miocene in the Erythrean Rift).

In Europe: the oilfields along the outer edge of the Carpathian arc, from the Vienna Basin, through Galicia, to Roumania, all produce from several horizons of the Miocene and Pliocene (occasionally from Lower Tertiary in Galicia), sometimes even from Quaternary beds; the oilfields of the Rhine Graben in Alsace (Pechelbronn) are in Oligocene; the important oilfields along both flanks of the Caucasus Mountains, from Maikop and Grozny (Miocene) to the Apscheron Peninsula in the east (several horizons in the Pliocene); beyond the Caspian Sea the oilfields of Cheleken and Nepthe-dagh also produce from the Pliocene.

Farther east in Asia oil is known in the Ferghana Basin (folded Eocene); in western Iran (Arabistan) petroleum is profusely produced from the Lower Miocene Asmari limestone; in Iraq (Kirkuk) the oil is more or less of the same age. In Burma and India the oil sands range from Middle Eocene to Lower Miocene. In the Netherlands East Indies the oil-bearing formations in Sumatra are of Lower Pliocene and Upper Miocene age (Middle and Lower Palembang series); in Java, Miocene; in east Borneo, Miocene to Pliocene; in Tarakan, Pliocene; in New Guinea, Pliocene.

In Sakhalin Island and in Kamtchatka the oil in Pliocene.

THE GEOGRAPHICAL DISTRIBUTION OF PETROLEUM

By W. A. J. M. VAN WATERSCHOOT VAN DER GRACHT, M.E., D.Sc., F.G.S.

Netherlands Bureau of Mines. Holland

In this article only accumulations of free hydrocarbons (oil, gases) and their oxidation products, such as asphalt, are considered; not the absorbed or otherwise fixed hydrocarbons in oil shales, boghead coals, or similar minerals, which only give off liquid oil and gases on heating.

Since the primary essential for the formation of commercial oil-pools is the accumulation of a suitable sedimentary sequence, it is obvious that the geographical distribution of oilfields must be closely related to zones of movement and special sedimentation. Mineral oil is a migratory fluid, made still more mobile by the presence of gases, dissolved under high pressure, and its accumulation into deposits of commercial value is only a stage in a considerable cycle of events. In geological history oil-pools are not only formed, but also become lost; are subject to dispersion of the oil; or the reservoir strata containing the oil may be demolished and carried away by denudation.

Oil-pools range in age from the Lower Palaeozoic to the Pleistocene, but their existence is always subject to the same fundamental law concerning genesis, accumulation, and preservation.

The distribution of commercial oil deposits, that is, the existence of 'petroliferous provinces', suggests regional affinities, not only as to source rocks, but also as to opportunities for accumulation and preservation. Since the uncertainty of the third factor becomes greater with the age of the deposit, the occurrence of pools in the older, especially the Palaeozoic, rocks is rarer than in the younger Upper Mesozoic and Tertiary sediments.

In consequence no commercial occurrences of oil are found in regions occupied by crystalline pre-Cambrian rocks, in ancient continental nuclei, or in the crystalline and metamorphic central zones of the great mountain systems of the earth. They occur preferably in two distinct structural provinces: (1) *the foredeeps of the folded mountain belts* and (2) on *mobile epicontinental shelf-regions.*

1. Oil provinces occur in those parts of geosynclines where conditions for the deposition of source sediments were favourable, but where posterior deformation through mountain folding, uplift, and subsequent denudation were not adverse to preservation of oil-deposits. This was especially the case in the so-called 'foredeeps', the depressions which almost always parallel the front of all larger folded chains, and where the sediments of relatively deep water have not been affected too seriously by the mountain building forces, and oil-deposits have not been destroyed, either by denudation or by metamorphism. Foredeeps of this nature occur in front of chains, formed by all three major orogenic cycles which have affected the crust since Cambrian time: the Early Palaeozoic (Caledonian) cycle, the Late Palaeozoic (Variscan) cycle, and the Late Mesozoic-Tertiary (Alpine) cycle. It is evident that oil-pools connected with the youngest of these cycles must be the more frequent, and those of the oldest extremely rare, not on account of the conditions which caused their formation, but because their chances of preservation diminish with their age. The areas occupied by the older orogenies have very frequently been affected again by movements connected with later cycles, not necessarily folding, but at least sufficient faulting and vertical displacement to cause the destruction or escape of these fluids.

2. In the unfolded solid and more *tabular forelands* of the folded mountain belt, or in tabular regions overlying older folded, but since solidified areas, that cannot be called forelands, there also occur relatively mobile regions which are affected mostly by vertical movements of considerable magnitude. Some regions are inclined to repeated and sometimes almost continuous uplift, accompanied by denudation, causing the absence or at least a very restricted development of sediments. Other regions have a tendency to subside through prolonged periods, and in consequence have been frequently submerged under epicontinental seas, and have accumulated considerable sediments of numerous geological formations. In these latter areas conditions may have occurred which were favourable to the formation of source rocks, and structures may have been formed which permitted accumulation and preservation in suitable reservoir beds (cf. the article on the Stratigraphical Distribution of Petroleum). The area affected by such movements may be of a wide regional character, like the great Mesozoic and Tertiary North Sea–German Basin of north-western Europe, the Palaeozoic region of the north American Mid-Continent, or the Caspian region of Russia. In other instances only a limited block may subside, like the petroliferous Rhine Graben of Alsace, or in tramontane basins overlying the peneplained surface of the Variscan chains of Europe (Thüringen). Frequently such subsiding regions contain saline deposits at certain stratigraphic horizons, which, under sufficient load, cause curious intrusions of the plastic saline rocks, known as salt-domes, as in the Gulf Coast of North America, in north-western Germany, and in several other regions. Since the saliferous facies may be accompanied by abnormally active deposition of source rocks, such salt-domes are not infrequently the site of oil-pools.

I. EUROPE

A. Foredeep Oil-pools

(*a*) **Alpine foredeep pools** occur along the outer zone of the Carpathian loop, from the Vienna Basin through Galicia, into Roumania. In the frontal zone along the Alps numerous indications of petroleum or oil gases exist, notably in western Switzerland, but commercial pools have not yet been discovered. The same conditions continue in the outer zones of the Pyrennean, Apennine, and Dinaric chains. Exploration, however, is still continuing and may be successful. Both in Italy and in Albania minor oil-pools have been found. Along the northern front of the Caucasus these indications are also found, but here they are accompanied by a string of important pools from Maikop, along Grozny, to the Baku region, which extends across the Caspian into Cheleken, and eastward into Asia (Neftjanaja Gora and Bujadagh in Turkmenia).

(*b*) **Variscan foredeep pools** have not yet been discovered in Europe, but here also, indications suggest the possibility

of pools having been preserved along the outer front of the Permo-Carboniferous chains: showings in the English Midlands (Hardstoft), in eastern Holland (Corle), and in Westfalia (Munsterland), and then again along the entire western front of the Timan and Ural Mountains (from Uktha and Tschussowskije Gorodki in the north to Sterlitamak in the south). The latter region is reported to be very similar to that of the Atlantic (Appalachian) oilfields of North America.

(*c*) In the region of the European Caledonides only a very few small showings have been reported in Scotland.

B. Foreland Pools and Pools in other Plateau Regions

(*a*) In **the basin of north-western Germany** several so far not very important and irregular oil-pools exist on the flanks of salt-domes in Hannover, and small seepages, gas-wells, or asphalt deposits suggest possible occurrences over a wide area, doubtlessly also connected with upthrusts of salt. On one of these production has been obtained recently at Heide in Holstein.

(*b*) In **the Hungarian Basin** and the depression of **Transylvania,** within the Carpathian loop, there occur fairly prolific gas deposits, and recently some oil was found in Hungary. These originate in Tertiary basins in the hinterland of the Carpathian loop, overlying peneplained older folds.

(*c*) A series of important showings, already partially developed into very promising oilfields occurs in **the Caspian Emba region**; some 300 salt-domes are reported in this area, of which several have been drilled successfully.

(*d*) Within narrow Tertiary graben-depressions, which traverse the old Variscan folds along **the Rhine and the Rhone Valleys,** are situated the oilfield of Pechelbronn in Alsace, and showings in Baden, and in the Rhone Valley (Ambérieu); this is repeated in graben-zones in the northern part of the French Central Plateau (Cortal).

II. NORTH AMERICA

A. Foredeep Oil-pools

(*a*) **Tertiary Chains.** Important oil-pools have been developed, and almost yearly new ones are being discovered, along the outer zone of the Late Cretaceous-Early Tertiary Rocky Mountains, from Alberta, in Canada, through Montana and Wyoming, into Colorado. A younger belt of late Tertiary mountains lies farther to the west and is accompanied by the famous oil-pools of California and eastern Mexico.

(*b*) Bordering the **Late Palaeozoic chains** petroleum deposits have been preserved in quantity. A series of oil-pools parallels the outer front of the Appalachian mountains from New York and Pennsylvania, through West Virginia, Kentucky, and Tennessee, with still some showings in Alabama. Modern petroleum production had its beginning in Pennsylvania.

(*c*) No oil-pools are known connected with the Early Palaeozoic (Taconic) orogeny in New England.

B. Foreland Pools and Pools in other Plateau Regions

A very important Palaeozoic oil province occupies the entire central tableland of the North American Mid-Continent. Generally these are extremely gently-warped structures, the dip increases slightly in the deeper Early Palaeozoic horizons, and is often accentuated by faults. In this class can be grouped the oilfields of Michigan and Ohio, of Illinois, Kansas, and Oklahoma, and farther south of Central and West Texas and eastern New Mexico (oilfields of the great Salt Basin). In South Oklahoma and North Texas the fields are in an intermediate class, being affected also by the folded Late Palaeozoic chain of the Wichita Mountain System. Then again the great Cretaceous-Tertiary depression of the Gulf Coast plain, from South Arkansas to Louisiana, East and South Texas, abounds in very important oilfields of this type, partly in the Cretaceous (Balcones belt, East Texas field, Sabine Uplift, Rodessa) partly connected with a great many productive salt-domes in the Late Tertiary formations along the coast, or with other Tertiary structures along the lower Rio Grande in the foredeep of the easternmost Sierra Madre ranges.

Apart from Europe and North America, the other continents have been much less explored for the occurrence of oil deposits. In South America and parts of Asia important oil provinces are known, and indications are encouraging that there is little doubt that sufficiently undiscovered deposits of commercial importance must exist; the opposite is the case with Africa and Australia. This is especially true if we consider the results obtained in North America by active and systematic exploration during the 35 years of the present century. It seems necessary, therefore, to mention the geographical distribution not only of the known oil-pools in these regions, but also to indicate briefly the major possibilities of reserves in this vast territory.

III. SOUTH AMERICA

A. **Foredeep Pools** of great importance occur all along the north-eastern branch of the South American 'Alpine' Cordillera Oriental and Cordillera de Merida from Ecuador, through Colombia and Venezuela, as far as Trinidad.

Several oil-pools and many more potentialities exist along the little explored eastern front of the main Cordillera in Bolivia and Argentina, as far south as Tierra del Fuego.

B. Oilfields within more **tabular regions** are those in the Argentine pampa of Rivadavia and in the coastal plain of Peru.

IV. ASIA

Asia has many oil provinces of importance and contains vast regions, very little explored, from which occurrences and indications of petroleum are reported.

(A) Along the front or inside of the 'Alpine' chains a number of oilfields and indications occur. The principal ones are:

(1) The Ferghana district of South Turkestan with notable oil-pools on Eocene folds. The entire area along the eastern shores of the Caspian, and along the northern rim of the chains which link the Elburs Mountains to the Hindukush, seems petroliferous; favorable Tertiary folding is indicated in the subsurface.

(2) The famous pools along the south-western front of the Iranian Mountains in Iraq (Mesopotamia) and Iran; and several promising indications within the mountain chains in Asia Minor and North Iran.

(3) The pools along the western front of the Arakan-Yoma and Naga-Chin Hills of Burma, and the southern front of the Garo-Khasi-Mikir Hills of India.

(4) The oilfields along the eastern side of the Barisan Mountains of Sumatra; this belt continues through Java and Madoera, and farther east, with various indications in the smaller Soenda islands.

(5) Oil deposits on Sakhalin Island (especially the east coast), and similar indications in the Kamtchatka Peninsula, with additional possibilities in the other island arcs of the western Pacific Ocean.

B. As oilfields within more unfolded regions may be mentioned the Bahrein Islands on the Arabian coast of the Persian Gulf, and the oilfields along the east coast of Borneo.

Many occurrences of oil are reported from the almost unexplored interior of Asia, most of which are probably within the frontal zones of **Late Palaeozoic (Altaid) chains,** although many observations suggest intercalated folding of the Alpine cycle in these same regions. Some of these oil deposits may also occur within unfolded sediments filling intramontane basins. The detailed geology of this vast region is still mostly unknown. The following may be mentioned:

(1) Oil seepages and ozokerite are reported on the southern flank of the Tien Chan Mountains in East Turkestan, in the region of Kutcha.

(2) Important oil seepages, exploited by natives, are said to be reported from the northern flank of the Nan Shan Mountains in West Kan Su.

(3) Supposedly abundant and widespread oil seepages are reported in North Shen Si and the Ordos country (Mongolia) within the big bend of the Hwang Ho River.

(4) The previously known saline oil and gas occurrences in Szetshwan, particularly 'the world's oldest Corefield' north-east of Fu Shun, near Tseliutsin. These showings, however, are very poor, and the natural exposures, from Cretaceous to Permian inclusive, give little encouragement.

Indications of oil are also reported from the provinces of Jehol and Liaoning in North China. Asphalt and tar seepages are also reported from the Dsungarian Gobi desert, near Telli-Nor lake.

From Siberia U.S.S.R. geologists report oil indications spreading from the extreme north (Taimyr, and the mouths of the Lena River) to as far south as the shores of Lake Bajkal. Of this vast and inaccessible region little precise information is so far available. Alpine chains circle the Archaean Siberian Shield to the north and east; great bundles of Late Palaeozoic folds, with Alpine intercalations, build up most of China and Mongolia.

V. AFRICA

The only regions of Africa of which so far there is precise information as to oil are situated near the mountains along the Mediterranean in the north-west, and in Egypt, in a downfaulted block along the Gulf of Suez. The first group belongs to the class of foredeep deposits connected with the Alpine chains of the Rif Mountains (Djebel Tselfat in Morocco, in front of the Gibraltar-Rif arc). Those in Egypt are tableland deposits connected with saline structures. Similar deposits may occur elsewhere in North Africa.

Indications of oil have been reported from Angola.

VI. AUSTRALIA

With the exception of New Guinea and New Zealand, the Australian Tertiary deposits are not affected by the Alpine cycle of folding. From New Guinea and New Zealand, however, indications of petroleum are reported. Most of the Australian continent is tableland. Evidences of petroleum are conspicuously absent. The only area which is actually producing a small quantity of oil is at Lakes Entrance in Victoria (Oligocene, resting on granite). This suggests the possibility of some occurrences in the major basin, which is largely filled with marine tabular Tertiary sediments. In the Palaeozoic sequence asphalt is conspicuous in association with Upper Cambrian rocks, but from the later Palaeozoic and the Mesozoic formations no seepages are known, with the exception of some wet gas near Roma, in South Queensland, and in Central Queensland.

OIL AND GAS IN THE UNITED STATES

By WALTER A. VER WIEBE, G.S.A., A.A.P.G., A.A.A.S.
Professor of Geology, University of Wichita, Kansas

I. Introduction

AT the time of writing the world seems to be amply supplied with petroleum and natural gas. The nation which uses the most oil certainly appears to have no cause for worry when a single field in the eastern part of Texas has the potential capacity of furnishing nearly one-half the amount consumed by the whole nation. At the present moment one billion barrels in round numbers is the amount needed annually by the United States, and the East Texas field, flowing for a short time without restrictions, produced in excess of one million barrels per day. However, a brief examination of the figures presented in the closing paragraphs of this section will reveal that at the present rate of extraction our supplies would last only a few decades. In addition, the inevitable decline in production of settled fields will tend to lower the amounts immediately available.

For these reasons the search for new supplies is going on feverishly. Simple means of finding new pools have been exhausted. A deeper and more fundamental understanding of the problems of oil occurrence is needed to ferret out and suggest the location of such pools. The only way in which a better conception of the peculiarities of oil accumulation may be gained is by the study of known fields.

Those familiar with the oilfields of the world will grant without hesitation that the oilfields of the United States afford the most fruitful source of information. Their areal extent is great and the distribution of petroliferous materials in a stratigraphic respect is unequalled elsewhere. Furthermore, the types of structural traps and other kinds of traps are exemplified at different points under differing sets of geological conditions, so that their importance may be evaluated. Producing horizons of varying age, of varying thickness, and of varying lithology may be compared. During the last 15 years special studies have been carried on by hundreds of geologists in the United States to bring out certain critical relationships. The study of well-cuttings both from the standpoint of lithology and of fossil content is revealing information of great value. Analyses of water and brines from shallow and deep horizons are being made on an extensive scale. Comparative studies of oil gravities from similar horizons and from varying depths have thrown some light on fundamental problems. Fortunately, and this fact is acknowledged by all who have an interest in these matters, the results of such studies have been made available by the liberal attitude of oil company officials. A vote of thanks is also due to the broad-minded policy of the officers of the American Association of Petroleum Geologists, by whose untiring efforts an enormous amount of detailed information has been published.

It would be a mistake, however, to assume that the path of the oil-finder has been made smooth and easy. Despite the great accumulation of data on origin of oil, its migration and accumulation, there probably never was a time in the history of petroleum exploration when new pools were so difficult to locate. Perhaps the simplest way to demonstrate this fact is to point out the known characteristics of each petroleum province in the United States. It may then be possible to point out in what untested portions of the province similar conditions exist.

Tectonic Classification.

In recent years it has become apparent that structural features of a certain magnitude have exerted a controlling influence on oil accumulation. These in turn are subordinate to, and genetically related to, other features of a greater magnitude which may be called tectonic elements. In accordance with these principles the author some years ago proposed the *Tectonic Classification* of oilfields in the United States. Since that time further drilling has strengthened the validity of the classification. In the following sections each petroliferous province based on such tectonic elements will be treated as a unit. Each of the provinces has certain outstanding characteristics which will be briefly summarized in order to give the reader a perspective for the many details which follow.

Appalachian Geosyncline Province. By far the greater portion of the oil and gas found in the Appalachian province is stored in sandstones of fine-grained texture. These extend through a vertical thickness of approximately 8,000 ft. and range in age from Pennsylvanian to the base of the Silurian. The most prolific sands appear about the middle of the section in the Lower Mississippian and the Upper Devonian strata. In certain parts of the province, as, for instance, in eastern Kentucky, limestones assume importance.

In the eastern part of the province the gas was trapped in rather long, narrow, and fairly high anticlines. Farther west the influence of anticlinal structure is present, but masked by the variations in porosity and permeability of the oil-containing sandstones. In fact, the more western part of the producing territory is characterized by almost total lack of structural control except that of homoclines. Two exceptions to this generalization are due to prominent intra-basin structures, the Burning Springs anticline and the Irvine-Paint Creek fault and uplift.

Cincinnati Arch Province. The Cincinnati Arch is a positive tectonic element which separates the Appalachian geosyncline from the Eastern Interior Coal Basin. In the Lima-Indiana district of the northern portion oil is typically associated with the Trenton limestone of Ordovician age. Selective solution by ground water provided the limestone with porous zones in which the oil accumulated. In the Cumberland Saddle district, which lies in south central Kentucky astride the axis of the Cincinnati Arch, conditions are somewhat different. For one thing the producing horizons are younger, ranging from Mississippian to Silurian. On the other hand, the nature of the producing horizons is similar because they are predominantly porous limestones and are saturated where unconformable relations exist with overlying strata.

Michigan Basin Province. In the Michigan Basin oil has been found chiefly in Middle Devonian and Lower Mississippian formations. The former are limestones and the latter sandstones. Gas has been derived principally from still higher levels in the Mississippian system. Erosional

unconformities associated with narrow anticlinal trends account for the oil accumulations. Scattered wells in many parts of the Southern Peninsula have outlined the trend and general nature of these anticlinal zones, and it is reasonable to suppose that many new pools will be found.

Eastern Interior Coal Basin Province. The oil-pools in north-western Kentucky, western Indiana, and in Illinois have much in common. The producing horizons are mostly of Upper Mississippian (Chester) and Lower Pennsylvanian age. Sandstones predominate, but a few limestone horizons are important locally. One intra-basin structural feature stands out because of its striking relation to the most prolific pools in the province, the La Salle anticline. East and south-east of this anticline the relation of structure to production is obscure. There oil accumulation is probably due to slight relief of strata along planes of unconformity. West of the La Salle anticline the oil accumulations seem to be definitely related to small domes and anticlines. On the anticlines there is some indication of unconformities associated with the producing horizons. This same relationship is very evident on the La Salle anticline, although there the rapid variation in the nature of the clastic sediments tends to prevent the demonstration of this fact.

Western Interior Coal Basin Province. The oilfields of Kansas and northern Oklahoma have certain similarities which point to a congenital relationship. Oil and gas are predominantly associated with two stratigraphic zones, one in the Lower Pennsylvanian and the other in the Ordovician system. In the former sandstones stand out as the main reservoir rocks, but in the latter calcareous rocks divide honours with the sandstones. In all horizons the influence of unconformable relations at the producing level is strikingly apparent. Two types of traps are typically developed. One of these is the low angle, unsymmetrical anticline, faulted at depth. This kind of trap is especially found along the western side of the producing area in Oklahoma and throughout the central portion of the Kansas fields. A great wedge-shaped fault block of comparatively low relief was pushed up in Early Pennsylvanian time, and the most productive pools found in the two States appear in long zones on the traces of the buried faults marking its limits. East of this intra-basin structural feature oil accumulations are associated chiefly with homoclinal structure or slight modifications thereof. There the up-dip decrease in porosity of sandstones has played the leading role. West of the intra-basin fault-plateau no important oil-pools have been found in Oklahoma. In Kansas, however, numerous small pools have been discovered, and at the present time new ones are being found almost monthly. These are mostly related to structurally high points along the trend of buried outcrop zones in the pre-Pennsylvanian strata. Inasmuch as these zones parallel the axis of the buried Barton Arch of post-Devonian age, they tend to line up along north-west lines. Complications are introduced by the narrow belts of Early Pennsylvanian deformation which cut across the older structural feature with a north-east trend.

Wichita–Amarillo Province. A series of fault blocks, partly buried and partly exposed in low mountains, cuts across the middle of the Mid-Continent region with a north-west trend. Oil- and gas-pools are associated with these tectonic elements in a number of ways. Some are located over buried fault blocks as the Panhandle fields of north-western Texas, the pools between the Arbuckle and Wichita Mountains in southern Oklahoma, and some of the pools in northern Texas on the so-called Red River Uplift. Some pools, notably those of southern Wichita County and northern Archer County, Texas, do not seem to be directly related to such pronounced structures. Although arranged in belts parallel to the Red River Uplift, they occur in strata which are only slightly deformed. The age and nature of the producing horizons vary somewhat in the three districts of this province. In southern Oklahoma and northern Texas the oil is stored predominantly in sandstones of Middle Pennsylvanian age (Glenn and Cisco). In the Panhandle district, on the other hand, the chief producing horizon is a limestone of Lower Permian age. There, furthermore, gas is far more abundant than oil. It should perhaps be emphasized that the influence of the faults mentioned above is not apparent at the level of the producing horizons unless the anticlinal structure be considered a reflection of the buried faults.

Bend Arch Province. A very broad arch with low flanking dips extends southward towards the central Texas mineral region. The scattered pools along its axis derive their oil from porous limestones of Early Pennsylvanian age or from sandstones of Pennsylvanian age. Oil traps of several kinds account for the accumulations. Small domes of moderate relief, terraces, and 'noses' have been found in the most important pools. Elsewhere homoclinal structure with pinching sands and limestones of varying porosity have served to trap the oil.

Gulf Embayment Province. In the fields of southern Arkansas, Louisiana, east and south Texas, the producing horizons are almost exclusively sandstones, although certain limestones are important locally. Only Comanchean, Cretaceous, and Tertiary formations are involved, but the range in thickness through which they are distributed is very great. Each district in the province shows characteristic structural features to account for the oil accumulations. The Balcones Fault district, as the name implies, is characterized by several zones of short faults arranged *en échelon.* The oil is trapped on the upthrow side of the faults. In the Sabine and Ouachita Uplifts district several kinds of traps have been found. Some pools are on small high domes which may or may not show subsidiary faults. Others are closely associated with pinching sands that lie above prominent unconformities. Some are in porous limestones close to unconformities. In south Texas and south Louisiana small domes with very great relief have served to trap the oil and gas. These are the well-known salt-dome pools. Other productive areas are associated with sand lenses of shoreline type in which differential porosity is the controlling factor.

West Texas Province. A great structural basin lies west of the Bend Arch. It has one outstanding intra-basin structure on which all important pools are located. The main producing horizon is a dolomitic limestone of Permian age called the 'Big Lime', but important production has also been found in a limestone of Ordovician age (one pool only). The reason for oil accumulation seems to be high structural relief on the central platform coupled with great porosity in a limestone below an unconformity.

Rocky Mountain Province. The largest petroliferous province in the United States extends from Montana through Wyoming and Colorado into New Mexico. Sandstones of Middle and Lower Cretaceous age contain most of the oil and gas. Locally, important amounts of oil have been found in Comanchean, Jurassic, Permian, Pennsylvanian, and Mississippian formations. The Permian and Mississippian horizons are limestones which produce from porous

zones along an unconformity. Ninety per cent. of the pools are located on anticlinal folds in which the strata dip steeply. These folds in turn are arranged in zones *en échelon* fashion close to the rims of structural basins. Geophysical data indicate that small subsidiary fault blocks, genetically related to the mountains bounding the basins, underlie the anticlines. If this should be corroborated by future exploration, the chances for additional pools are very slight. Some intra-basin structures have been discovered, as, for instance, the Baxter Basin dome in the middle of the Green River Basin and the Rangely dome in the Uinta Basin.

Pacific Geosyncline Province. The oil-pools of southern California are concentrated in four structural basins, in which structural and stratigraphic similarities are marked. Tertiary sands produce the oil, and up to date the Pliocene has accounted for the larger portion. Miocene sands are important in the Santa Maria district and the San Joaquin district. Oligocene sands are important in the Ventura district. One striking feature of all these sands is their great thickness and complete saturation.

As regards structural control a striking similarity to the Rocky Mountain province may be pointed out. Here also the predominant trap is the anticline. Furthermore, the arrangement of the anticlines and domes in nearly straight lines or zones above pronounced fault lines is significant. A third similarity appears in the steep dip on the flanks of the anticlines.

Migration and Accumulation of Oil.

A careful comparison of all details of oil occurrence in the various provinces of the United States leads to certain definite inferences. It appears reasonably certain that oil in calcareous reservoir rocks has not migrated any considerable distance. In many cases it can be shown that no migration has taken place at all. In some districts the underground channels have been developed on such a large scale that veritable subterranean caverns were produced. In these there has been some migration and gravitational separation of the fluids.

In sandstone reservoirs migration has been somewhat more extensive, but even here it may be measured in miles and not tens of miles. The path traversed by petroleum and gas has been primarily between bedding planes in the same reservoir rocks. Some cases are on record which plainly indicate vertical migration along fault planes. However, the inference is not justified that such vertical migration is common. In both types of migration gas has travelled much farther than oil. In fact, there is some indication that gas may have travelled tens of miles. This appears to be the explanation of the fact that gas-pools frequently occur in the high peripheral structures which bound petroliferous basins. A case in point is the Appalachian province, which is almost completely surrounded by gas-pools.

Origin of Oil.

The most difficult problem in petroleum geology concerns the mode of origin of the oil. It is still too early to make confident assertions on this important point. The straws in the wind lead to the conclusion that plant matter contributed most of the oil and that animal matter was decidedly subordinate. Furthermore, it appears that certain conditions favoured organic accumulation and petroleum generation. One of the fundamental concepts is that the locus of accumulation was an area close to sea-level. Such an area would be the gently sloping sea floor parallel to the shoreline of the time. A similar one would be provided by slightly submerged islands or archipelagos. The latter explains why important oilfields are so commonly found on intra-basin structures, as, for instance, the La Salle anticline, Barton Arch, Burning Springs anticline, &c. Even the Cincinnati Arch would be an illustration of the same situation because it was an intra-basin structure during Early Palaeozoic time.

Environment for Oil Accumulation.

If the foregoing inferences prove to be correct, then the environment most favourable for oil accumulations may be deduced. Three primary and equally essential factors determine this environment. One of these is *porosity*, for without openings large enough to contain oil and gas no accumulation can take place. Subcapillary openings provide storage space for petroleum and gas, but do not produce commercial pools, for the reason that the permeability is too slight to permit free flow of the fluids. For that reason oil shales and bituminous shales do not make oil-pools. Openings in siltstones (Bureau of soils classification 0·005 to 0·05 mm.), on the other hand, are large enough to make commercial gas-pools possible. Still coarser sediments (fine, medium, and coarse sands) in which the grain size ranges from 0·05 to 2 mm. may contain commercial accumulations of oil, but Nutting reports [3, 1934, p. 826] that most producing oil sands examined lie between 0·07 and 0·21 mm.

The second factor in the environment of oil-pools is the *relief* of the porous reservoir rock. This is commonly called a 'high' in oilfield terminology. A 'high' may be a portion of deformed strata which is elevated above the rest of the structure, or it may be a topographically elevated rock unit. Hence anticlines, domes, the upthrow side of fault blocks, &c., produce favourable 'highs'. On the other hand, the truncated edges of inclined strata which form topographic relief features may be just as favourable under certain conditions of cap-rock relations. The same effect is provided by the up-dip termination of porosity in a homoclinal reservoir rock.

The third factor is the local abundance of organic source material. In the absence of definite knowledge of the constitution of such material no further elucidation is possible. The inferences regarding migration, however, lead us to believe that such source material must have been present within or in immediate contact with the reservoir rock at the time of its burial and before the cap-rock was formed over it.

Future Reserves of Oil.

In the past nearly all estimates of future oil reserves in the United States have erred in being too small. It is hoped that the estimates given below will also prove to be too small. In most cases they should be looked upon as conservative. By projecting the production curves of nearly exhausted fields and groups of fields it is possible to anticipate their total ultimate production in some provinces and in some districts. On the basis of a close study of drilling results between producing areas it is possible to reach a reasonable conclusion regarding the possibility of undiscovered pools. By adding the two sets of figures a satisfactory prediction of future production can be made. From the following summary it appears that the future reserves for the whole country total at least 13 billion

barrels and that the total ultimate production will exceed 30 billion barrels.

Province	Production to end of 1935	Reserves	Total ultimate

II. Appalachian Geosyncline Province

The Appalachian geosyncline province is the oldest and best-known province in the United States. It was named from the fact that the producing area corresponds to the central portion of the Appalachian geosyncline which extends from New York State southward into the State of Alabama. The producing area includes south-western New York, western Pennsylvania, eastern Ohio, western West Virginia, and eastern Kentucky. Geologically the area is limited on the east by the strong Hercynian folds of the Appalachian Mountain system. On the west the Cincinnati Arch forms the natural boundary. The northern end is closed in by the Laurentian shield and parallel bands of Early Palaeozoic strata. (See Fig. 1.)

Stratigraphy.

The Appalachian geosyncline existed from earliest Palaeozoic time until the close of the era. Therefore every system of that era is represented from the Cambrian to the Permian inclusive. As a rule each system is very thick in the eastern part of the geosyncline because of the proximity of the sediment-yielding land mass (Appalachia) and much thinner towards the west. The thicknesses given in the table on this page are averages for the oil-producing area only.

It will be seen from the table that the Permian system does not contain oil- or gas-producing sands. The Monongahela contains the highest producing sand, the Goose Run, which yields a little oil near Marietta, Ohio. In the Conemaugh there are five sands of which the First Cow Run is the most important, having produced considerable quantities of oil and gas in south-western Pennsylvania and in south-eastern Ohio. The three gas sands which appear in the Allegheny in south-western Pennsylvania are unimportant, and the same applies to the Macksburg sand of south-eastern Ohio. In West Virginia, however, the upper 'Gas Sand' has furnished considerable quantities of gas. The Salt sands of the Pottsville were so named because they contain much salt-water in Pennsylvania. In the adjoining portions of Ohio, West Virginia, and Kentucky some oil has been obtained from them. All sands of the Pennsylvanian system are interbedded with thin shales, limestones, and coals. In position they are usually referred to the Pittsburgh coal which marks the base of the Monongahela.

The Mississippian system may be conveniently divided into three portions, the Mauch Chunk red and green shales, the Greenbrier (or Maxville) limestone (Ste Geneviève and St. Louis in Kentucky), and the Pocono or Waverly clastic series. On account of the prominent unconformity at the top of the Mississippian, the Mauch Chunk is thin in the petroliferous area and disappears from the section in south-eastern Ohio. The Maxton sand appears at this unconformity either as reworked rubble at the base of the Pennsylvanian or residual material at the top of the Mississippian. Much oil and gas have been obtained from it

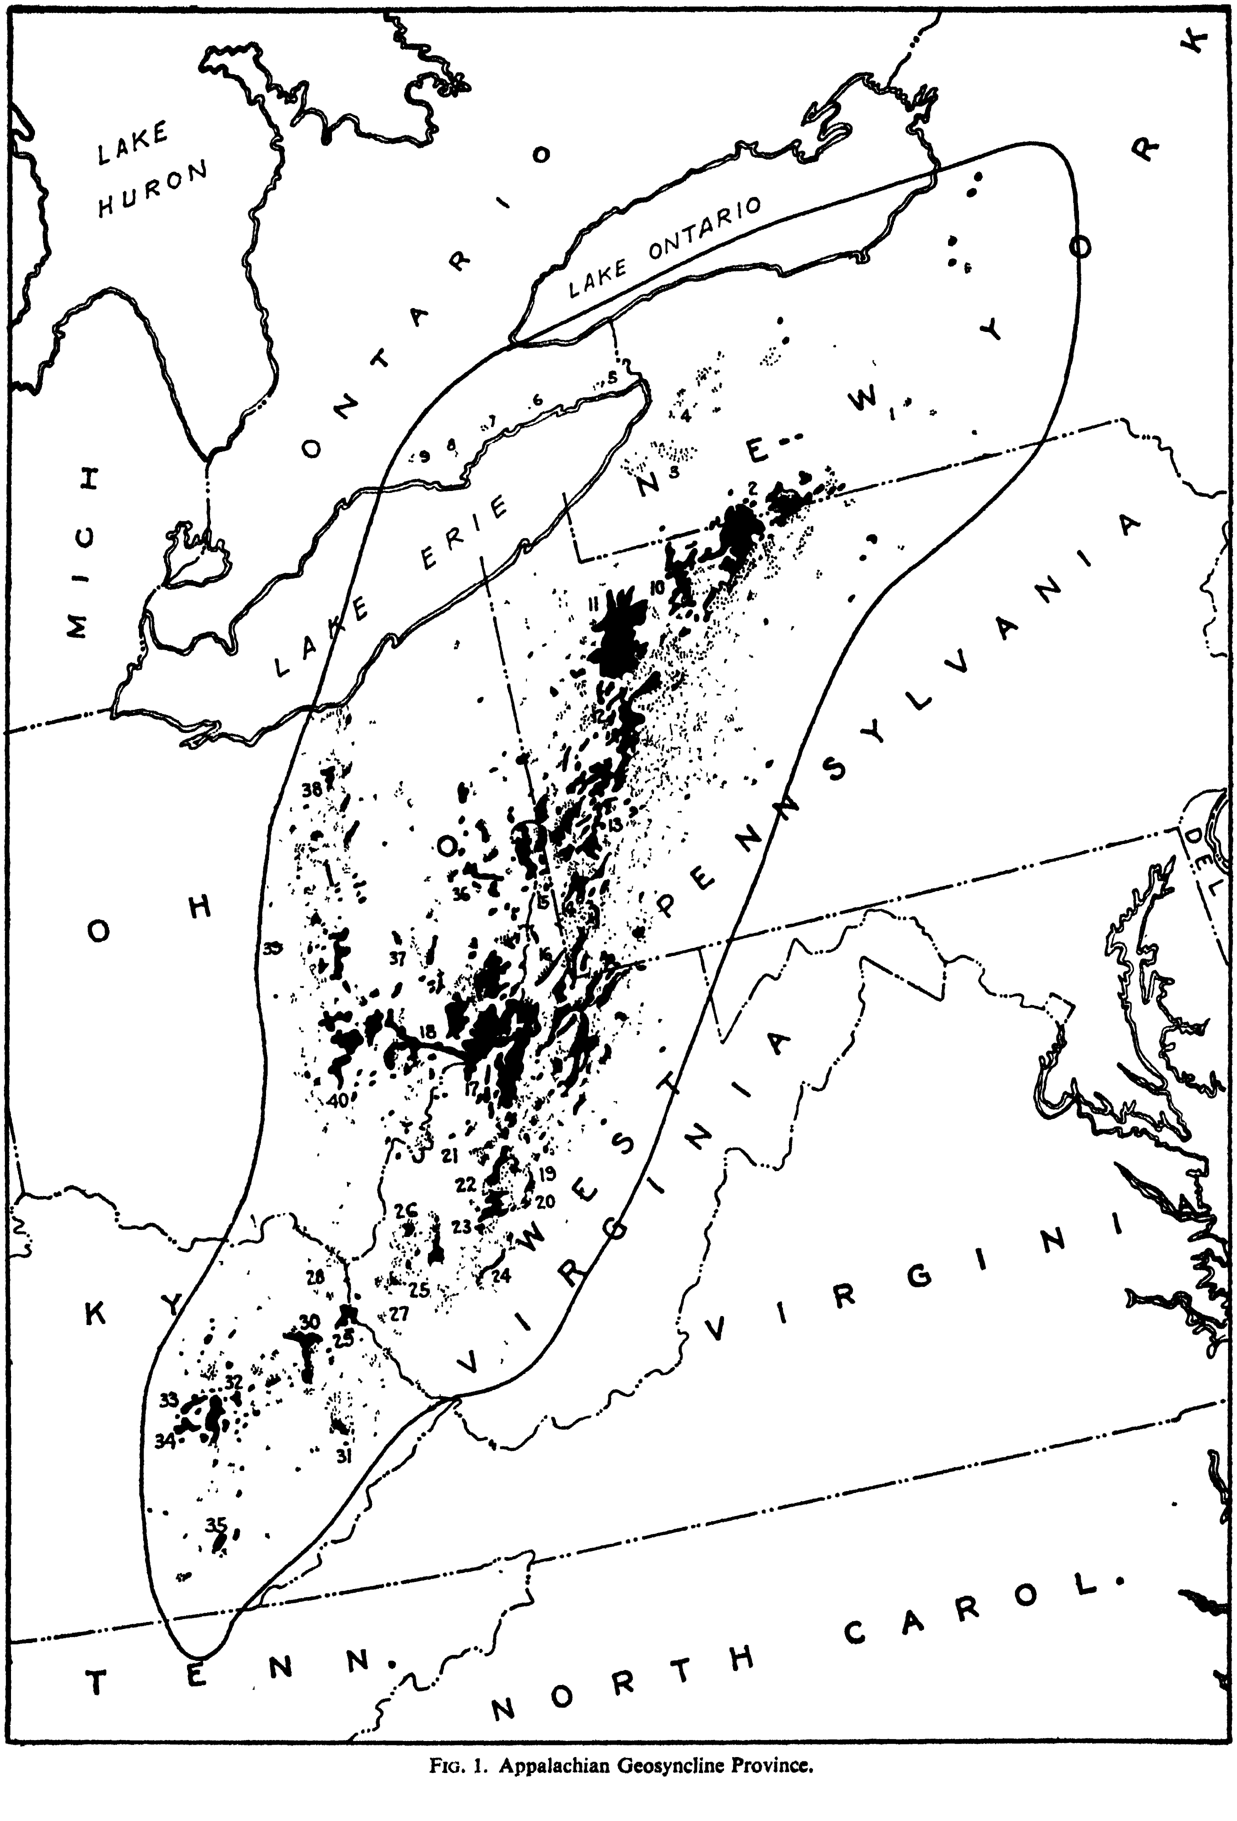

FIG. 1. Appalachian Geosyncline Province.

in south-eastern Ohio and a small amount in eastern Kentucky.

The most productive sands of the Mississippian system appear in the Pocono or Waverly division. The Big Injun produces over a wide area bordering the Panhandle of West Virginia. The Squaw and Weir sands are more local but quite prolific. The Berea sands cover the widest area, since they extend over all of eastern Ohio and north-western Pennsylvania as well as south-western Pennsylvania and adjacent parts of West Virginia and Kentucky. The Murrysville and Hundred-Foot sands are included in the Berea sand group by Torrey. The Hundred-Foot is the equivalent of the First Venango, made famous by I. C. White's reports on north-western Pennsylvania. The Thirty-Foot sand, which lies close beneath the Hundred-Foot, is the equivalent of his Second Venango.

The Devonian system, consisting predominantly of drab-coloured shales contains twelve or more important sands. In the Catskill the Gordon is the most important, as it produces from a large area in western Pennsylvania and West Virginia. The Fourth and the Fifth are large producers from a somewhat more limited area. The Bayard, Gordon Stray, and Elizabeth sands produce mostly gas. Another important group of sands are those of the Chemung division. They are limited to the northern portion of the Pennsylvanian fields. The Speechley, Tiona, Balltown, and Sheffield sands produce mostly gas, while the Warren and Bradford sands are large producers of oil. The Bradford sand also has produced the major portion of the oil and gas in southern New York. The Kane sands of the Portage division have produced enormous quantities of gas in north-western Pennsylvania. In the same area the Elk sands produce gas.

At the base of the thick body of Devonian shales lies the 'Corniferous' or Onondaga limestone. In Kentucky, where it lies unconformably beneath the Chattanooga shale, it is considered the most important producing horizon of oil. There it includes the Irvine, Ragland, and Campton sands. Beneath the limestone lies the Oriskany sand which has recently come prominently into the limelight. A number of gasfields in southern New York and northern Pennsylvania, as well as the Cambridge field in eastern Ohio, derive their gas from this formation.

The Silurian system consists of fine clastics and evaporites at the top, calcareous materials in the middle portion, and coarse clastics at the base. The latter contain gas sands (Medina) of importance in southern New York as well as the outstanding 'Clinton' sand fields of central Ohio. Gas has been produced in small quantities from the unconformable top of the Niagara limestone in Kentucky.

Rocks of Ordovician and Cambrian age come to the surface around the periphery of the producing area, but within it they lie at great depths. For that reason little is known at present about their possible productivity. In New York State some small gas-pools were found years ago in the area east of Buffalo in which the Trenton limestone contained the gas. Similarly, in the vicinity of Watertown (Jefferson County) gas was found in the Potsdam sandstone. These pools have long since been abandoned.

Relation between Structure and Production.

The prominent long, narrow anticlines so characteristic of the eastern Appalachians die out towards the west. They are still prominent in the gas belt which marks the eastern side of the producing area. The Warfield–Chestnut Ridge anticline very nearly forms the eastern boundary of these fields. Shorter and lower anticlines have been delineated by geologists west of it, but in general the producing area is characterized by a gentle regional dip towards the south-west of approximately 30 ft. to the mile. One striking exception is furnished by the Burning Springs anticline which trends nearly north and south and has great relief.

Some years ago the author prepared a map showing the oil- and gas-pools as well as the anticlines and synclines. This map indicates that about 60% of the pools are located upon or close to the axes of anticlines. In general the gas-pools show a closer relation than the oil-pools. In Pennsylvania the relation is closer in the north-eastern part of the producing area and less close towards the south and south-west. In West Virginia the relation is very obscure, except that very prominent anticlines, such as the Arches Fork, Burning Springs, and Chestnut Ridge anticlines, are somewhat more completely spotted with pools than the synclines between them. In Kentucky the pools are significantly alined with the Paint Creek fault zone and several cross folds. In Ohio the influence of the Burning Springs anticline is notable because the largest cluster of oil-pools occurs along its trend. A very striking zone of gas-pools through the centre of the State traces the zone in which the Medina sandstone comes to a feather edge on the Cincinnati Arch. Between these two there are numerous scattered oil-pools and gas-pools that appear to bear no definite relation to large structures.

The relations pointed out indicate that structural relief has controlled migration to some extent. Much gas and some oil have accumulated in elevated portions of the strata. Some of the gas and most of the oil have accumulated without regard to structure. In both cases the controlling factor has been the permeability of the reservoir sands. The author believes that the oil and gas originated at the same time that the reservoir sand was deposited. Pools formed where porosity and permeability conditions were favourable. Gas accumulated in sands with small porosity and oil in those with greater porosity. When folding took place some rearrangement of gas, oil, and water was possible where continuous porosity in the same sand existed. At the same time gas (being more volatile and needing only minute pore spaces) migrated from west to east towards the stronger anticlines. This sequence of events explains why only gas is found in the peripheral portions of the province. It also explains why gravitational arrangement of the fluids is found on the stronger anticlines, but not in areas where the dip is less than one degree. For, as Torrey [5, 1934, p. 466] points out, there are extensive areas in south-western Pennsylvania and portions of the adjoining States where certain sands contain mixtures of oil, gas, and water under conditions that preclude migration. He has also published many illuminating data on porosity and permeability conditions in various parts of the Pennsylvania fields.

The productive area in Pennsylvania is nearly 200 miles long and averages 60 miles in width (7·6 million acres). About 25% of the area is gas territory and about 15% oil territory (somewhat over 1 million acres). It has produced 900 million barrels of oil and almost 5 trillion cubic feet of natural gas. On this basis the per acre production is less than 1,000 barrels of oil. The largest pool, the Bradford pool, covering an area of 105,000 square miles, has a per acre production of somewhat over 2,600 barrels to the end of 1936. Based on present methods of extraction and exploitation it is reasonable to predict that the Pennsylvania fields will produce an additional 200 million

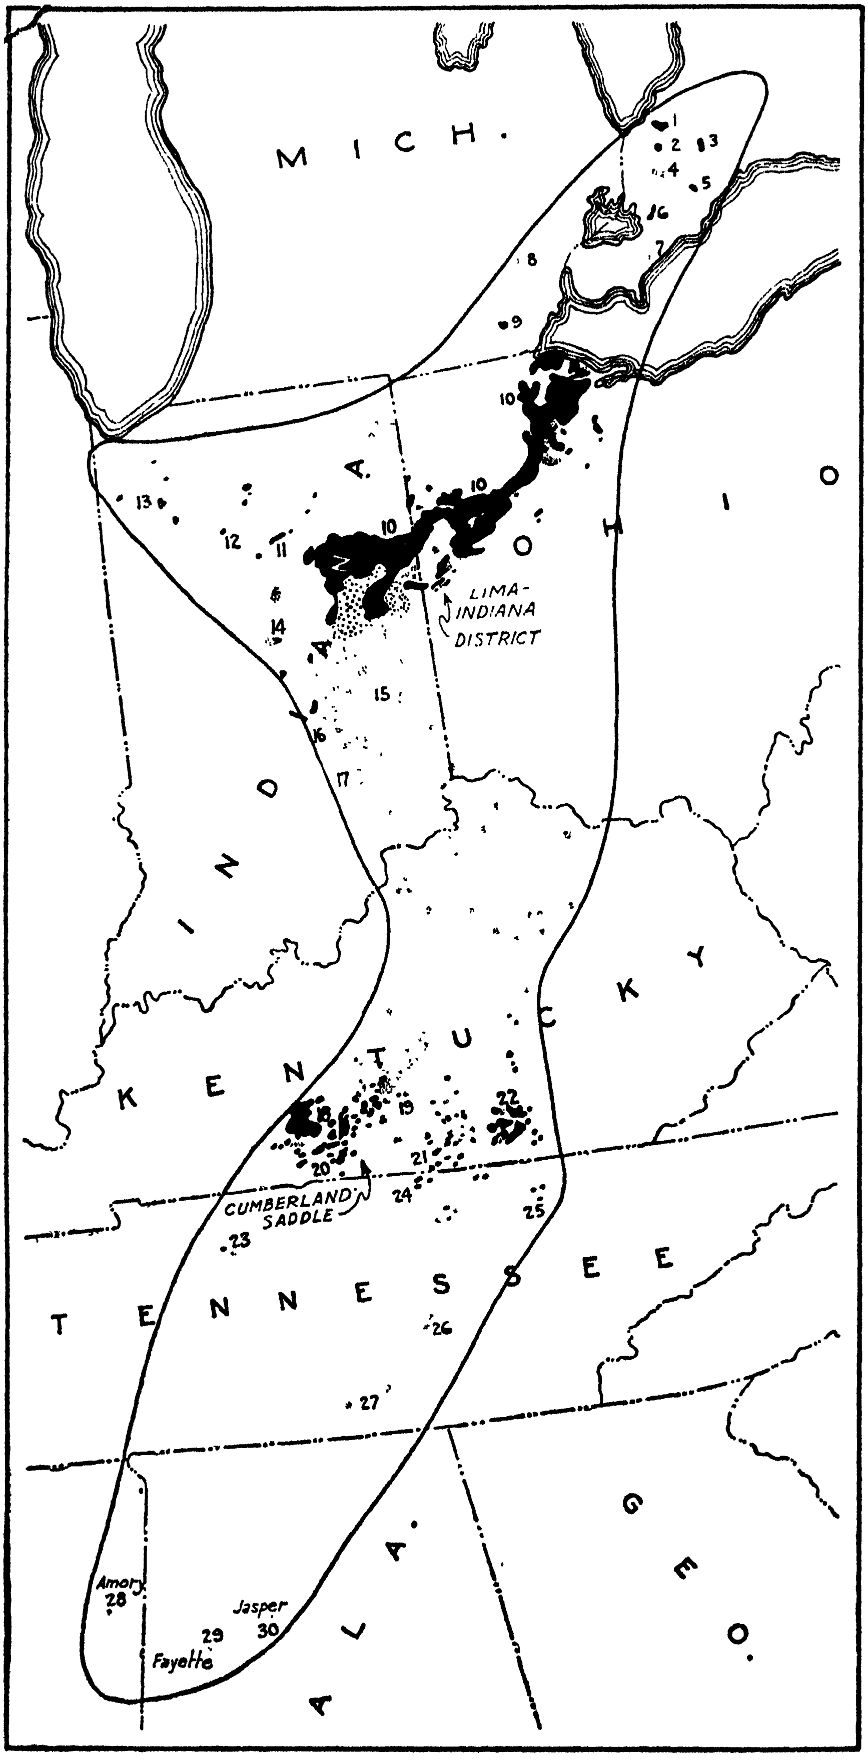

Fig. 2. Cincinnati Arch Province.

barrels before they are abandoned. For somewhat more optimistic estimates see Cathcart [4, 1935, p. 373].

The Pennsylvanian fields have accounted for slightly more than 50% of the total production of the province. West Virginia stands in second place with slightly less than 25% and a per acre production of somewhat over 500 barrels of oil. Ohio follows with about 11% of the total, while Kentucky and New York share equally in the remainder. Allowing for a total production of 1,740 million barrels to the end of 1936, it may be estimated that the reserves amount to about 500 million barrels for the whole Appalachian province.

III. Cincinnati Arch Province

The oil- and gas-fields of the Cincinnati Arch province are located in western Ohio, northern and eastern Indiana, central Kentucky, central Tennessee, north-western Alabama, and north-eastern Mississippi. Geologically they are related to the large broad geanticline known as the Cincinnati Arch. The axis of this positive tectonic element passes southward through the centre of Kentucky, Tennessee, into Alabama and Mississippi. Northward from Cincinnati it bifurcates, one branch passing through western Ohio into Ontario and the other through northern Indiana towards central Wisconsin. (See Fig. 2.)

Stratigraphy.

The names of formations used in this province are not uniform because different parts of the area involved were studied by different geologists at various times. It will be convenient, therefore, to divide the province into *districts* in which the nomenclature is similar. The most important district is the northern one usually referred to as the *Lima–Indiana* district. It is located in north-western Ohio and north-eastern Indiana. Pleistocene glacial deposits cover the older rocks to a large extent. Below the drift the drill passes through the Monroe formation of Upper Silurian age. The underlying Niagara and Clinton limestones are about 300 ft. thick and the Medina red shales average 50 ft. in thickness. The Ordovician Cincinnati shales are divided into the Richmond and Utica formations, the former being blue and the latter dark in colour. They are succeeded

by the oil-bearing Trenton limestone which, as the table shows, is approximately 750 ft. thick.

In those wells which have penetrated the Trenton a considerable difference in thickness is apparent. This fact, as well as the caverns and sinkholes at the top of the formation, indicates an erosional unconformity between the Trenton and overlying shales. During the period of erosion oil and gas formed in the solution holes and have remained in these traps ever since. Evidently three zones of porosity were produced, for oil has been found at three more or less distinct levels. The first and by far the most prolific lies within 50 ft. of the top of the limestone. As a rule drillers encounter a few feet of impervious rock which they term 'cap-rock', and below that a varying amount of porous 'rotten' rock. This upper producing horizon accounted for nearly all the oil and gas until 1900. The lower 'pays' in the Trenton have been of small importance, and this applies also to the other three 'stray' sands encountered at various times. They are the Clinton limestone, the Cincinnati shales, and the 'St. Peter' sandstone.

	Canadian	400	..	..	..	.	..	..	..	..	..

The 'St. Peter' horizon is an interesting one and deserves further testing. From the meagre data available it seems to be the erosional detritus at the top of the Canadian limestones which has been discovered in many parts of eastern United States. In the early reports on the Indiana portion of the district sandstones of some thickness are mentioned at this horizon, but drilling in Ohio has failed to corroborate this.

Carman and Stout [5, 1934, p. 521] have brought out some interesting details regarding the structure of the Lima–Indiana district. Among them is the description of the fault which bounds the producing area south-west of Toledo. The fault trends nearly north to south and has a displacement of 200 ft. for 7 miles, beyond which it passes into a monoclinal fold. Production is obtained from both sides of the fault, but it is better from the down-thrown side.

Cumberland Saddle District. The undulations of the crest of the Cincinnati Arch bring into relief two prominent domes, the *Jessamine* and the *Nashville* domes. The former is located in north-central Kentucky and the latter in central Tennessee. The axis of the saddle between them trends nearly east to west in south-central Kentucky, through Cumberland County, and for that reason it has been named the Cumberland Saddle [8, 1930, p. 103].

Where the axis of the saddle crosses the Cincinnati Arch Ordovician rocks are unconformably overlain by Mississippian (Chattanooga) shales. Eastward and westward thin wedges of the Devonian Corniferous limestone, the middle Silurian Niagara limestone, and the lower Silurian shales and limestones appear in the sequence. On the east side of the axis the Chattanooga is overlain by the shales and cherty limestones of the Waverly, and in this formation practically the only important oil sands occur. They are not true sands, but porous limestones to which the name *Beaver Creek Sand* has been applied. The oil-pools are located in Wayne and McCreary Counties. Above the Waverly the Meramec limestones (Newman) and the Chester shales (Pennington) complete the stratigraphic sequence.

On the west side of the axis the Chattanooga shale, on account of its black colour, again serves as the best key horizon. Above it lie the Waverly (New Providence and Ft. Payne) cherty limestones and shales. Some oil has been found in eastern Warren County in the upper part of the New Providence in the so-called *Beaver Sand.* The overlying Meramec consists of the Warsaw, St. Louis, and Ste Geneviève limestones in ascending order. A few large wells found a mixture of oil, gas, and salt-water in porous layers near the base of the *St. Louis limestone*, especially in the Bowling Green field.

Below the Chattanooga there is a limestone of Devonian age which was evidently exposed to erosion for a long time because it is quite porous. Oil, gas, and water accumulated during the erosion interval in the openings so developed, and the *Corniferous* has proved to be the second most important horizon in the district. Some wells in the Moulder and Sledge pools came in for 1,000 barrels per day. Another erosional unconformity appears in the section between the Corniferous and the Silurian *Niagara* limestone. Actively circulating ground waters dissolved this formation to a great depth, for the oil-bearing cavities have been found as much as 100 ft. below the top. The pay zones appear at different levels in the limestone and vary from 1 to 17 ft. in thickness. This is the most important producing horizon in the western part of the Cumberland Saddle district and quite satisfactory quantities of oil have been secured from it in Allen and in Warren Counties.

Tennessee. The amount of oil produced from Tennessee to the end of 1935 is about 300,000 barrels. This has come from counties adjacent to the productive area of Wayne and McCreary Counties in Kentucky on the east side of the Cumberland Saddle. The most important producing horizons are porous zones in the Ordovician limestones

approximately equal in age to the 'Trenton' of the Lima–Indiana district. Some small oil- and gas-pools have secured production from the Ft. Payne division of the Waverly and from the Meramec (St. Louis) limestone.

Alabama and Mississippi. By extending the axis of the Cincinnati Arch under the cover of Cretaceous rocks in northern Alabama and Mississippi, it may be assumed that the small gas-pools of those States are related to it. The Fayette gas-pool of north-western Alabama has produced perhaps 200 million cu. ft. since 1909. It is derived from a sand in the Pottsville division of the Pennsylvanian system. The first commercial gas-well was drilled in Mississippi in October 1926 near the town of Amory, Monroe County. It was rated at 5 million cu. ft. per day. Subsequently several smaller wells were drilled in north-eastern Mississippi. The producing horizon is a sandstone in the Chester division of the Mississippian system which may be correlated with the Hartselle sandstone in which asphaltic residues have been found on the outcrop. The important producing area near Jackson will be described in § VIII.

Relation of Structure to Accumulation.

The outstanding cause for oil and gas accumulation in this province is the porosity of the reservoir rocks. The Lima–Indiana district has a number of large pools that are narrow, elongated, and have irregular fringing borders. These pools extend down the dip of the Cincinnati Arch a distance of 800 ft. from the crest in Delaware County, Indiana, to a point near Toledo, Ohio. In a general way they follow the zone where the flat dips on the arch give way to the rather steeper dips on the north and north-west sides leading down into the Michigan Basin. Evidently, the oil and gas are indigenous to the reservoir rock, and accumulation took place in solution channels before the capping shales were deposited. Intercommunication between the solution channels is indicated by the fact that gravitational separation has taken place in local areas.

In the pools of the Cumberland Saddle district porosity has also been the controlling factor. The important producing horizons are porous limestones subjacent to a prominent unconformity. The fact that oil, gas, and water mixtures are commonly encountered shows clearly the lack of migration. Evidently, the eroded edges of pre-Mississippian limestones furnished an ideal environment for the oil-producing plant matter.

Production Statistics.

Gas escaping along the Blanchard River first called attention to the natural resources of the Lima–Indiana district, and the records show that gas was used for illumination in Findlay as early as 1838. The first oil-well was drilled in 1885, and since then the district has furnished nearly 475 million barrels of oil. The production curve and the results of recent exploration indicate that the district is more than 90% exhausted, leaving a future reserve of less than 50 million barrels.

In the Cumberland Saddle district oil production began (as a by-product of the salt-boring industry) in 1819 with the drilling of the famous Beatty well. A gusher was drilled in 1829 in Cumberland County, but the commercial urge for intensive exploration did not come until 1860. Subsequently many small pools were discovered, and these accounted for a total of 20 million barrels of oil. Considering the peculiarities of oil occurrence in this district, it is not unreasonable to assume that 40% of the original reserves are still stored underground. However, the low per acre production, estimated by Hunter and Browning [4, 1935, p. 311] to be 700 barrels, will not encourage drilling within the near future.

IV. The Michigan Basin Province

The oil- and gas-pools of the Michigan Basin province are located in the Southern Peninsula of Michigan. The map, Fig. 3, indicates their location within the State. Geologically the producing areas are located on long, narrow anticlinal trends which pass across the basin from south-east to north-west. The most prominent one is the Howell–Broomfield trend which begins in township 1 N.—range 7 E., and can be traced to township 23 N.—range 16 W. Near the town of Howell drilling has revealed a fault with a throw of about 1,000 ft. (down to the west). This indicates that the whole trend as well as the more prominent parallel trends are probably located over deep-seated faults. Among the important anticlinal trends lying north-east of the *Howell trend* may be mentioned the *Greendale trend* on which the Porter, Yost, Mt. Pleasant, Denver, and Vernon oil-pools and the Clare gas-pool are located. The next pronounced trend is the *Port Huron–Saginaw trend* which is at present poorly defined. Still farther north-east lies the *West Branch trend* in Ogemaw County.

Stratigraphy.

The stratigraphy is outlined by means of a table which appears below. The highest formation consists of red coloured shales and gypsums with sandstone at the

Stratigraphy and Producing Horizons in Michigan Basin

System	*Formation*	*Thickness*	*Sands*
Pennsylvanian	Red Beds	100	..

base. They do not crop out extensively, inasmuch as the whole Southern Peninsula is more or less completely covered with glacial drift that in places exceeds 800 ft. in thickness. In the basal sandstones some gas has been found (Parma). Below the Pennsylvanian strata the unconformity so common in eastern United States appears in the sequence. Therefore the Upper Mississippian limestones, shales, and evaporites are missing in many places and over considerable areas. In the lower part of this series stray sands occur which contain large quantities of gas. Practically all the gas from the *Clare*, *Broomfield*, *Mecosta*, and *Elba* pools is derived from this horizon. The middle

or Osage division of the Mississippian contains the Marshall or Napoleon sandstones from which the chemical materials of the Dow Chemical Company at Mt. Pleasant are secured. These brines occur low down on the flanks of a deep syncline. Higher on structure the sandstones produce gas.

The lower division of the Mississippian system consists mostly of shale, much of it black in colour. Near the base lies the Berea sandstone which has produced considerable quantities of oil in the *Saginaw* pool.

The Devonian rocks are the most important in the basin. They consist of dark to black shales at the top, limestones in the middle, and dolomites at the base. The calcareous rocks have proved to be the most valuable from the standpoint of oil production. Among them the *Dundee* ranks first as a source of oil. It produces in the *Denver*, *Mt. Pleasant*, *Yost*, *Porter*, and *Leaton* pools. A small amount of the oil in the *Ogemaw* (West Branch) and other pools seems to come from the Dundee. The oil may appear in one, two, or three porous zones near the top of the formation. The porosity may involve only a few inches or may range to more than 20 ft. Cores and fragments blown from wells indicate by their honeycombed condition that solution has produced the porosity.

The *Traverse* formation consists of limestones and shales. The former are often found to be porous and in a number of places contain commercial quantities of oil. This is especially the case in the Muskegon field where two different zones are oil bearing. Much of the oil in the *Ogemaw* and *Oceana* pools comes from the Traverse.

The unconformity below the Dundee which is so prominent in south-eastern Michigan has evidently produced a zone of cavities on the structure of central Michigan, for some oil (and some gas as well) has been found at this level. For instance, in the *Vernon* pool indications seem to point to the absence of the Dundee over much of the structure, so that the Detroit River or '*Monroe*' dolomites appear directly under the lower Traverse shales. In the *Muskegon* pool most of the gas comes from this horizon.

Cause of Oil Accumulation.

Exploration for oil began in 1865 near the town of Port Huron in south-eastern Michigan. Because of the small size of the wells further efforts were delayed until 1913, when some small wells were drilled near Saginaw. This led to further desultory prospecting in other parts of the State, but it was not until 1925 that a real interest was aroused in the possibilities of Michigan. In that year a fairly good well at Saginaw started an active drilling campaign. As a result the *Muskegon* pool was discovered in 1927 and the *Greendale* pool (Mt. Pleasant) one year later. Since then the valuable reserves in the central part of the State have been found to be much larger than was suspected.

Because of the recency of active exploration, knowledge of underground conditions is still very limited. It is gradually becoming apparent, however, that unconformities and structural 'highs' furnish the clue to the oil accumulations. The unconformity at the top of the Detroit River (Monroe) dolomite has been described by Newcombe [5, 1934, p. 550]. He also states that the break between the Dundee involves the removal of 200 ft. of strata in short distances. A break at the Berea horizon is indicated by its general absence in western Michigan and the presence of red clay and calcareous material at this stratigraphic level. Abundant evidence is also at hand from well-cuttings of a break between the Marshall and the Michigan series. Finally, the unconformity between the Parma sandstone and underlying formations is very striking and very widespread. The very interesting maps published by Newcombe reveal the fact that the oil has favoured the structurally

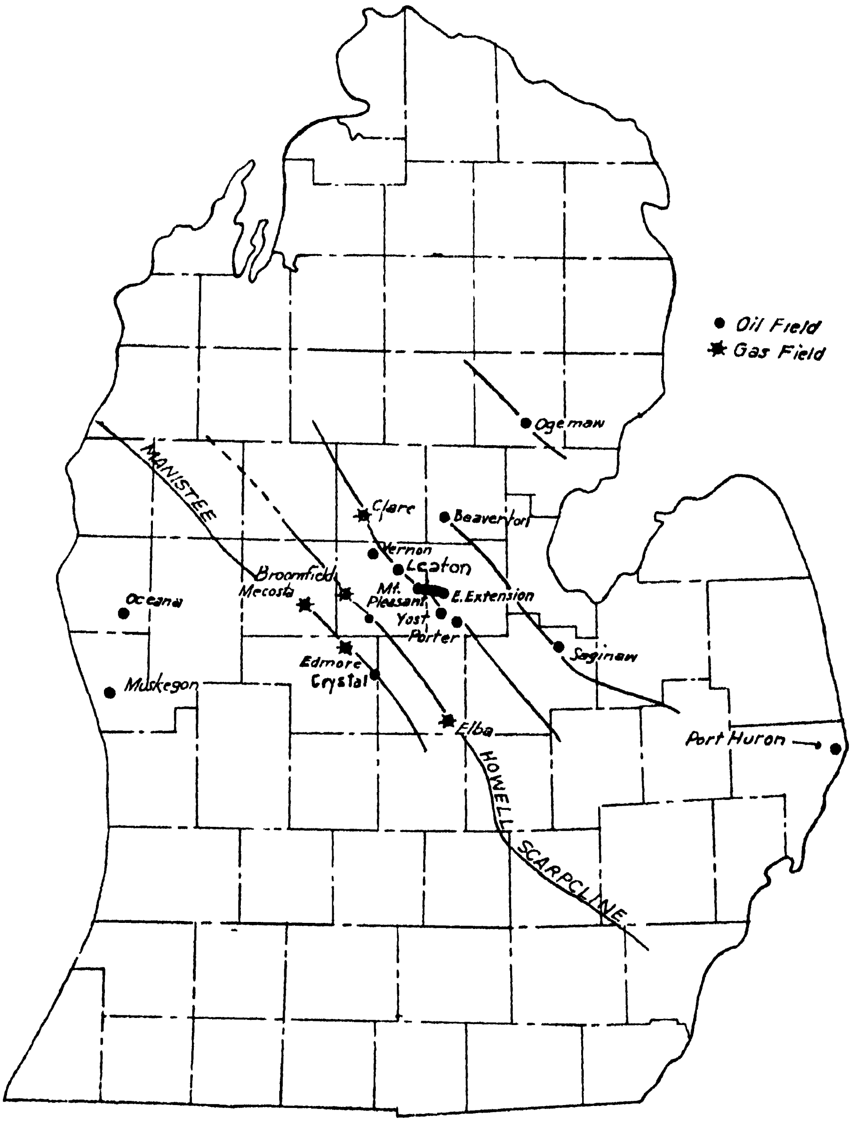

FIG. 3. Michigan Basin Province.

high places. The most prolific pools discovered up to date are located on the Greendale anticlinal trend described on page 74.

The general correspondence of structures in the Marshall Traverse, Dundee, and Monroe horizons indicates that uplift was repeated along the same lines and spasmodically. Whenever the uplift was great enough to lift the calcareous rocks out of the water an opportunity was presented for ground water to produce the necessary porosity. Thus the two essentials in providing a favourable environment for oil-forming materials were produced over wide areas in the Michigan basin.

Production.

Since 1925, when the yearly output amounted to only 4,000 barrels, the total has rapidly risen to over 15 million barrels in 1935. Considering the peculiarities of oil occurrence and the wide area over which the present pools are spread, it is not unreasonable to estimate that less than 10% of the ultimately productive territory has been found. Assuming that the total prospective area is over 10,000 square miles and allowing for a per acre production of 2,000 barrels on 2% of that area, the probable reserves exceed 250 million barrels.

V. Eastern Interior Coal Basin Province

The Eastern Interior Coal Basin province includes western and southern Indiana, north-western Kentucky, and practically all of Illinois. It is a natural geologic unit, being bounded on the east and north-east by the Kankakee branch of the Cincinnati Arch and on the south-west by the Ozark. The deepest part of the basin practically coincides with the point where the three States intersect. (See Fig. 4.)

Depositional History.

The history of sedimentation in this basin closely parallels that of the other large basins in the eastern part of the United States. After the Upper Cambrian and Lower Ordovician dolomites and sandstones were laid down, earth movements of considerable magnitude took place. The new sequence introduced by the St. Peter sandstone was probably not interrupted until the close of Silurian time. During the ensuing period of erosion some oil was formed on small domes in western Illinois (McDonough County, &c.) where the Hoing sand produces oil.

An angular unconformity at the base of the Upper Devonian (or Mississippian?) New Albany (Chattanooga) shale reveals the second period of deformation. Erosion and truncation of beds beneath the unconformity was probably widespread, but insufficient data make further elaboration impossible. Nevertheless, it is logical to assume that the small production found in the so-called 'Corniferous' limestone is genetically related to it. Such production has been found in Clark County, Illinois, and at Terre Haute, Indiana. The overlying Mississippian sediments are very thick and include the most valuable oil horizons in the province.

The *Kinderhook* at the base is made up of shales, limestones, and thin sandstones, one of which produced oil in a well drilled in Martinville township of Clark County. The overlying Osage division includes the *New Providence* shale, near the base of which some oil has been found in Kentucky (Ohio and Grayson Counties). The *Meramec* limestones (Ste Geneviève, St. Louis, Spergen, and Warsaw) contain porous zones in which important quantities of oil and gas have accumulated. In Illinois the producing horizon is called the *McClosky* 'sand', in Indiana it is referred to as the *Ste Geneviève* limestone, and in Kentucky only the *Warsaw* limestone is productive. The oil and gas in these limestones are probably related to the unconformity which appears in the section between them and the Chester division.

The Chester division is made up of an alternation of thin limestones and sandstones, each of which has received a name. By far the largest part of the production of the province is derived from the sandstones. In Illinois they are called by various names such as *Lindley*, *Benoist*, *Stein*, *Biehl*, *Carlyle*, *Tracey*, and *Kirkwood*. The last two have been traced over the widest area and therefore take on the greatest importance, although it is very probable that they are not continuous sandstones. In Indiana the important

producing sandstones are the *Cypress*, *Elwren*, *Brandy Run*, and *Mooretown*. Some of the Chester limestones also produce oil and gas. Outstanding among them is the *Paoli* limestone at the base of the division. In Kentucky the producing sandstones in descending order are the *Stephens*, *Jett*, *Jackson*, and *Barlow* sands.

Following uplift and deformation at the close of Chester time much of the series was removed from the structurally high places. The materials were reworked in Pottsville time, with the result that the Lower Pennsylvanian strata are very lenticular. Some of them have large accumulations of oil and gas, especially in south-eastern Illinois. The *Bridgeport*, *Robinson*, and *Buchanan* sands, for instance, have accounted for a considerable portion of the oil recovered to date. In Indiana one of the important sands in the Pottsville is the *Mansfield* sand. The '*Channel*' sand in Kentucky is interesting because it occupies an old river channel cut out of Chester rocks in early Pottsville time.

Structural Control.

The intimate association of the pools of these States with the *La Salle anticline*, the *Rough Creek fault* zone, and certain smaller 'structures' proves that they are genetically related. The La Salle anticline, at the southern end of which the most prolific pools were found, had its inception early in the Palaeozoic era. It is probable that the Trenton production of Clark County and the Waterloo pool (south-western Illinois) was formed as a result of deformation in Late Ordovician time. Much more definite evidence of deformation appears between Meramec and Chester time. Renewed uplift with the formation of porous zones in the Middle Mississippian limestones created ideal conditions for the trapping of oil and gas. This was the first pulsation of the Appalachian revolution. More followed during Chester time, with the result that numerous sandstones in the sequence are oil saturated. Many pools of small extent

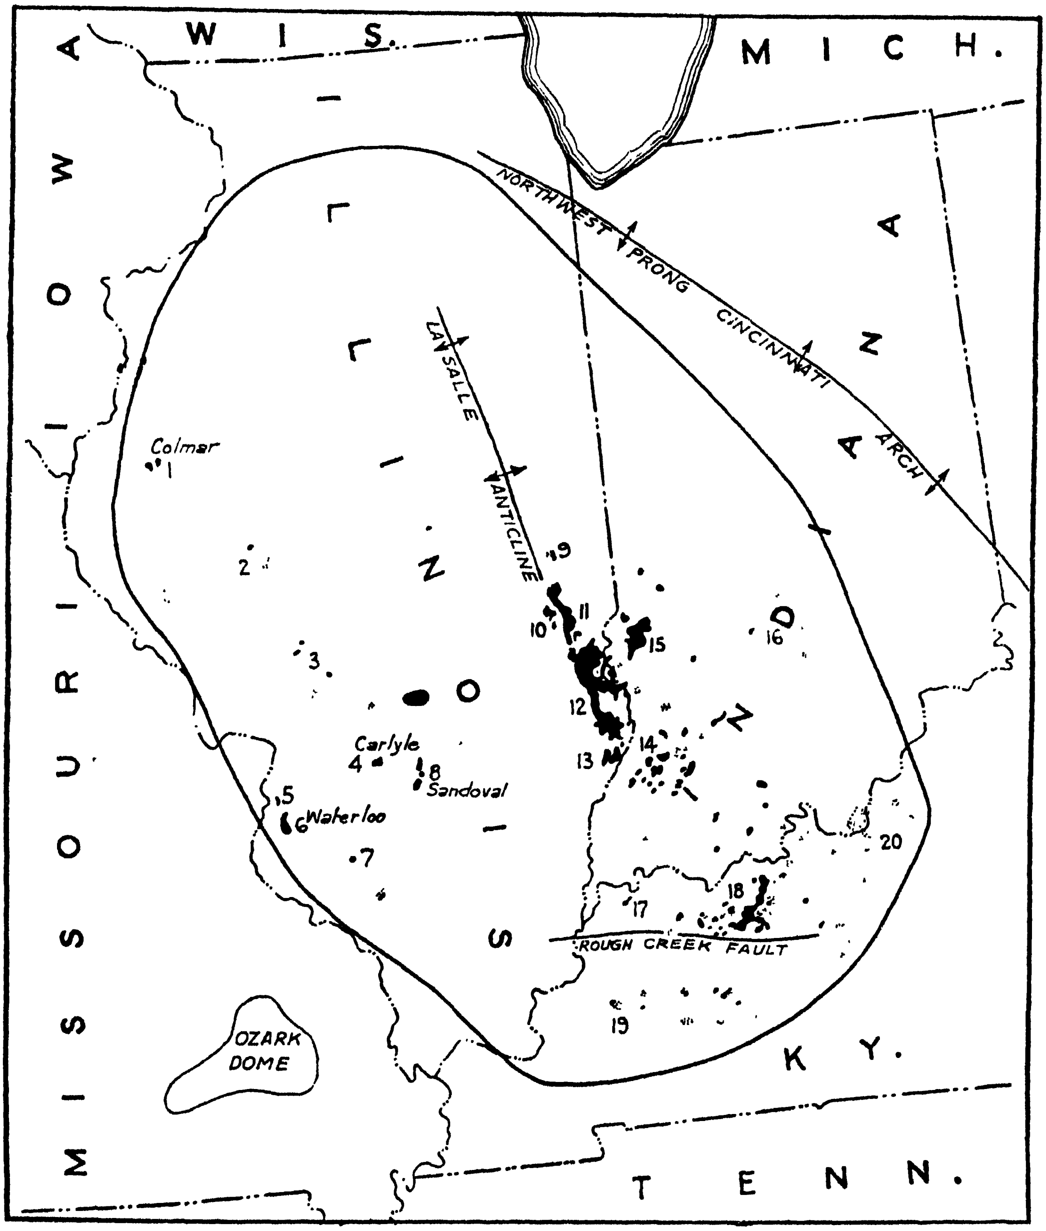

FIG. 4. Oil- and gasfields of Eastern Interior Province.

have different oil and water contact levels in approximately the same sands, which proves that there was no intercommunication or migration. The oil must have formed in place at the time of uplift. Much oil was undoubtedly lost during the long erosion interval between Chester and Pottsville time. But when renewed deposition took place spasmodic uplift brought portions of the anticline into the zone of optimum conditions for oil formation so that successively higher zones in the Pennsylvanian were saturated.

The oilfields in Kentucky are located mostly on the north side of the Rough Creek fault zone, but the reason for this is still more or less of a puzzle. Russell [2, 1932, p. 246]

50% exhausted. Probable reserves, therefore, can be estimated at 15 million barrels. Taking the province as a whole, the most that it can be expected to contribute in the future (with present exploitation methods) is 100 million barrels, even allowing for additional pools in south-western Illinois and south-eastern Kentucky.

VI. Western Interior Coal Basin Province

The Western Interior Coal Basin covers parts of Iowa, Nebraska, Kansas, Missouri, and Oklahoma. Geologically, it is limited by outcrop belts of Early Palaeozoic rocks such as those of the Ozark Dome in Missouri and of the Arbuckle

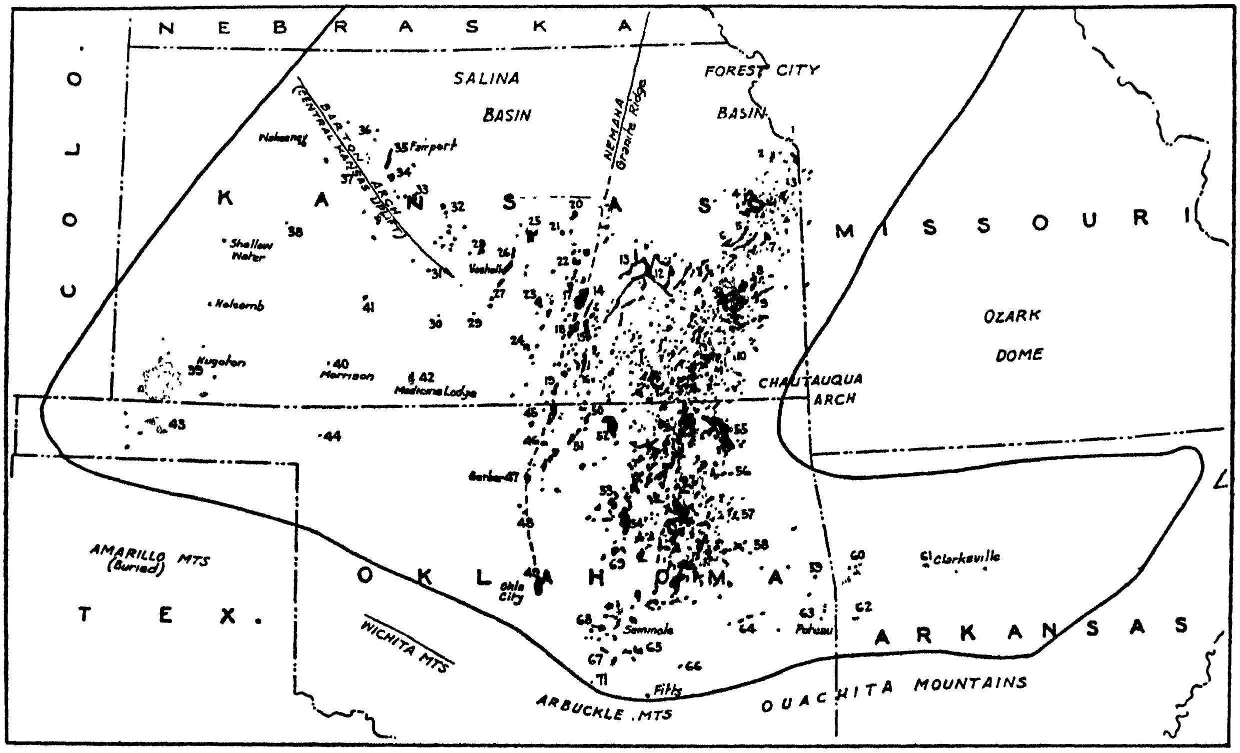

FIG. 5. Western Interior Province.

states that the strata north of the fault zone are somewhat folded and that some of the pools are associated with anticlines. In the eastern part of the productive belt there is little or no folding. Many pools show no relation to structure whatever. The information at hand with regard to the pools in south-eastern Indiana is also meagre. Those discovered in recent years and for which drilling records were well kept seem to be located on structural 'highs'.

Production Data.

The amount of oil produced in this province up to the end of 1935 totals approximately 465 million barrels. Illinois should be credited with 421 million barrels of this. Since the productive acreage in south-eastern Illinois is about 92,000 acres, Bell [5, 1934, p. 565] estimates the per acre production to be 4,400 barrels. The future production still in reserve may be placed at nearly 50 million barrels. South-western Indiana has produced about 20 million barrels to date, which indicates a per acre production of less than 800 barrels. It is believed that the area is 80% exhausted, so that the reserves probably do not exceed 4 million barrels. North-western Kentucky has accounted for about 24 million barrels and is scarcely more than

and Wichita Mountains in southern Oklahoma. Within the area there are similar prominent tectonic elements concealed under a cover of Pennsylvanian strata. The best known is the *Nemaha Granite Ridge* which is a very narrow belt of deformed rocks trending nearly north and south through eastern Nebraska, Kansas, and Oklahoma. Another is the *Central Kansas Uplift* which trends south-easterly from north-western Kansas into south-western Missouri (sometimes called the *Barton* and *Chautauqua* arches). These two are genetically related to the richest oil- and gas-pools in the province. (See Fig. 5.)

Stratigraphy.

The stratigraphical sequence is shown in the table on page 79. Tertiary rocks cover the area in the western part, but have no economic interest. They are underlain by a considerable thickness of Cretaceous rocks which also have no economic value. The Permian system is represented by two distinct types of materials, an evaporite series at the top with much red and green shale and a marine sequence below. The latter bears a striking resemblance to the Pennsylvanian sequence, for it consists of alternating layers of limestones and shales. Occasional sandstones or sandy

phases in the shales have enough porosity to become reservoirs for oil. Sometimes the limestones have original or secondary porosity characters which allow them to serve in that capacity.

The highest producing horizon, for instance, seems to be a porous limestone in the Big Blue series and it is usually referred to as the Hugoton gas sand. The *Hugoton* gasfield is located in south-western Kansas and appears to be one of the large gas areas of the country. In Oklahoma the *Hoy* and *Kisner* sands produce some oil and gas in the north-central part of the State. The list of petroliferous zones in the Pennsylvanian system is quite impressive and the reader will find the names of the more important ones in the table on this page. The most prolific sands lie close to the base of the system in the Cherokee division, and among them the *Bartlesville*, *Burbank*, and *Glenn* sands stand out because of large production east of the Nemaha Granite Ridge. They are extensive sheet sands in which the oil and gas deposits are trapped by lack of permeability in the up-dip areas.

The Mississippian system contains limestones and shales in the upper part (Chester), thick limestones in the middle (Boone), and black shales at the base. The Chester division produces oil in Scott County, Kansas (*Vaniman*), and in south central Oklahoma where the *Cromwell* and the *Dutcher* sands have accounted for important amounts of petroleum. The Boone is usually the uppermost portion of the system, because of the extensive unconformity between it and the Pennsylvanian. On structural 'highs' much chert and other insoluble material have collected which seem to furnish an ideal gas reservoir and have also trapped much oil in central Kansas. This is commonly called the '*chat*' horizon or the *Welch* chert. At the base of the system is another prominent unconformity which is often marked by the local occurrence of sandstones. Oil at this level is referred to the *Misener* sand.

In the basins between the positive structural features older rocks appear. In some basins the Silurian and Devonian limestones, usually called collectively the *Hunton* formation, are quite thick. Where their eroded and truncated edges appear beneath the unconformably overlying strata some oil has been trapped. It has been found quite productive in central Kansas and also in south central Oklahoma. The older Ordovician rocks also appear in narrow bands beneath the unconformity. The Sylvan at the top is mostly shale, the *Viola* largely limestone and dolomite, the Simpson mostly green shale and sandstone. The *Arbuckle* formation was named from the mountains in southern Oklahoma where it is 8,000 ft. thick. Farther north it thins abruptly and on structures it is quite thin or even entirely absent. Each of these Ordovician formations that has either initial porosity (Simpson sandstones) or secondary porosity (limestones and dolomites) may be oil bearing. Indeed, in recent years by far the largest part of the production has come from strata of this age. The various sands in the *Simpson* lead in Oklahoma where they have considerable thickness. In Kansas, on the other hand, the *Arbuckle* (*Siliceous Lime*) is the most prolific horizon at the present time.

Relation of Structure to Accumulation.

The producing horizons in this province may be divided into two classes according to their relation to unconformities. The pre-Pennsylvanian horizons show unmistakable relationship to unconformities. The most striking of these is the post-Mississippian unconformity, for deformation was profound along narrow lines. The best fields such as the *El Dorado* in Kansas and the *Oklahoma City* field in Oklahoma are associated with the buried Nemaha Granite Ridge. Faulting brought up the older Palaeozoic rocks along narrow and straight *en échelon* belts. Subsequent solution of the calcareous strata produced the necessary porosity, and their relatively high position with reference to surrounding basins provided optimum conditions for oil formation. Some pools which lie in a parallel trend, such as the famous *Cushing* pool in eastern Oklahoma (east of the Granite Ridge) and the *Voshell-Burrton* trend in central Kansas (west of the Ridge), were formed at the same time and in the same manner.

The post-Devonian unconformity is best illustrated in the *Central Kansas Uplift* which extends from the north-western part of Kansas south-easterly towards the south-eastern part of the State where it merges with the Ozark Dome. It is a broad, turtle-back type of fold from which every formation except the Arbuckle is missing over large areas. Oil- and gas-pools dot this plateau wherever local 'highs' or narrow cross trends intersect it. On the periphery where the truncated bands of older rocks appear beneath the Pennsylvanian, oilfields are being found at the present time.

The producing horizons in the Pennsylvanian and Permian do not reveal such striking relation to unconformities. Nevertheless, it is believed that they also owe their productivity to similar environments. Deformation and uplift along the older zones continued during Pennsylvanian time in spasmodic fashion. This is abundantly

proved by the familiar 'thinning of the section' above older 'structures'. (See especially McCoy [5, 1934, p. 581]). Therefore it is not uncommon for wells to have numerous 'shows' and shallow gas sands in the higher formations when located on prominent buried structures. This was the case notably at El Dorado, Kansas, and Garber, Oklahoma.

As a general rule these upper sands become more valuable with depth. At present the highest one of great production is the porous zone at the top of the Lansing (or Kansas City) limestone sequence. In western Kansas this is called the *Oswald* horizon and in northern Oklahoma the *Stalnaker* sand. In the Russell pool of western Kansas where the Oswald was named there are at least eight distinct porous levels in the limestone which have produced oil. They lie at various levels below the top down to 285 ft. It is interesting to note that in one well this lowest level lies immediately above the pre-Cambrian granite.

Still lower are the sands in the Marmaton and in the Cherokee. These sands produce almost exclusively from areas lying east of the Nemaha Granite Ridge. In general the oil and gas are trapped by the up-dip termination of their permeability. Sometimes this is due to the thinning of the sandstone, sometimes to the complete thinning out of the sandstone, and in a few cases to the presence of cementing materials. Somewhat peculiar conditions are exemplified by the so-called '*shoestring sands*' which extend for many miles through Butler and Greenwood Counties, Kansas. They are now believed to be off-shore bars or barriers formed in the Cherokee seas. It should also be added that many small pools in eastern Oklahoma produce from these sands on local domes and anticlines.

Production Data.

At the close of 1935 the production figures for Kansas stood at 779 million barrels and for northern Oklahoma at 3,500 million barrels. Of the total for Kansas 688 million should be credited to the eastern part of the State (east of the prime meridian), and if this is equally distributed over the 566 square miles of productive territory, it gives a per acre figure of 2,000 barrels. A reasonable estimate of the reserves in eastern Kansas is 200 million and for western Kansas 800 million barrels. A similar estimate for Oklahoma is 1,500 million barrels. It is interesting to note that each State has had certain rich spots or bonanzas. For Kansas these spots are Rainbow Bend (10,000 bbl. per acre), Churchill (20,000 bbl. per acre), Oxford (20,000 bbl. per acre), Valley Center (15,000 bbl. per acre), Voshell, Houry, Burrton, and El Dorado (7,000 bbl. per acre). For Oklahoma the two mort important field are Oklahoma City (estimated ultimate 75,000 bbl. per acre) and Seminole (estimated ultimate 40,000 bbl. per acre). Other rich spots are Burbank, Cushing, Garber, Glenn, and Tonkawa.

VII. The Wichita Amarillo Mountain Province

The oil- and gasfields in southern Oklahoma, north central Texas, and the Panhandle of Texas have distinctive characteristics which entitle them to separate treatment. The reason for this is the fact that they are associated with pronounced structural features due to Hercynian (Appalachian) mountain building movements. These are well displayed in the Arbuckle Mountains and Criner Hills of southern Oklahoma and the Wichita Mountains of southwestern Oklahoma. They have also been revealed by drilling in the Amarillo district of Texas and the Red River Uplift district of northern Texas. Some of the pools are superposed on the buried mountains, others on their flanks and some on small parallel zones of deformed rocks. (See Fig. 6.)

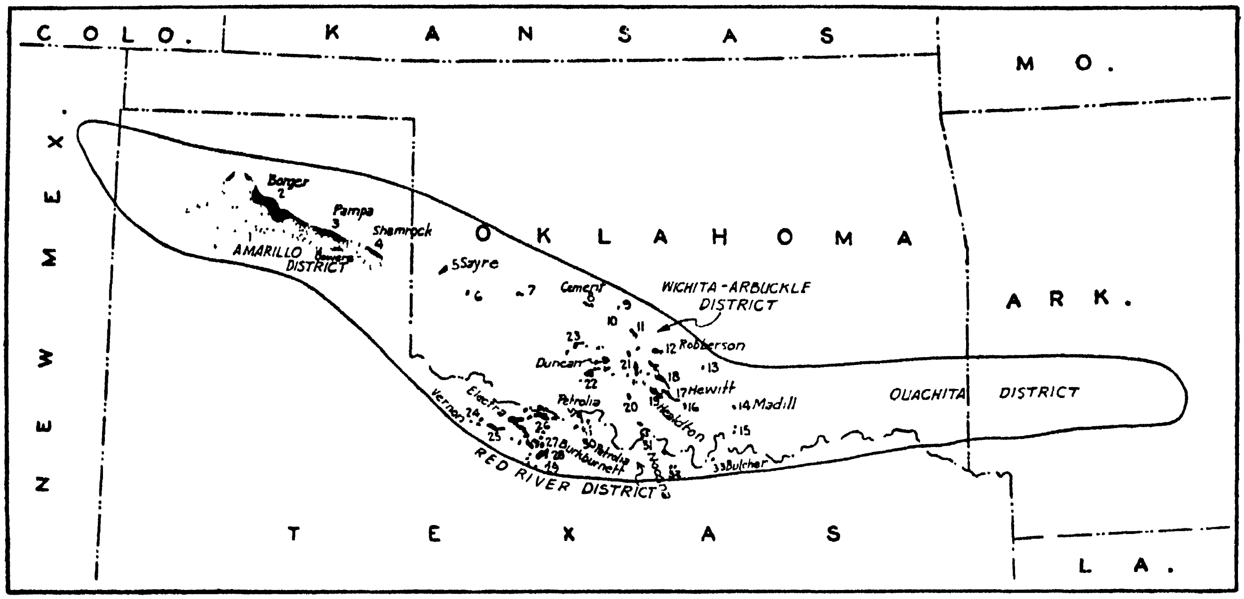

FIG. 6. Ouachita–Amarillo Province.

Stratigraphy

The stratigraphy of this province is very interesting and also very difficult because of variations in lithology from east to west. The surface rocks in the western part of the area are Tertiary and Mesozoic sediments which have no economic interest. They rest unconformably upon Permian strata which crop out in successively older bands towards the east. No production has been found in the Double Mountain or Clear Fork groups, but the Lower Permian rocks called *Wichita-Albany* contain large quantities of gas and some oil. In Oklahoma production has been obtained from pools in Beckham, Caddo, Grady, Stephens, and Garvin Counties. In northern Texas small production has

been found in pools located in Wichita, Clay, and Archer Counties. In these States the Wichita-Albany consists of shales and sandstones which have prominent red-coloured zones in the east and grade into calcareous rocks towards the west. For instance, in the *Sayre* pool of Beckham County and in the large *Panhandle* district the producing horizon is dolomite (top of *Big Lime*). It is about 250 ft. thick and contains porous zones throughout, making it the most widespread gas horizon in the Panhandle district. Oil occurs in the same dolomite farther down the dip.

The so-called '*Gray Lime*' of the Panhandle district is believed to be of Pennsylvanian age. It has furnished the largest gas-wells and has accounted for some of the oil as well. Farther east the Upper Pennsylvanian rocks are called the *Pontotoc* formation and consist of very coarse clastics. It is not improbable that the '*granite wash*' of the Panhandle district is the correlative of the Pontotoc, for it consists of similar detrital materials. Much gas and considerable oil have been recovered from it.

the pre-Cambrian igneous rocks, and there some gas has been found in the crevices of the weathered surface of the granite.

Relation of Accumulation to Structure.

It appears from the above that practically all the oil and gas in this province originated during Pennsylvanian and Early Permian time. The oldest producing horizons are directly associated with the unconformity at the base of the Pennsylvanian. The relationship is emphasized by the fact that the granite produces gas in Texas, showing that only the necessary porosity was needed to trap the gas formed during the break in sedimentation. The rest of the gas and the oil in the Texas Panhandle is associated with the other unconformity which is post-Glenn and pre-Pontotoc, for, although much of it lies at stratigraphically higher levels, the available evidence indicates that migration within and about the periphery of the large structure at that point has been rather free and easy.

Stratigraphy and Producing Horizons—Wichita–Amarillo Province

Pre-Cambrian	Granite, &c.	..	..	..	..	..	Some gas

The base of the Pontotoc is marked by a widespread unconformity. In the basins between the mountain uplifts of this province an enormous thickness of older Pennsylvanian shales and sandstones (Glenn, &c.) was laid down. Many of the porous strata yield large quantities of oil where they appear on the flanks of structures. In Stephens County, Oklahoma, for instance, eight different sands are productive in the *Empire* pool and the *West Duncan* pool. Indeed, by far the largest portion of the oil has been derived from sands in the Glenn formation. This is true in northern Texas as well as in southern Oklahoma. Important pools in Oklahoma producing from these horizons are the *Healdton Graham*, *Hewitt*, and *Crinerville* pools in Carter County.

Below the Glenn formation and its correlatives there is another unconformity which is both widespread and marked by great deformation in the older rocks. It is common, therefore, to find the Mississippian, Devonian, Silurian, and Upper Ordovician strata absent in this area and always on the prominent structures. Some oil has been found on the truncated tops of these older rocks. For instance, in the *Robberson* pool of Garvin County the Viola limestone and the Simpson sandstones produce some oil. In the Franksgraben the Viola and Simpson produce oil. At Crinerville the Arbuckle limestone has accounted for some of the oil. Recently production has been found in the Arbuckle (Ellenburger) in the north Texas district. In the Panhandle district the Pennsylvanian rocks rest directly on

Structural Control.

In addition to the evident importance of unconformities the influence of structure should be emphasized. From all published information at hand it now appears probable that this province is underlain by a vast series of block-faulted uplifts. They are arranged in *en échelon* groups. Some are high and some are low, but all seem to have the steepest side to the north or west. On the basis of van der Gracht's monumental studies [2, 1931, p. 991] these fault blocks were produced during the 'Wichita phase' of orogeny which came early in the Pennsylvanian period and which corresponds to the unconformity at the base of the Glenn formation. The Wichita phase extended over a period of geologic time which includes the Upper Mississippian and the oldest Pennsylvanian. Its effects may be noted as far north-east as the Criner Hills, but not in the Arbuckle Mountains or the Ardmore Basin which lies between them. The latter tectonic elements were produced by the Arbuckle phase of orogeny which came in Late Pennsylvanian time and corresponds to the unconformity between the Pontotoc and older strata. No doubt some rejuvenation of the more southerly structures took place at this time, for unconformities are found in the sequence.

In addition to the buried mountain ranges mentioned in previous pages, the Wichita group includes the *Red River Uplift* which has been traced from eastern Cooke County, Texas, to central Foard County and the Landreth–Sigler

line of disturbance on its southern flank. Between the Criner Hills and the Wichita Mountains the Hewitt, Healdton, Woolsey, Loco, and other short ridges have been discovered by deep drilling. Each of these is directly and intimately associated with important oil accumulations. Indeed, the subsurface correspondence between anticlines and oil occurrence is as striking as it is in the Rocky Mountain province. Steep dips are the rule here in distinction from the fields of the Western Interior province. This has facilitated short-distance migration within the structure. In this connexion it should be emphasized that the patchy, disconnected porosity in many Pennsylvanian sands of this province has produced quite a number of anomalous oil accumulations. They are especially common in the north Texas district.

Production Statistics.

Up to the end of the year 1935 the Panhandle district of this province has produced 257 million barrels of oil as well as a very large amount of gas (over 4 billion thousand cu. ft.). The gas-productive area is nearly 1 million acres, and competent engineers estimate that its future production will be 10 billion thousand cu. ft. Oil production extends over approximately 100,000 acres and is expected to contain about 200 million barrels in reserve. To date this production has been only on the north side of the structure. Several small wells drilled within the last year indicate that some additional reserves may be stored on the south side of the Amarillo Mountain area.

Ultimately there will probably be a zone of pools eastward through south-western Oklahoma (where oil was recently discovered near Altus) which will connect with the pools in northern Texas. The total production from the latter amounts to 490 million barrels. Considering the peculiarities of oil occurrence in the Red River Uplift district it may confidently be predicted that at least 200 million barrels are still stored underground. Data on the southern Oklahoma district of this province were furnished by C. W. Tomlinson who states that the production to the end of 1935 was 420 million barrels and that estimates of reserves amounted to 100 million barrels.

VIII. The Bend Arch Petroliferous Province

Somewhat closely associated with the fields of the Red River Uplift are the fields of north central Texas. They extend southward through Archer, Young, Stephens, Eastland, and Brown Counties and include a few scattered pools in the adjacent counties. Geologically they are related to an arch prominently developed in the earliest strata of Pennsylvanian age, the Bend Arch. To the east of this arch lies the Strawn Basin, in which were laid down great thicknesses of coarse clastics as a 'molasse' from the land mass of Llanoria. The north-western side of this land mass was rising rapidly at the time of the Wichita phase of orogeny described in the preceding section. Therefore the Strawn sediments thicken very markedly towards the east up to the 'boundary fault' of the ancient land area. In Upper Pennsylvanian time the whole region was tilted towards the west. Inasmuch as the lowest Pennsylvanian strata (Bend series) had been subsiding towards the east with the formation of the Strawn wedge of sediments, this tilting movement produced a broad arch at that level.

Stratigraphy.

The stratigraphical sequence as revealed by deep drilling on the arch is shown in tabular form below. Since the arch is highest at the south end and pitches gently towards the north the oldest rocks crop out south of the big bend in the Colorado River in the eastern part of San Saba County. This area is often referred to as the Llano-

Stratigraphy and Producing Horizons—Bend Arch Province

System	*Formation*	*Thickness*	*Sands*
Permian	Wichita	200 (north) only)	..

	(Unconformity)		
Ordovician	Ellenburger	1,000	..

Burnet Uplift or the Central Mineral Region of Texas. Pre-Cambrian, Cambrian, and Ordovician rocks are exposed there as well as the black shale of Mississippian age (Barnett) which rests unconformably upon their eroded edges. The Bendian strata of earliest Pennsylvanian age rest upon the Barnett shales with unconformable relations. They are divided into two formations, the lower (*Marble Falls*) consisting of dark-coloured limestones and the upper (*Smithwick*) consisting of black shales and interbedded limestone. These two formations have furnished the largest proportion of the oil and gas of this province. Porous zones are found at various levels in the Marble Falls limestone and also in the so-called Caddo Lime which appears about 200 ft. above the top of the Marble Falls. The upper 'pay' is the chief producing horizon in Stephens County, where it is from 40 to 50 ft. thick and variously called *Caddo Lime*, *Breckinridge Lime*, or *First Pay*. Near Ranger in Eastland County, where the most prolific production in the province was discovered, the *Second Pay* or *Ranger Lime* yields the oil.

The *Strawn*, which lies above the Smithwick unconformably, consists of shales, sandstones, and thin limestones. The sandstones are very patchy and vary greatly in thickness from place to place. However, they are porous and therefore serve as reservoir rocks in many small pools extending as far north as Stephens County. Local names have been used for these sands. The *Canyon* also consists of shales, sandstones, and limestones, but does not seem to contain any petroliferous sands. On account of the northward pitch of the arch the *Cisco* attains its full thickness only at the northern end of the province. There it is 2,000 ft. thick and contains strata similar in lithology to those of the Canyon formation. The sandstones, again, are very lenticular, but contain important accumulations of oil at various horizons in the formation. In southern Archer County, where this formation has been found most important, the better sands are in the lower half of the formation. They have received local names such as *Dalmar*, *Wilmot*, *Swastika*, *Gose*, and *Texhoma*. The porosity of the best sands averages about 22%, and the per acre production is estimated to be 7,000 barrels.

Conditions of Oil Accumulation.

The striking alinement of pools close to the highest portions of the arch indicates plainly that structural relief is

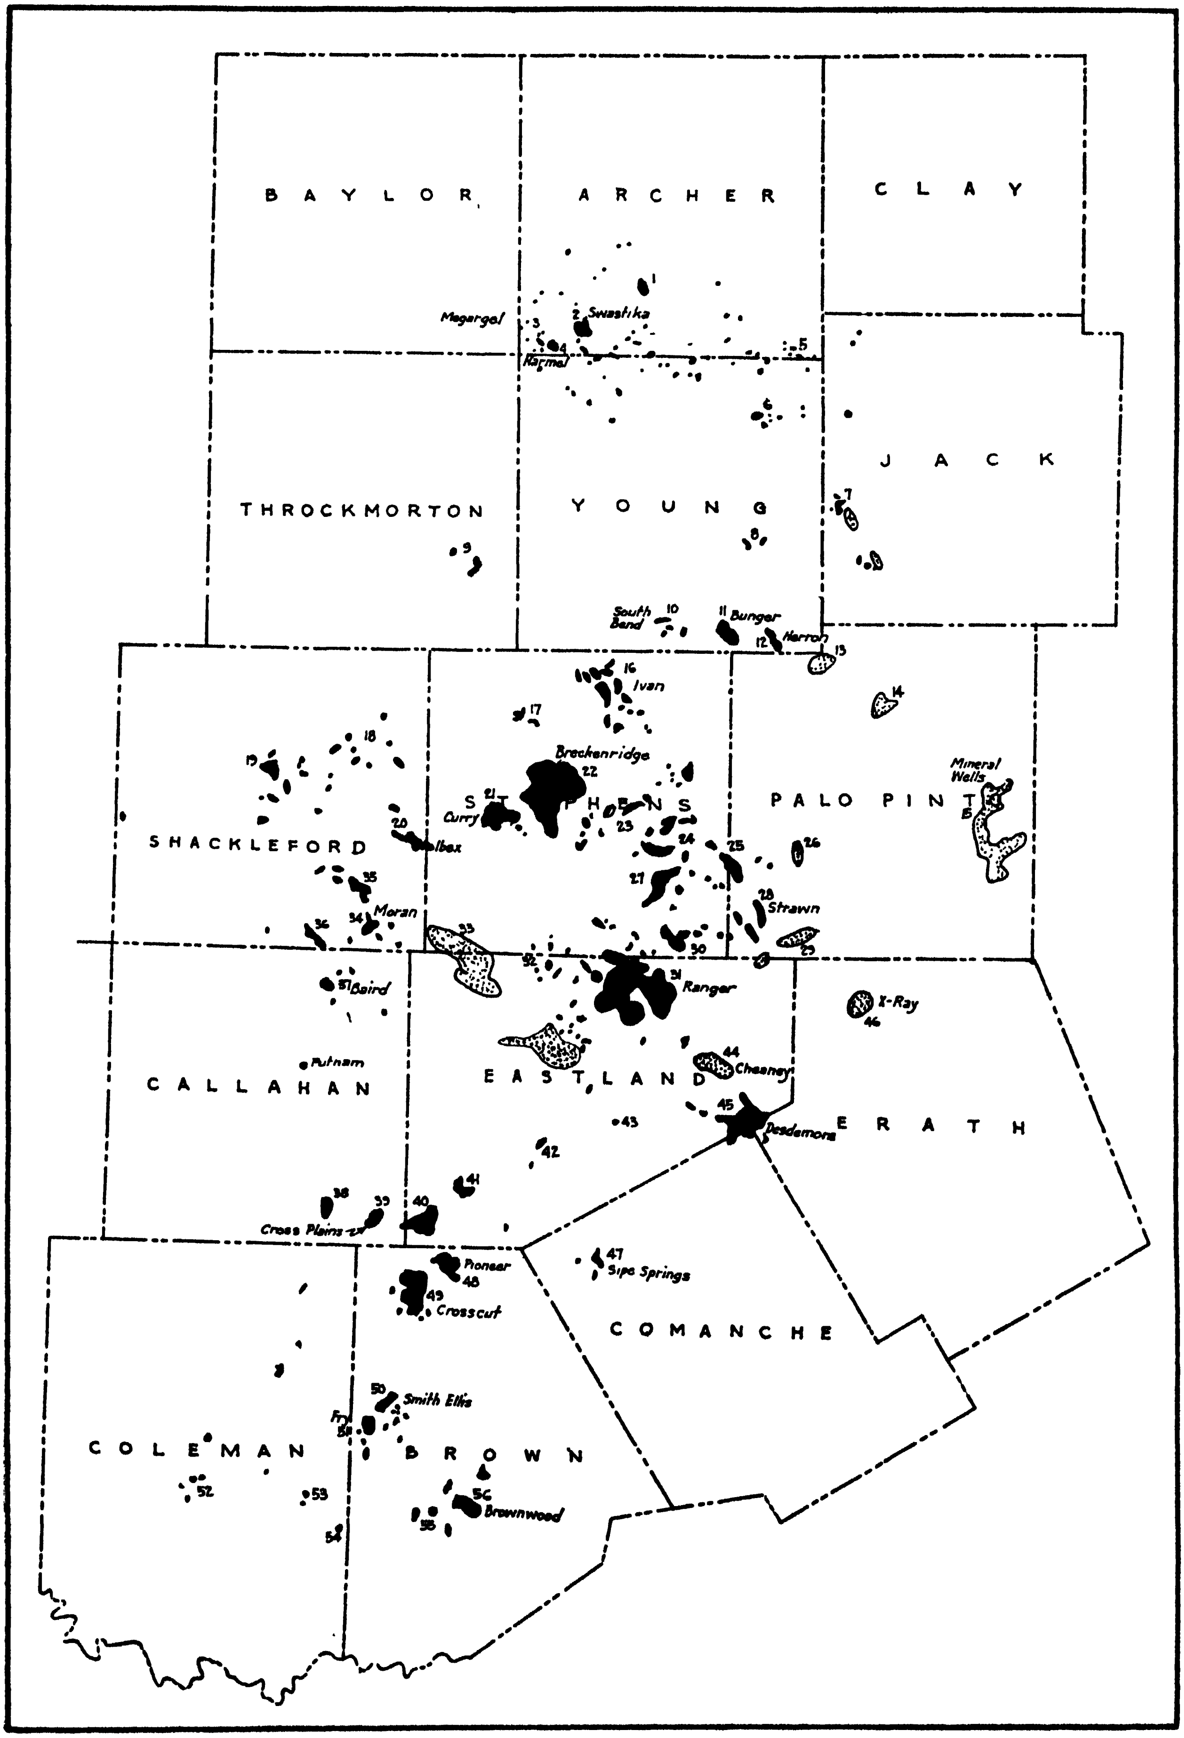

FIG. 7. Bend Arch Province.

important in this province. The relatively broad axis of the arch is modified by local domes, anticlines, noses, and other minor structures. Quite a number of them, like the Breckinridge dome and the Ivan dome in Stephens County, the Ranger and Eastland noses in Eastland County, and the Strawn dome in south-western Palo Pinto County, have large accumulations of oil upon them. In many pools, however, the structural relationship is not obvious. There the accumulations are controlled entirely by porosity conditions. Many cases are on record where the producing sand becomes thin or merges with shale beds at the boundary of the producing area. On the whole this has been the most difficult province to locate oil-pools in, and therefore has the doubtful honour of showing the largest percentage of dry holes.

Production.

The amount of oil produced from this province up to date exceeds 354 million barrels. Of this total more than one-third should be credited to Stephens County. Eastland and Shackelford Counties rank next in importance. It may be conservatively estimated that 70% of the productive area has been discovered. The per acre production over much of the province has been disappointingly low, although certain of the richer areas have reached close to 6,000 barrels per acre. The future reserves will therefore hardly exceed 125 million barrels.

IX. The Gulf Embayment Province

The Gulf Embayment involves eastern Texas, southern Arkansas, all of Louisiana, and a considerable portion of Mississippi. It is so called because the Tertiary and Cretaceous rocks which were laid down as ancient delta deposits by the Mississippi River reach into the United States as a large bay from the Gulf of Mexico. Because of the large area affected and the somewhat different conditions existing in its various parts it will be convenient to subdivide it into four districts. These have been named the *Balcones Fault district* (east central Texas), the *Sabine–Ouachita Uplifts district* (northern Louisiana, southern Arkansas, and north-east Texas), the *Reynosa Escarpment district* (south Texas), and the *Salt Dome district* (southern Texas and southern Louisiana). (Fig. 8.)

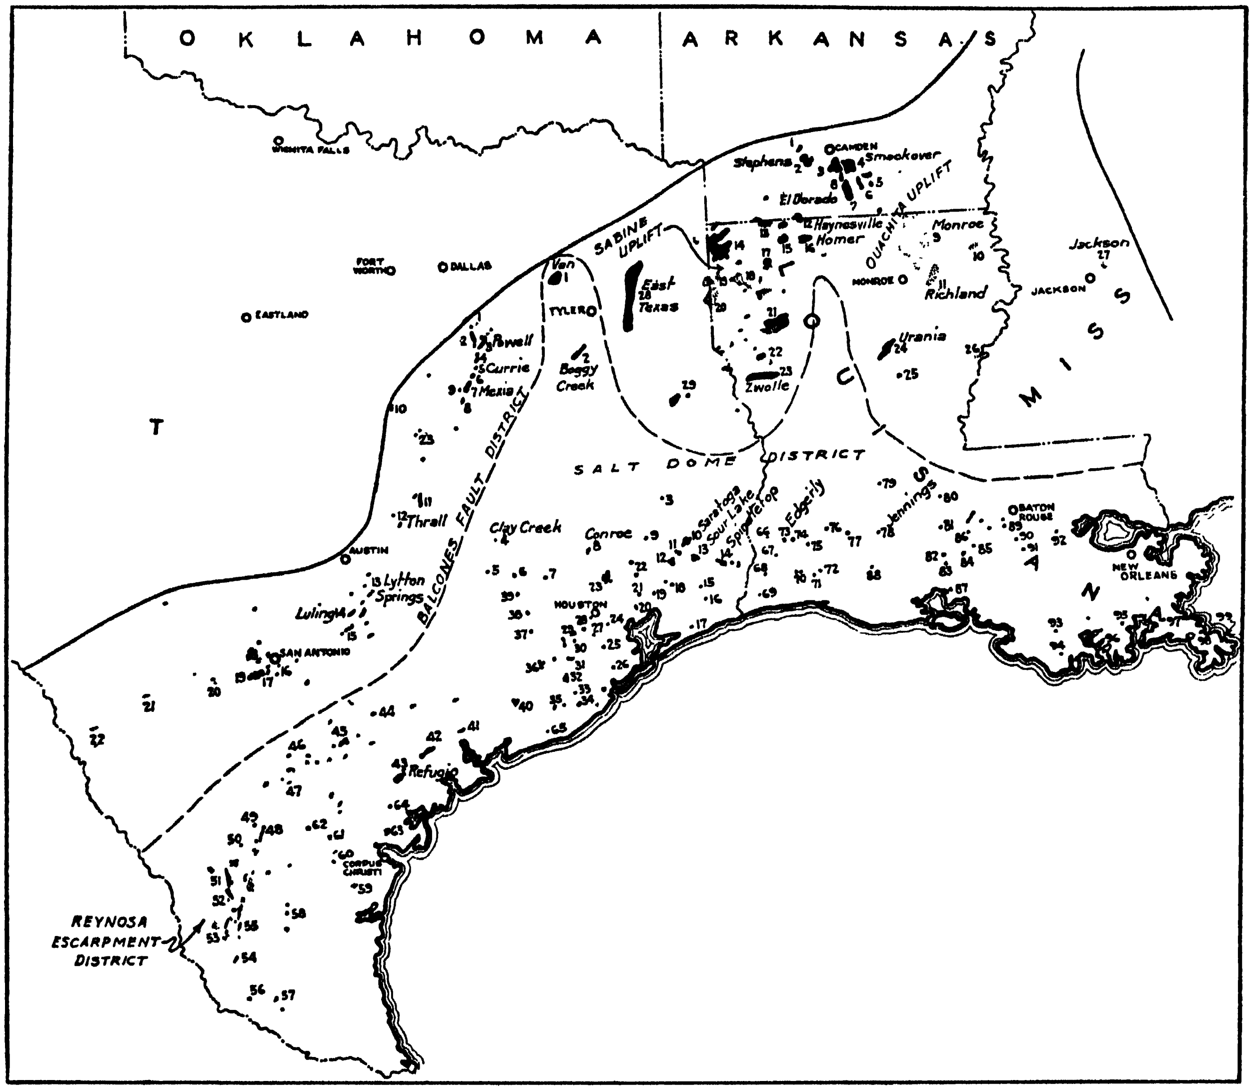

Fig. 8. Gulf Embayment Province.

Geological History.

The geological history of this area begins with the sinking of Llanoria, that ancient land in Louisiana which had

furnished sediments to Texas and Oklahoma during Palaeozoic time and which culminated its role as a positive element with one grand orogenic flourish in Pennsylvanian time. The tensional stresses which followed the Appalachian Revolution allowed Llanoria to sink and slip towards the Gulf. By Comanchean time it had become submerged by ocean waters and sank rapidly so as to accommodate 4,000 ft. of red shales, sandstones, limestones, and anhydrite. These materials have been reached and penetrated in a few wells in the northern part of the province. The fact that they are commonly found dipping more steeply than the Cretaceous rocks indicates that some deformation took place between the two periods.

been known for a long time. It extends through east central Texas from a point east of Dallas southward to a point west of San Antonio. It seems to coincide closely with the surface trace of the line marking the north-west boundary of the folded Palaeozoic rocks of the Ouachita facies. Another belt of short *en échelon* faults has been found in a closely parallel zone some distance east. It has been named the *Mexia fault zone* after one of the prominent oilfields discovered within it. In general, the area between the two zones is a belt of graben which has recently been traced into south-west Arkansas. The Mexia fault zone seems to coincide with the north-west boundary of the buried Llanoria. These two zones of faulting are

	Fredericksburg	500	Edwards	1,000	..	..	..	..	..
	Trinity	800	Paluxy	4,000	Glen Rose	..	..	..	..

The principal structural features of the province were no doubt initiated at that time. Two wells in McLennan County show that about one-third of the total displacement along the Balcones Fault in that area was produced then. The common absence of the Woodbine and Eagle Ford formations from the Sabine Uplift and the Ouachita Uplift (Monroe and Richland fields in Louisiana and northward into Arkansas) show clearly that these important structures had been started.

Earth movements during the Cretaceous period were infrequent and subdued. The most important break came at the close of Navarro time, when a widespread retreat of the seas brought many structures into the sphere of subaerial erosion. Such have been described from the *Dixie oil-pool* on the Sabine Uplift and the *Richland gasfield* on the Ouachita Uplift. At these places renewed deformation produced angular unconformities. During ensuing Midway time there was another period of relative stability. But quite the opposite is true of the remainder of the Tertiary. Very great variations in the thickness of the Wilcox indicate continued uplift of the positive areas such as the Sabine Uplift. Differential uplift and deformation were marked in Claiborne time. It is also noticeable in the succeeding Oligocene and Miocene epochs. Many of the salt-domes show the effects of these spasmodic recurrences of upthrusting by a thinning of the strata across the top.

Balcones Fault District. The Balcones Fault Zone has

therefore surface indications of prominent structural lines in the subsurface.

The producing horizons in this district are listed in the table of formations given above. The most prolific is the *Woodbine sand* which appears at the base of the Cretaceous system. Next in importance is a limestone in the Comanchean Fredericksburg division called the *Edwards lime*. The upper 25 to 35 ft. of this limestone are porous and contain oil in the *Luling*, *Joe Bruner*, *Salt Flat*, and *Darst Creek* structures. It will be noted that these are in the southern part of the area, whereas the Woodbine produces only in the northern part. In the district some small production has been obtained from various formations in the Cretaceous system. The *Austin chalk* produces some oil from cavities associated with the fault zone in the *Joe Bruner* and the *Darst Creek* fields. The overlying Taylor contains several producing horizons in different parts of the district. Perhaps the most interesting is the altered igneous rock (serpentine) which produces at *Thrall* and at *Lytton Springs*. Several thin sand lenses which lie close to the top of the Taylor produce some oil and gas at *Corsicana*. In the Navarro there are also sand lenses which are correlated with the Nacatoch sand so important farther east. In this district they have produced considerable amounts of gas and some heavy oil at *Powell*.

Sabine–Ouachita Uplifts District. The Sabine Uplift is a very large and broad dome-like structure in north-eastern

Louisiana and north-eastern Texas. The largest field in the world is located on its western flank, the famous *East Texas* field. Other famous pools on it are the *Caddo*, *Haynesville*, and *Homer* oil-pools. On its southern flank lie the *Bull Bayou* and the *Zwolle* pools. The producing horizon in the East Texas field is the *Woodbine*, but in the others higher strata contain the oil and gas. The *Tokio sands* near the base of the Austin chalk formation produce oil in the *Dixie* and the *Caddo* pools. The '*Blossom*' *sand*, by some placed in the Austin and by others in the Taylor, yields oil at *Homer* and *Haynesville*. It is also an important source of gas. Higher in the Taylor lies the *Annona chalk* which accounts for some of the oil at *Caddo* and probably some at *Zwolle*. In the latter field production is very erratic and comes from a cavernous marly limestone which probably is in part the Marlbrook. The most consistent and largest producer of oil and gas is the *Nacatoch* sand of the Navarro formation.

The Ouachita Uplift trends north-west and south-east from south central Arkansas into north-eastern Louisiana. On it the very prolific *Smackover* and *El Dorado* fields of Arkansas are located as well as the *Monroe* and *Richland* gasfields of Louisiana. In the former oil is found within the *Nacatoch*, *Taylor*, and *Tokio* formations. The two large gas-pools derive their gas from the *Annona chalk* and some porous tuff beds within the *Tokio*. At *Richland* some gas-wells have been drilled into the deep sand within the *Glen Rose* portion of the Trinity. The same horizon has also furnished some gas in several gas-pools of the Sabine Uplift (*Bethany* and *Cotton Valley*). By contrast the oil and gas at *Urania* comes from the topmost portion of the *Wilcox* of Tertiary age.

Reynosa Escarpment. In southern Texas (often called south-west Texas) one of the well-cemented Pleistocene formations called the Reynosa makes prominent escarpments. Because the early fields were discovered close to the western edge of this escarpment the district was named after it. Now the pools and fields have spread out towards the north and especially towards the north-east into Duvall, Jim Wells, Live, Bee, and Victoria Counties, so that the name is no longer applicable. In this district many sands produce oil or gas or both. Gas is more common in the upper sands and oil in the lower ones. The highest sands occur in the Oakville of Miocene age. The *Frio* clay of Oligocene age contains important sands at *Refugio* and *Saxet*. The *Jackson* of Eocene age is the most productive at the present time. It contains sands in the *Fayette* sandstone (*Cole* and *Driscoll*), the *McElroy* member at *Government Wells* and *Mirando*, and the *Cockfield* member at *Pettus* and *Jacob*. The deepest sands found to date are in the Claiborne. The *Yegua* member produces at *Tuleta* and at *Conroe*. The *Cook Mt.* member seems to be the producing horizon at *Jennings*. Most of the oil from the Laredo part of the district is derived from the *McElroy*, and most of the gas from the *Cole* sand 170 ft. higher in the section.

Salt Dome District. The Salt Dome district takes in all of southern Texas and southern Louisiana as well as a synclinal area in eastern Texas and a similar one between the Sabine and Ouachita Uplifts in Louisiana. Since the Gulf geosyncline deepens towards the south-east, all formations thicken notably in that direction. Furthermore, younger strata crop out towards the south-east, and for that reason the stratigraphy of the 'Interior Domes' resembles that of the Balcones Fault and Sabine Uplift districts, while the southern domes have a section similar to that of the Reynosa district. In the latter the Pleistocene and Pliocene series are very thick, but carry no oil. The *Miocene*, on the other hand, is at present the most important, because it produces about 50% of the oil. Many sands are involved, and these have local names. Because of their lenticular nature they cannot be correlated from one field to another as a rule. Similarly, the *Oligocene* contains many productive horizons, and these account for approximately 40% of the oil from the district. The remainder comes from sands in the Eocene or the cap-rocks of the salt-domes. The only dome which has production from the Eocene at present is the *Clay Creek dome* in Washington County. The only 'Interior Dome' which produces oil is the *Boggy Creek dome* in Cherokee County, and it produces from the basal Cretaceous *Woodbine sand.*

Relation of Oil Accumulation to Structure.

In this province the importance of unconformities stands out prominently. Almost without exception the prolific horizons can be shown to be either above or below marked unconformities in the stratigraphic sequence. In the *Balcones Fault district* the most oil comes from the *Woodbine* which lies unconformably above the Comanchean strata. The second most important horizon is the *Edwards* limestone, which has an unconformity above it. Structural deformation accounts for the unconformities. In this case normal faults raised the strata on the east side, allowing calcareous rocks to acquire porosity and remain in the zone favourable for oil accumulation. In those structures in which porous sands were deposited above the unconformity the oil continued to accumulate and remained trapped in them. Several pools show clearly that some migration has taken place along the fault, because small saturated zones were formed in higher strata carrying oil of the same physical character.

In the Sabine and the Ouachita districts unconformities are well marked. On the high parts of the uplifts the lower formations of the Cretaceous, for instance, are missing, and oil has accumulated in the next overlying basal sands (*Tokio* and *Woodbine*). The unconformity between the Cretaceous and the Tertiary is indicated also by missing formations. In some pools the *Nacatoch* lies at this level and produces the oil. In others the *Annona* chalk appears at the unconformity level. Here also it should be added that deformation has played an important part, for it raised the strata to structurally high elevations above surrounding areas. Small domes and faulted domes are characteristic of the district.

In the *Reynosa district* the controlling feature seems to be porosity in sandstones which are elongated in the direction of the shorelines of the time. Much evidence points to the conclusion that many accumulations have taken place in *barriers* or *off-shore bars* such as characterize the present coastline. A few years ago it was believed that faults bounded the producing areas on the west, but now only one example of that kind is definitely known (Carolina–Texas). A search for such shoreline trends has been rewarded in recent years with the discovery of Conroe and Raccoon Bend besides many pools of smaller magnitude; a number of maps have been published for portions of the Reynosa district, and they usually show the gulfward dipping monocline modified by small noses and ravines. Brace interprets the latter as probably due to irregularities in thickness of the sand rather than due to structure. He states, furthermore, that the gas tends to accumulate in the up-dip areas where the porosity of the sand is reduced.

In the *Salt Dome district* oil occurs in sands flanking the

salt mass, secondly in the porous calcareous cap-rock, and thirdly in sands arched above the salt mass. In each case the porous horizons were elevated by the repeated upthrusts of the growing salt mass, causing them to lie at a structurally high position. Simultaneously, oil-producing material was incorporated within their pore spaces, where it was trapped by impervious clays later.

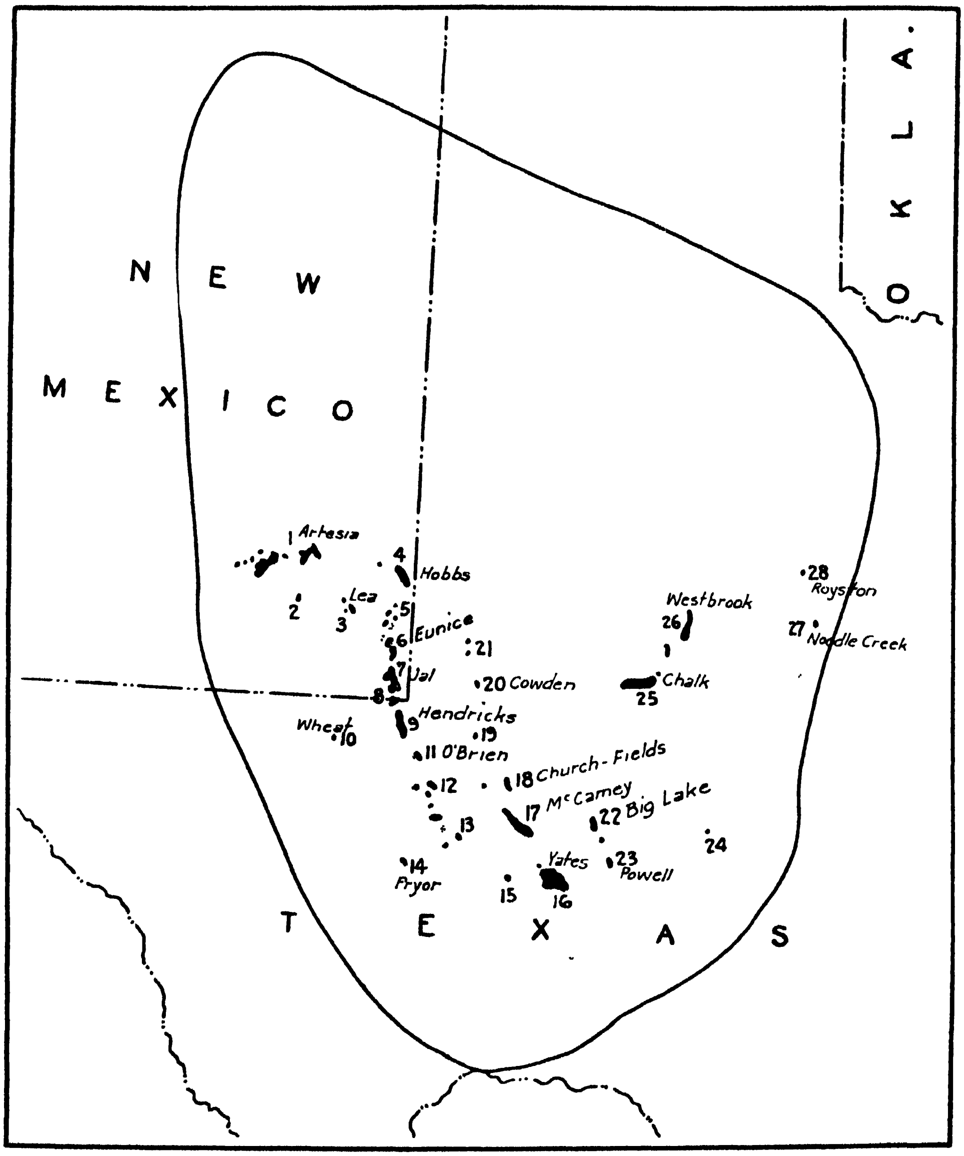

FIG. 9. West Texas Basin.

Future Reserves.

The Gulf Embayment province probably contains the largest reserve supply of oil in the United States. It has already produced practically 3 billion barrels. Of this total the Balcones Fault district has contributed 416 million, the Sabine–Ouachita Uplifts district 1,600 million, the Reynosa or South Texas district 104 million, and the Salt Dome district 1,060 million barrels. The first-named district is fairly close to exhaustion and can hardly be expected to furnish more than 120 million barrels in the future. The Sabine–Ouachita district is about 50% exhausted and will supply close to 1,500 million barrels. The South Texas district is just beginning to show its possibilities and can confidently be counted on for at least 650 million barrels. While the Salt Dome district is closer to exhaustion, the author believes that future discoveries will provide at least 500 million, and reserves in sight another 750 million. A rather moderate estimate for the whole province, therefore, shows future reserves of nearly 3½ billion barrels.

Some bonanzas are the Powell pool (122 million), Mexia pool (93 million), East Texas (800 million), Caddo (138 million), Spindletop (120 million), Humble (117 million), West Columbia (77 million), Sour Lake (76 million), Goose Creek (73 million), Haynesville (63 million), and Homer (61 million). These figures indicate only production up to date. On a per acre basis these amounts reveal a number of fields with over 100,000 barrels per acre.

X. The West Texas Basin Province

When oil was discovered in Mitchell County of western Texas in 1921 no excitement was aroused among oil men. Two years later the now famous Big Lake pool in Reagan County was discovered. It also failed to create interest

because it was generally believed that Permian rocks known to be thick there could not contain large accumulations of oil. Wild-catting continued, however, and in 1925 a large pool was found in south-western Upton County, the McCamey pool. Meanwhile, in 1924 the Artesia pool in New Mexico had also come into production. The most remarkable pool in the province was discovered in 1926 on the Yates ranch in Pecos County.

Tectonic Setting.

These pools are located in a broad, shallow basin which lies west of the Bend Arch described in § VIII. On the south it is bordered by the older Palaeozoic rocks which crop out in the Marathon region. The western rim is marked by prominent mountain ranges in which the producing horizon of the basin makes elongated limestone ridges. Within the deep portion of the basin there is a 'central platform' having its apex under the Yates pool and trending north-west from there. The oil-pools located along the line between Upton and Crane County and thence north-westward lie along the eastern side of this platform. The other prominent line of pools through Ward and Winkler Counties towards the Hobbs pool in New Mexico lie along the western side of the platform.

Stratigraphy and Producing Horizons—West Texas Province

	Ellenburger	..	'Deep Pay' at Big Lake

This important buried 'high' is characterized by steep dips to the north-east and the south-west (at least in the southern part). Stratigraphic evidence indicates that it was formed during Permian time by strong upthrust movements. A fault has been found in the pre-Triassic rocks along the south-east side of the Yates pool with a downward displacement to the east. In the Big Lake pool, which lies on a parallel fault block to the east of the central platform, there is a similar pre-Triassic fault. The pronounced thinning of Late Permian evaporite materials across the structures also indicates Early Permian deformation. At Hobbs it has been estimated that one-third of the total amount of deformation shown in the beds is due to this early diastrophism.

Stratigraphy.

The table above shows the sequence of rocks which is customarily penetrated in the deep wells on structure. The thicknesses shown are averages for the abbreviated section found in the oilfields. Much greater thicknesses have been found in the basins away from the structures. The Comanchean rocks form an unconformable blanket over the older rocks, while the Triassic rocks form a wedge thickening towards the west. A broad regional unconformity separates them from the Permian strata. The latter consist essentially of two units, an upper *evaporite series* and a lower *dolomite series*. The upper series is composed of several oscillatory sequences of the materials usually formed in desiccating seas. Red shales, anhydrites, and salt alternate in such a way that three well-marked zones of salt may be distinguished. In one of these cycles polyhalite was precipitated. Strange as it may seem, oil and gas in commercial quantities are found within this series. At Yates, for instance, the *Yates sand* appears 500 ft. above the base. In the Hobbs pool there are three producing horizons in the evaporite series. The highest is called the *Brown lime*. It carries gas and appears 1,200 ft. above the base. A few hundred feet lower the *Bowers sand* contains showings of oil and gas, and 500 ft. still lower lies the '*Big Gas Pay*'. The potentialities of these horizons are not known because drilling is carried on to the Big Lime.

The *Big Lime series* varies from 1,800 to 2,200 ft. where it has been penetrated by the drill. It consists essentially of dolomite, but contains sandy streaks and bentonitic material. The top portion is usually separated from the rest as the 'Brown Lime' on account of its colour. Very often this upper zone is characterized by the presence of numerous sand grains. In the *Yates pool* the brown sandy lime is 130 ft. thick and in the *Hendricks pool* from 180 to 350 ft. thick. It may contain oil as at Yates or considerable gas as at Hendricks. However, much larger quantities of both are found below it.

The discovery of detrital material near the base of the 'Brown Lime' in the Hobbs pool shows that an unconformity separates it from the 'White Lime' below. Usually the top of the latter is dense and hard and thus forms a caprock for the porous and cavernous rock below. At Hobbs there are two porous zones, one of which is 80 ft. thick and the other (the 'Capps' zone) somewhat thinner. At Yates there appear to be five zones within a vertical distance of 125 ft. (the total porous zone including 100 ft. of 'Brown Lime' being 225 ft.). At Big Lake the porous zone lies 40 ft. below the top of the 'White Lime' and is about 30 ft. thick. Much evidence is now at hand which shows that the porosity of this dolomite is due to solution.

Lower zones in the 'Big Lime' have not been explored on the central plateau because of the large amount of oil at the top. However, in the north-eastern part of the basin at *Westbrook* in Mitchell County several porous zones have been found at 900 ft. and 1,500 ft. below the top. Still lower 'pays' have been discovered at *Big Lake*. A *crinoidal limestone* which appears to be a basal Pennsylvanian formation lying upon the angular unconformity which separates it from the Ordovician has produced some oil. The Ordovician rocks dip away steeply from under the unconformity so that a thickness of several hundred feet is truncated. Some geologists believe that the *Hunton* limestone of Siluro-

Devonian age appears in the older sequence. Below it lie the *Sylvan, Viola, Simpson*, and *Ellenburger* formations in the same order and with similar lithologic characteristics as in the producing area of Oklahoma. The Ellenburger dolomite seems to carry the oil which is found in the deep wells (8,250 ft.).

Cause of Oil Accumulation.

Although a number of the producing horizons described above are capable of furnishing much oil and a great deal of gas, the outstanding one is the porous zone in the '*Big Lime*'. It has supplied not only some of the largest wells in the world (up to 205,000 bbl. per day), but also shows potentialities of very large per acre production. The 16,000 acres in the *Yates pool* have produced 224 million barrels (end of 1936), which means nearly 14,000 barrels an acre. It is reasonable to assume that this figure will be more than doubled, judging by the performance of the wells. The *Big Lake pool* shows nearly 25,000 barrels per acre for the 'Big Lime' pay and 33,000 barrels per acre for both pays.

As pointed out above, the 'Big Lime' is related to a prominent unconformity which indicates uplift and erosion before the evaporite series was deposited to make an effective cap-rock. This also explains the great porosity in the dolomite, because it was doubtless subject to the solution effects of circulating ground water. The relative elevation of the central plateau and its string of 'highs' provided the necessary structural relief.

Production Data.

A total of 750 million barrels of oil has been recovered from the various pools in the West Texas Basin. Over 90% of this amount has come from the pools in the State of Texas where the Yates pool alone has accounted for nearly 224 million and the Hendricks pool about 180 million. Another 100 million were derived from the pools in Crane and Upton Counties (Church, Fields, McElroy, McCamey, Taylor). The other bonanza pools are the Big Lake with 80 million and the Chalk pool with 60 million barrels yield to the end of 1935. In New Mexico the bulk of the oil has come from the Hobbs pool, which is now producing 12 million barrels annually and has a total of nearly 65 million to its credit.

A large reserve is still available from the proven pools, and 500 million barrels seems a reasonable estimate. Allowing for the probability that the province is less than 50% explored, one must assume that somewhere between one-half and one billion barrels of oil lie concealed in undiscovered structures.

XI. The Rocky Mountain Geosyncline Province

The Rocky Mountain geosyncline was best developed in Mesozoic time. It occupied all or large portions of Montana, Wyoming, Utah, Colorado, Arizona, and New Mexico. The bounding land area on the west had its axis along the 115° parallel of longitude, but varied somewhat in size and height from time to time. For instance, during Triassic time practically all of Montana was part of the land area and subject to erosion. The significance of this will be apparent when the oilfields of the Sweetgrass arch are discussed. Subsidence of the geosyncline was very rapid and great along the eastern border of the land area throughout the Mesozoic, but reached a climax in Cretaceous time. The thickness of Cretaceous sediments is measured in thousands of feet and exceptionally, as in western Wyoming, as much as 14,000 ft. is recorded. (Fig. 10.)

Tectonic History.

At the close of Cretaceous time and during the early portion of Tertiary time these sediments were greatly deformed by orogenic disturbances. Vertical displacements involving 28,000 ft. are characteristic results of this deformation. As the older rocks came up on the borders of huge fault blocks they were stripped of their overburden and the detritus gathered in the large basins between them as Tertiary sediments. Such basins are particularly well developed in Wyoming and western Colorado. They are named after the principal river which flows through the basin. In north-eastern Wyoming lies the *Powder River Basin*, in north-western Wyoming the *Bighorn Basin*, and in south-western Wyoming the *Green River Basin*. In north-western Colorado lies the *Uinta Basin* and in north-western New Mexico the *San Juan Basin*.

Structures.

Each of these basins has a zone of folded rocks around the periphery in which the strata are arranged in short *en échelon* anticlines with steep dips. The Bighorn Basin illustrates this arrangement most perfectly, while the other basins depart from the ideal grouping more or less. For instance, in the Powder River Basin and the Julesburg Basin the high anticlines are found only on the west side. In other words, the anticlinal zones are complementary effects associated with the mountainous tracts on their borders and are better understood when examined in that light. (Parallel *en échelon* fault blocks.)

The important structures in Montana are not so simply classified. In the centre of the State there is a prominent plateau-like structural feature called the *Big Snowy anticlinorium*. It is bounded on the north as well as the south by very asymmetrical anticlines. Some of these have been found to carry oil and gas. Another large structural feature lies in the northern part of the State somewhat west of the centre. It has been named the *Sweetgrass Arch* and harbours the most productive fields of the State. In the extreme eastern part of the State lies the *Cedar Creek anticline* (sometimes called *Baker-Glendive*) on which only gas has been found up to date.

Distribution of Oil-pools.

The productive oil- and gas-pools extend from the Canadian border through Montana, Wyoming, and Colorado into north-eastern Utah and north-western New Mexico. On account of the steep dips of the anticlines most of the pools (now numbering over 100) are separate and distinct. The largest number of pools and the most prolific ones are located in Wyoming within the confines of five basins. The Colorado pools are located in the Uinta, Green River, and Julesburg basins. Practically all the pools in the Uinta Basin are gas-pools, but those of the Julesburg Basin are primarily oil-pools. The San Juan Basin in New Mexico contains three oil- and two gas-pools at the present time.

Stratigraphy.

Because of the uniform geological history of this province the stratigraphy is similar in the various districts. The table below summarizes the important formation names and also shows the producing horizons. In

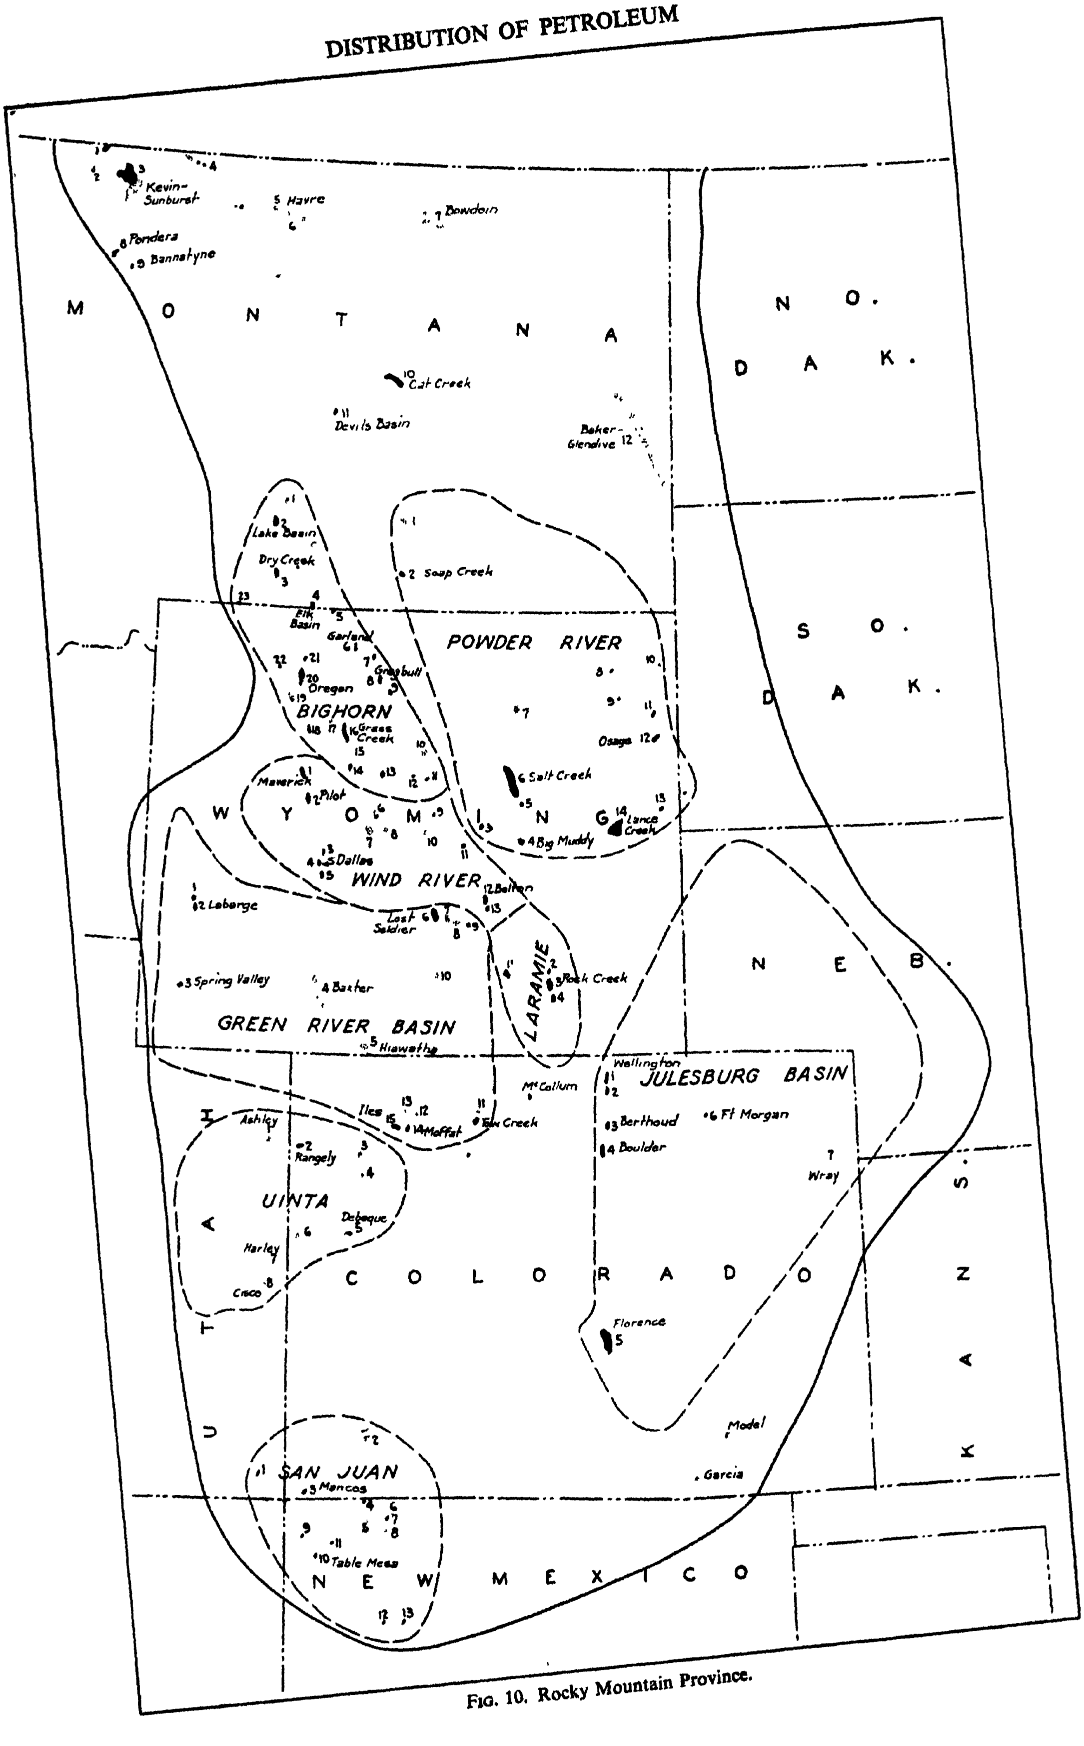

Fig. 10. Rocky Mountain Province.

each of the districts there is a great thickness of Tertiary sediments in which no commercial quantities of petroleum occur. The Cretaceous system is usually divided into the Laramie, Montana, Colorado, and Dakota divisions. The *Montana* consists of shales in which there are occasional sandy zones and lenticular sandstones. One of these, the *Shannon*, produces small quantities of oil or gas in three pools and another, the *Eagle*, gas in four pools.

The Colorado shales also contain sandstones, among which the *Frontier* group is outstanding. Most of the oil produced in Wyoming up to date has come from the *Wall Creek sands* of the Frontier group. In Montana oil has been found in the Frontier at *Elk Basin* which lies in the Bighorn Basin. It has produced gas at *Big Lake* and at *Bowdoin*. In Colorado the Mancos shale yields oil at *Rangely* in the Uinta Basin and at *Tow Creek* in the Green River Basin. Shale oil has also been found in the remarkable *Florence* pool of central Colorado. The production is long lived and comes from the *Pierre* shale.

Next in importance to the Frontier sands are those of the *Dakota* zone. Three well-defined levels of sands occur in this zone. At the base lies the *Lakota* or basal Cloverly which is usually considered to be of Comanchean age. The true *Dakota* lies about 150 ft. higher in the section and marks the base of the Upper Cretaceous. It is succeeded by the *Muddy sand* within the Thermopolis or lower portion of the Colorado shales. In every basin or district of the Rocky Mountain province, with the exception of the Wind River Basin, one of these three sands is outstanding either as a producer of oil or of gas. In fact most of the large gas-pools derive their gas from this zone. In Montana the *Cat Creek sand* in the centre of the State and the *Sunburst* in the north-western part of the State are correlated with the Dakota zone.

In pre-Cretaceous rocks practically every system can boast of one or more producing horizons, but these are limited to very local areas. The *Morrison* produces at *Grass Creek* in the Bighorn Basin and a little oil at other places as, for instance, at *Salt Creek*. Gas was found at this horizon in the *Big Sand Draw* pool near the middle of the Wind River Basin. In the Jurassic there are several sands near the base usually called either *Sundance* or *Nugget*. They produce oil at a number of pools in the *Wind River Basin*, *Lost Soldier* in the Green River Basin, and at *Salt Creek* in the Powder River Basin. In north-western Colorado some production in the *Moffet* and *Iles* pools comes from the Sundance. The *Chugwater* of Triassic age produces oil at *Bolton* in the Wind River Basin.

Oil is obtained from the *Embar* limestone of the Permian, the *Tensleep* sandstone of the Pennsylvanian, and the *Madison* limestone of the Mississippian. The principal production from the Embar is found in the pools along the western side of the Wind River Basin, but a few pools in the Bighorn Basin also derive oil from this horizon. The *Tensleep* produces over a much greater area. Two pools in the Bighorn, one in the Wind River, two in the Green River, and three in the Powder River Basin of Wyoming as well as the Rangely pool in north-western Colorado derive some oil from this thick-bedded, even-grained sandstone. Deeper drilling in other parts of the province will undoubtedly uncover more production in it. The *Van Duzen* sand of the *Devils Basin* and the *Soap Creek* pools of southern Montana lies in the *Quadrant* formation of Pennsylvanian age.

Stratigraphy and Producing Horizons in Rocky Mountain Province

Mississippian	Madison	600	Frannie	700	Campbell, &c	..	.	..	..

The *Madison* limestone is the outstanding petroliferous unit in the Sweetgrass Arch district of north central Montana. There it is often referred to as the *Campbell pay* in the *Kevin-Sunburst* field where it was first found. The upper 10 to 20 ft. of the limestone were rendered porous by solution during the long interval of time between the end of the Mississippian and the later Jurassic when the *Ellis* formation was laid down. In these cavities the oil has been trapped. Elsewhere the results of drilling to the Madison have been disappointing. At *Garland* and *Frannie* in the Bighorn Basin some oil occurs throughout a thickness of 800 ft. of the limestone.

Relation between Structure and Production.

In the typical pools of this province (and this includes 90% of present pools) oil and gas occur only on the high portions of anticlines or domes. Here the anticlinal theory of oil accumulation finds its most convincing illustrations. Gravitational separation of oil, gas, and water is almost perfect. In some pools oil and gas extend down to the lowest closing contour, but in most pools they occupy only a portion of the closed structure. In many structures, unfortunately, oil or gas are entirely wanting, as the wildcatter has found out. In a general way only gas occurs in the higher sands, both oil and gas in the sands of the Lower Cretaceous, and oil only in the lower horizons.

The importance of unconformities in the sequence is not known at present. Since drilling is rarely carried on away

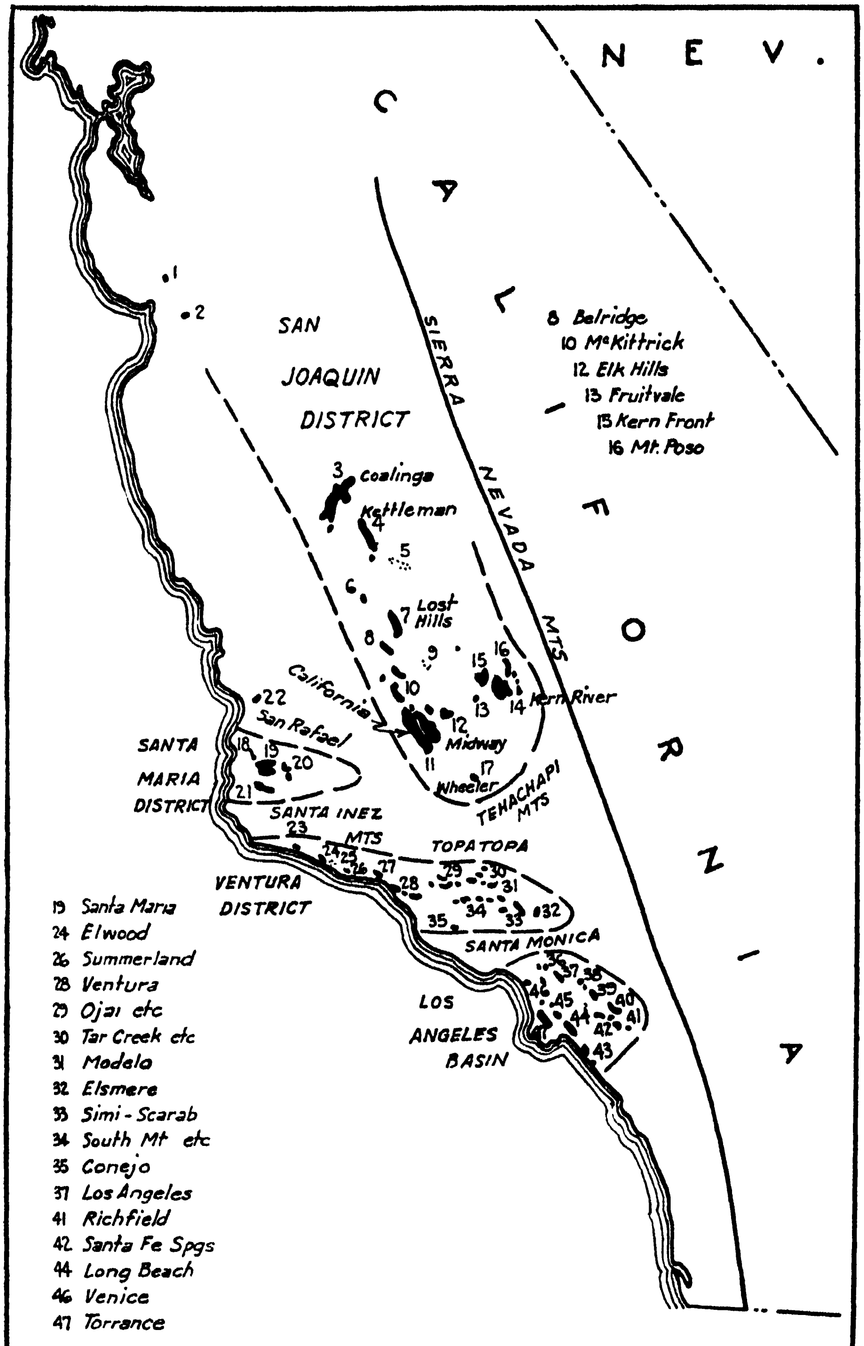

FIG. 11. Oilfields of California.

The trend of the large wells is nearly rectilinear or gently sinuous, thus reflecting the trend of the underground caverns. The behaviour of certain wells indicates intercommunication for considerable distances. Dobbin and Erdman [5, 1934, p. 708] describe several wells which directly influenced the flow and the production of other wells located as far as 2 miles away.

Exceptional Structural Control. In the pools that lie along the north and east fringes of the province the influence of anticlinal structure is subdued or wanting. In the Sweetgrass arch, for instance, the *Bannatyne* and *Pondera* fields lie well down on the northward plunging slope of the structure. Still farther north lies the *Kevin-Sunburst* group of fields. Here, however, a subordinate dome may have had some influence on accumulation. More probably the relief of the dome facilitated the work of ground waters and favoured the formation of solution channels. On the east side of the Powder River Basin a few oil- and gas-pools have been found. In one of these, the *Osage* pool, the oil has been trapped on two terraces separated by a zone of steeper dips. These pools are located on the west side of the Black Hills, an isolated mountain uplift which differs greatly from the type found farther west. The *Florence* pool in central Colorado is located in a syncline. Oil is produced from crevices in the Pierre shale throughout a considerable vertical range.

Production Statistics.

Up to the end of 1935 this province has accounted for a total of slightly less than 500 million barrels of oil. More than three-fifths of this total should be credited to five pools in Wyoming. They are the *Salt Creek* pool in the Powder River Basin, the *Grass Creek* pool in the Bighorn Basin, the *Big Muddy* in the Powder River Basin, the *Lost Soldier* in the Green River Basin, and the *Rock Creek* pool in the Laramie Basin. These five are not equal in rank because Salt Creek produced 10 times as much as the second or a total of 261 million barrels. By projecting the present production curves it will be seen that hardly more than 200 million barrels are now in reserve. Only a few new pools can be expected in the future, because all prominent known structures have been tested. Some slight additional reserves will be secured by deeper drilling. The most likely spot for a large pool is in the Julesburg Basin of eastern Colorado.

from the steeply dipping structures, evidence of thinning of formations cannot be established. A few cases are on record where the subsurface structure is steeper than the structure at the surface (Davies [5, 1934, p. 690]). In the lower strata evidence of unconformities is more apparent. For instance, in the Embar formation the main pay is found from 25 to 125 ft. below the top of the limestone at a level characterized by chert residues and phosphate. These features imply unconformable relations. In the Madison limestone the evidence is complete. For not only is there a large gap in the record, but the action of the wells implies solution channels connected with an unconformity.

XII. The Pacific Geosyncline Province

The Pacific Geosyncline Province lies west of the Sierra Nevada Mountains and their northern continuations through Oregon and Washington. Oil and gas have been discovered in two of the States involved, California and Washington, but the important fields are limited to the former. In fact, only the southern part of California merits consideration at the present time from the standpoint of commercial production. (Fig. 11.)

Tectonics.

Southern California is broken up by fault block mountains which trend in two directions. The main trend is from north-west to south-east as illustrated by the Coast Ranges southward from San Francisco. They form the western limits of the San Joaquin Valley, the most prominent structural depression in the State. It is closed at the southern end by the northernmost of a series of short disconnected ranges which trend predominantly from east to west. These ranges diverge somewhat towards the Pacific Ocean producing two small wedge-shaped valleys, the Santa Maria valley of Santa Barbara County and the valley occupied by the Santa Clara and Simi Rivers in southern Ventura County. The Santa Inez Mountains, which produce the unusual deflexion in the California coastline north-west of Los Angeles, also form the boundary between the two valleys described. The Santa Monica Mountains similarly divide the Ventura Valley from the Los Angeles Basin in which the influence of the north-west trend is again manifest.

San Joaquin District. The oilfields of California, therefore, fall naturally into four districts, named after the valleys with which they are associated. In the northern or *San Joaquin Valley district* the oil-pools are located on subsidiary structures which closely parallel the outer rim of the valley. Beginning with the *Coalinga* pool at the north-west one zone of structures includes the famous *Kettleman Hills* and *Lost Hills* pools. Offsetting this zone in an *en échelon* fashion towards the south-west are the *North Belridge, Belridge, McKittrick, and Elk Hills* pools. West of the latter lies the remarkably productive area known as the *Midway-Sunset field,* which has a homoclinal structure like the Coalinga field. In contrast to these the others mentioned are all located on anticlines. At the southern end of the valley lies the *Wheeler Ridge* anticline. East of the Elk Hills pool and on the opposite side of the San Joaquin Valley lie five pools which are homoclinal in structure. They are the *Fruitvale, Kern River, Kern Front, Round Mountain,* and *Mt. Poso* pools. The last three are known to be faulted and the first two are suspected of being faulted homoclines.

Producing Horizons.

As the table below shows, the important producing horizons in this district lie in the *Pliocene* and *Miocene* series. The outstanding pools associated with each series or formation are listed in the table. Up to date the sands in the lower part of the Pliocene have accounted for the larger half of the production, one pool alone (Midway-Sunset) having yielded nearly 800 million barrels of oil. This has been taken from three zones distributed throughout 1,000 ft. of strata. Deeper drilling in recent years has uncovered vast treasures in the Miocene sands. The middle portion of the Miocene, usually referred to as the *Temblor,* furnishes oil from four zones in the *Coalinga* pool. This formation is productive throughout 1,450 ft. in the North Dome of the *Kettleman Hills,* which suggests that the total ultimate production will be very great. The Temblor formation is made up of alternating layers of silty sands, shales, and coarse sands. Several zones of shaly layers divide the formation up into *three producing sections* in which every layer of sufficient porosity contains oil. Such thick producing horizons account for the unusually high per acre production that characterizes the California fields. No production has been found in Oligocene strata, but one pool has production in *Eocene sands.* A little oil has also been found in the still lower *Cretaceous sands* in the *Coalinga* field.

Santa Maria District. The Santa Maria district consists of three river valleys separated by two anticlinal dividing areas. On the northern anticlinal trend are located the *Casmalia, Santa Maria,* and *Cat Canyon* pools. Production comes mostly from sands in the *Monterey* formation, but in the *Santa Maria* pool some production also comes from the *Vaqueros* at the base of the Miocene. On the southern divide lies the *Lompoc* pool in which the *Monterey* is also the producing horizon. The pools in this district are old ones and were located by means of extensive asphalt seepages.

Stratigraphy and Producing Zones—Pacific Geosyncline Province

	San Joaquin District		*Santa Maria District*		*Ventura District*		*Los Angeles District*

						Scarab	..	..
Eocene	Kreyenhagen	N. Belridge	..	..	Eocene	Simi	Tejon	..
	Avenal	..	..	..	..	..	..	..

Ventura District. The pools of the Ventura district may be grouped into four trends. The most prominent one of these extends along the ocean shore of southern Santa Barbara County and includes the *Capitan*, *Elwood*, *Santa Barbara*, *Summerland*, *Rincon*, and *Ventura Avenue* pools, the last being by far the most remarkable pool in the whole district. On the north side of the Santa Clara River there are 11 pools, all small and most of them rather old. The best known among them are the *Sulphur Mt.*, *Ojai*, and *Sespe* pools. The structure is not well understood, but the rather intimate relation to the San Cayetano thrust fault and branch faults indicates that fault traps are present. Production comes mainly from Lower *Miocene* and from *Oligocene* sands.

On a trend which seems to be the *eastward continuation* of the *Ventura Avenue trend* lie the *South Mt.*, *Bardsdale*, *Shiels Canyon*, *Torrey Canyon*, *Tapo Canyon*, *Pico Canyon*, *Wiley Canyon*, and *Elsmere* pools. These, like the pools in the Capitan to Ventura trend, are located on anticlines. The *producing horizons* vary greatly, as indicated in the preceding table. *Pliocene* production is most important from the standpoint of total amount, for Ventura Avenue pool alone (in which production comes from 12 zones throughout 8,000 ft. of Lower Pliocene) has accounted for more than half the production from the district. *Upper Miocene* and also *Lower Miocene* sands are quite prolific in certain pools. The most widespread producing horizons occur in the *Sespe* formation of Oligocene age. In one pool (Simi) oil has been found in *Eocene* sands.

The Los Angeles District. The Los Angeles district is bounded on the north by the Santa Monica Mountains, on the east by the Repetto Hills and the Puente Hills, on the south by the Santa Ana Mountains and the San Joaquin Hills. The last four appear on the north-west trend mentioned previously and delimit a more or less quadrilateral area known as the Los Angeles Basin. Paralleling the tectonic trend there are *four lines* or *zones* of *pools*. The easternmost zone includes the *Salt Lake*, *Los Angeles*, *Montebello*, *Whittier*, *Puente*, and *Brea-Olinda* pools. In these the influence of the *Whittier fault* bounding the eastern mountain uplifts is clearly discernible. They involve oil accumulations on the downthrown side of single or multiple faults and usually show a *homoclinal* dip into the basin. The Middle Miocene *Puente* formation is the important producing horizon in this belt of pools, but the Middle and Lower *Pliocene* sands also produce considerable oil.

The *second line* of pools lies a short distance west of the former and includes the *Santa Fé*, *West Coyote*, *East Coyote*, and *Richfield* pools. In all these the structural control of oil accumulation is the *anticlinal* arrangement of the strata. The axes of the Santa Fé pool are so nearly equal that it should be called a dome. This is one of the most interesting pools in California. It covers roundly 1,500 acres and has scored the amazing per acre production of over 220,000 barrels. The oil-producing zones are distributed through a vertical range of 4,600 ft. and are arbitrarily divided into *six Pliocene zones* and *one Miocene zone*. Sandy shales separate the petroliferous zones from each other, and as a rule brackish water occurs in them. The thickest oil zone is the seventh or *Clark zone* divided by geologists into *three members* aggregating 800 ft. in thickness. The other zones vary from 135 to 670 ft. in thickness. The two shallow zones produce oil of 28° and 32° gravity, while the lower ones all carry oil of approximately 34° gravity.

Farther east lies the *Inglewood fault line zone* of pools. It includes the *Beverly Hills*, *Inglewood*, *Potrero*, *Athens-Rosecrans*, *Dominguez*, *Long Beach*, *Seal Beach*, *Huntington Beach*, and *Newport* pools. In these the anticlinal structure stands out prominently, but is modified occasionally by subsidiary faults. It is believed that the faults have not had a controlling influence on accumulation. The oil comes from the *Pliocene sands* for the most part, and in some pools these sands occupy a great vertical range (Long Beach 3,000 ft.). Recent deeper drilling has uncovered *three zones* of oil-bearing strata in the *Miocene* at *Long Beach* and one zone at *Seal Beach*. The westernmost belt of pools includes the *Venice* (Playa del Rey), *Lawndale*, and *Torrance* pools. These differ markedly from the others because of structural peculiarities. At Torrance, for instance, the anticlinal structure is unusually gentle for California, and at Lawndale no structural trap is apparent. Interesting also is the discovery of old (pre-Cambrian ?) schists at a comparatively shallow depth at Venice and at Torrance below the Miocene.

Production Data.

The total amount of oil produced by the California fields up to the end of 1935 approximates 4,460 million barrels. The San Joaquin and the Los Angeles districts share almost equally in this stupendous total, the former accounting for slightly less than 2,000 million and the latter for slightly more than 2,000 million barrels. The Santa Maria district should be credited with 133 million and the Ventura district with twice that amount. In the San Joaquin district the banner field is the *Midway-Sunset* field with nearly 785 million barrels to its credit. It will ultimately produce nearly 1 billion barrels. Its rival will be the Kettleman Hills pool, which has produced slightly over 100 million barrels, but whose ultimate production is now estimated to be 1 billion barrels. A reasonable estimate of future production from all pools in this district other than Kettleman Hills is 1 billion barrels, thus making a total available of about 2 billion barrels.

The *Santa Maria district* is nearly exhausted and can hardly be counted on for more than 50 million barrels. In the *Ventura district* the banner pool is the Ventura Avenue pool. It has produced 75 million of the 280 million total for the district, and may be expected to produce an additional 150 million. Allowing 100 million future reserves for the remainder of the district makes a total of about 250 million. The Los Angeles district has two outstanding pools in Long Beach with nearly 550 million to date, and the Santa Fé pool with 400 million. These two have thus accounted for nearly half of the total production from the district. The future reserves from these two may be estimated at 200 million, and from the remainder of the district about twice that amount. Summing up the future production from all districts we arrive at a probable total of 3 billion barrels. This estimate makes no allowance for new discoveries either of additional pools or of deeper producing zones. The San Joaquin district offers the most promising territory for new pools, and these are likely to be uncovered by geophysical explorations now under way. Such new pools may double the estimates of future reserves as stated above.

CANADA

By G. S. HUME, B.A., Ph.D.
Geological Survey of Canada[1]

PETROLEUM is produced in Canada from such widely separated parts as New Brunswick, Ontario, Alberta, and the North-West Territories. With the exception of a relatively small production of crude oil from Mesozoic rocks in Alberta, all production comes from strata of Palaeozoic age. In New Brunswick the age of the oil-producing horizons is Mississippian. The Devonian has provided most of the fields and the greatest yields in Ontario, but oil has been produced also from Silurian and Ordovician beds. In Alberta sustained production from Palaeozoic rocks has been obtained only in the Turner Valley field from strata presumably of Late Mississippian age. Shows of oil have been found in Devonian strata in the foothills and in Mississippian beds in southern Alberta, and in the foothills in Turner Valley petroleum also occurs in one Jurassic and three Lower Cretaceous horizons. On the plains, with the exception of the Skiff field, where petroleum is found in marine Jurassic beds, all the production comes from Lower Cretaceous strata. In the Mackenzie River area, 50 miles north of Fort Norman, the producing horizon is Upper Devonian shales.

The petroleum produced in New Brunswick comes from the Stony Creek field near Moncton. The producing horizons are in the Albert formation of Mississippian age. The petroleum presumably originated in shales in the Albert formation, which in part is highly bituminous and shows deposition under relatively quiet conditions in a lake-like expanse of fresh water without any evidence of torrential stream action. The main features of the oil-producing area are: the fresh-water origin and predominantly fine-grained nature of the sediments, their great thickness, considered to be more than 5,000 ft., the absence of conglomerates except at the base of the formation, and the remarkably complicated geological history of this region during the Carboniferous period. It is thought (Bell [1, 1922]) that 'Carboniferous sedimentation was controlled by a definite tectonic system ... of the nature of intermittent but long-continued warpings' and 'proceeded in progressively sinking, structural river valleys separated by progressively rising watersheds'. Subsequent to deposition the Albert formation was folded and subjected to erosion. Younger non-marine sediments were deposited over the bevelled edges so that in many areas, including part of the Stony Creek field, the structure of the Albert formation is concealed. The petroleum occurs on the south flank of what formerly may have been an anticline but which is now truncated northward. The producing horizons are groups of sandstones that seem to hold their relative positions very consistently, but the individual sandstone members may be lenticular and discontinuous.

All the petroleum fields of Ontario (Fig. 1) are in the peninsula bounded by Lakes Huron, Erie, and Ontario. This area is underlain by gently dipping strata ranging in age from Late Devonian to Early Ordovician. Some of the first discovered fields are still the main producers after continuous operations extending over 70 years. The productive strata of these early discovered fields are Devonian rocks, but petroleum also has been produced from both Silurian and Ordovician beds. In this part of Ontario a basal Ordovician arkose lies directly on a surface of Pre-Cambrian rocks at a depth of 3,000 to 4,000 ft. In Romney township, Kent county, some petroleum was produced from this basal arkose, but presumably the rock was merely a reservoir for oil that originated elsewhere. Above the arkose there are Black River and Trenton limestones. The Trenton has not been a prolific source of oil in Ontario as is the case in Ohio and Indiana to the south of Lake Erie, but in the Dover West field, east of Lake St. Clair, petroleum is produced from the upper 300 to 400 ft. of this formation in a narrow eastward trending area that either represents a fracture zone or a sharply defined and broken syncline. It is believed that porosity is the controlling feature here, as the Trenton is generally barren elsewhere where porosity is lacking. The remaining part of the Ordovician above the Trenton has yielded no oil in Canada.

In the Niagara Peninsula the Whirlpool sandstone, 5 to 20 ft. thick, forms the base of the Silurian. This sandstone yielded oil in the Onondaga field of Brant county, but the production was very small. The Whirlpool sandstone is considered to be an aeolian deposit [1, 1922] and, like the basal arkose of the Ordovician, is a reservoir for oil that is not indigenous to this horizon. The Silurian strata immediately above the Whirlpool sandstone, or its correlatives in the north and west, are very variable in character and with a thickness not exceeding 200 ft. They are overlain by limestones and dolomites, the upper member of which is the Guelph dolomite. The top of the Guelph is an erosion surface and on it rests a variable succession of beds belonging to the Cayugan group, the lowest member of which is the Salina formation. The Salina locally contains salt and gypsum but as a whole consists of interbedded dolomites and shales, the dolomites of which are indistinguishable in well samples from those of the Guelph, which are thought to have been deposited in a partly enclosed sea under conditions of excess salinity. Petroleum occurs in these dolomite beds at the base of the Salina or the top of the Guelph, particularly in the now exhausted Leamington field, Essex county, and in the still active Tilbury and recently discovered Dawn fields, Kent county. All fields are anticlines, and both gas and oil occur in the Tilbury field.

The Cayugan strata in the Niagara Peninsula and to the north dip westerly beneath Middle Devonian strata which farther west are succeeded by Upper Devonian beds. The main producing oil horizons of Ontario occur in the Middle Devonian Onondaga and Delaware limestones, and in most fields the production has come from depths of 300 to 500 ft. In every field the oil accumulation is directly related to a dome or a simple type of anticline. These minor features are superimposed on a broad, shallow, basin-like structure.

The Turner Valley field (Fig. 2) in the foothills of Alberta is at present the largest producing field in Canada. The major part of its production is high-grade naphtha occurring with large volumes of gas in the upper 300 ft. of a group of Palaeozoic limestones. Marine Jurassic sediments rest on the eroded surface of the Palaeozoic beds. There are no Triassic, Permian, or late Pennsylvanian beds.

One producing horizon occurs in the Jurassic strata and three in the overlying non-marine Lower Cretaceous beds, but none of these horizons has afforded a persistent or uniform production. It is generally admitted that the Jurassic marine beds may be a source of oil and that little, if any, oil originated in the Lower Cretaceous strata of this area. The lowest producing horizon in the Lower Cretaceous is the Dalhousie sand at the base of the Blairmore formation which in most places in Turner Valley rests directly on Jurassic beds, although in a few places 100 ft. or less of Kootenay coal-bearing strata intervene. It is believed, therefore, that the oil found in the Dalhousie sand was derived from a Jurassic source and migrated upwards. The Home sand also in the Blairmore formation, 250 ft. above the base, is productive in certain areas of Turner Valley. The source of this oil is problematical, but owing to the great amount of faulting and fracturing of the rocks migration presumably could have taken place from lower horizons. The uppermost productive horizon, the McDougall-Segur sand, yields oil only in an area where faulting is known. Since this sand is free of water and is connected by fractures to a known source in overlying marine shales of Colorado age, it is believed that in this case the oil migration has been downwards.

In the Turner Valley field the harder, more competent rocks such as the Palaeozoic limestones and to a less extent the Blairmore strata are apparently much more shattered than the overlying shales which yielded by folding and crumpling. The forces of deformation within the foothills were very intense and not only folded the strata but caused great low-angle overthrust faults, one of which underlies Turner Valley and has a displacement measured in thousands of feet. Subsidiary faults to this low-angle overthrust also cut the strata and cause large repetitions in drilling. On the surface Turner Valley appears to be nothing more than a faulted anticlinal structure, but at depth it is apparent from drilling that westerly dips predominate and particularly on the east flank overturned beds occur. This is due to the fact that the east side is cut off by the major low-angle overthrust underlying the whole structure.

On the plains the Skiff field alone has yielded oil from marine Jurassic beds that underlie southern Alberta and Saskatchewan. The origin of the oil found in this and all other fields in southern Alberta is most easily explained if it be granted that the oil originated in the Jurassic sediments and now occurs either in these beds or in strata contiguous to them. The producing horizon in the Red Coulee field, for example, is near the base of the non-marine, Lower Cretaceous beds in which the oil could hardly have originated. The oil could have migrated, however, from the underlying Jurassic beds. Although no sustained production of oil has been obtained in the Canadian plains from the Palaeozoic limestone underlying the Jurassic, there have been excellent shows in a few wells and production occurs in the Kevin-Sunburst field of Montana. Weathering of the limestone surface in the period following Mississippian and preceding Jurassic time may have produced the porosity necessary for an oil reservoir, and the oil entering this reservoir rock may have had a Jurassic source. If this is so, it follows that the distribution of marine Jurassic beds is the factor controlling the prospective oil territory, and since Jurassic strata possibly do not occur

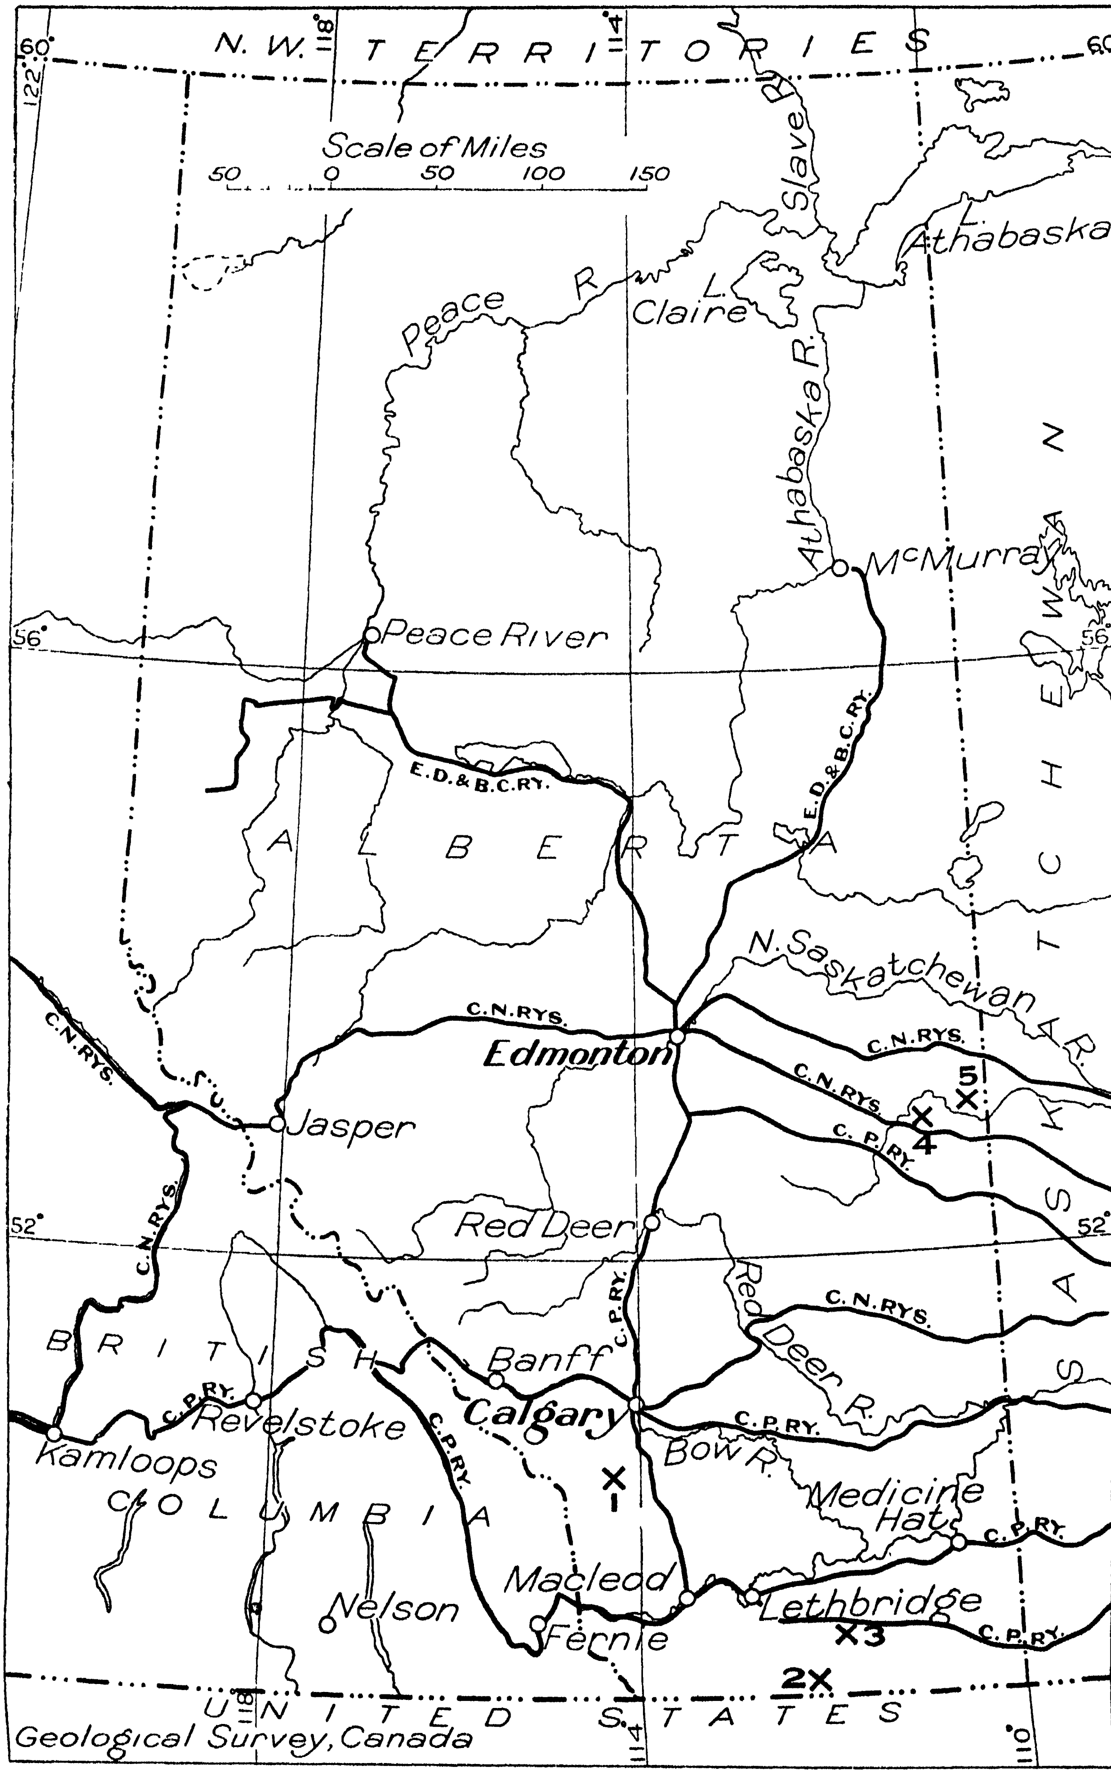

FIG. 2. Index map of Alberta showing position of oilfields. 1, Turner Valley; 2, Red Coulee; 3, Skiff; 4, Wainwright; 5, Ribstone.

more than 150 miles north of the International Boundary in the plains of Alberta and Saskatchewan no oil of Jurassic origin may be expected in the plains north of this limit. Both the Skiff and Red Coulee fields are on anticlinal structures projecting northward from the Sweetgrass arch uplift, the main part of which is in Montana. Gasfields of large capacity also occur on this uplift, and they too are related to local folds.

In the north on Athabaska River, both marine and non-marine Lower Cretaceous strata occur. Southward the marine beds decrease and the non-marine sediments become more and more predominant until in the south-western plains only non-marine beds occur. The edges of the marine formations, representing the shore-lines of former Lower Cretaceous seas, extend south-easterly across north central Alberta to south-western Saskatchewan. These shore-lines with their offshore marine deposits are believed to provide not only good reservoir rocks but abundant source materials for petroleum, and hence it is considered that the oil of the Wainwright field and of the now abandoned Ribstone field and the bitumen in the McMurray ('Tar Sands') formation on Athabaska River had their origin in Lower Cretaceous strata. A number of small folds on a major fold that culminates near the Alberta-Saskatchewan boundary in eastern central Alberta are thought to be directly responsible for the accumulations of oil and gas in this area.

In the Mackenzie River area north of Fort Norman two wells supply oil to mining companies operating on Great Bear Lake. The wells are on the east flank of a basin structure that is bounded by mountains on either side and underlies Mackenzie River valley, here about 20 miles wide. The wells were drilled in westerly dipping beds near an oil seepage and production was secured in Upper Devonian shales. There is no easterly closure, and a short distance east of the wells the truncated edges of the producing beds are exposed. The oil encountered in the wells is probably contained in fracture zones in the shales. Several cross-folds eroded below Upper Devonian beds are known within the basin, and it is probable other less deeply eroded folds exist, although for a number of reasons their location is difficult to determine. The features of this area related to oil prospects are: (1) numerous seepages of oil where the bevelled edges of the Upper Devonian beds are exposed; (2) the presence of Upper Devonian sandstones suited to act as reservoir rocks; (3) the occurrence of marine Cretaceous shale lying on the Devonian beds over most of the basin structure and forming adequate cover to retain the oil; (4) the existence of several cross-folds in the basin structure and the probable occurrence of other less deeply eroded folds. Thus, although the present wells may not yield any large amounts of petroleum, the prospects within the Mackenzie area appear to be excellent on favourably located structures.

GEOLOGY OF THE TÁMPICO-TÚXPAN OILFIELD REGION[1]

By J. M. MUIR
Fort Worth, Texas

THE oilfields of the Tampico Embayment lie from 20 to 70 km. inland from the Gulf of Mexico between north latitudes 20° 30′ and 22° 30′. There are three fields of major importance, namely:

(1) The Northern Fields, including Pánuco, Topila, Ebano, Cacalilao, Corcovado, Chijol, Altamira, and other sectors. This group lies west of Tampico. The productive area is spotted and irregular in outline. Its greatest width from Ebano in the west to Quebracha in the east is about 50 km. Its north–south extension from Altamira (Los Esteros) to Chijoles (Pánuco area) is about 60 km. (see Fig. 1). Profitable production was found at Ebano in 1904 and at Pánuco and Topila in 1910–11.

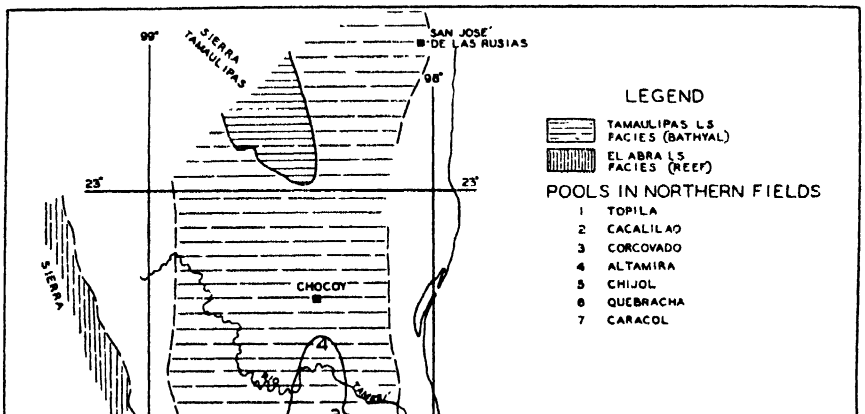

FIG. 1. Map showing location of oilfields and approximate known surface and subsurface distribution of El Abra and Tamaulipas limestone facies.
(*Courtesy of the American Association of Petroleum Geologists.*)

(2) The Southern Fields (Golden Lane) consist of the following divisions from north to south: Dos Bocas, San Gerónimo, Tepetate, Juan Casiano, northern Amatlán (Los Naranjos), southern Amatlán, Zacamixtle, Totcco, Cerro Azul, Potrero del Llano, Cerro Viejo, Tierra Blanca, Chapapote Nuñez, Alamo, Jardín, Paso Real, and San Isidro. The South Fields Ridge forms an arc convex to the west (see Fig. 1). It averages about 1,000 metres in width and has a total length of about 82 km. Excluding the Dos Bocas well [24, 1909] (San Diego No. 3), which was a total loss by fire in July–August 1908, commercial development of the field dates from the latter part of 1910.

(3) The Poza Rica Field is a development of the last few years dating subsequent to the discovery of oil in Mecatepec at the end of 1928. The field lies roughly 50 km. south of Túxpan.

Several small fields of relatively little importance occur such as Furbero, Tierra Amarilla, and Tanhuijo, besides a few other areas where small production has been found.

Stratigraphy

The succession found in wells in the Northern Fields is shown in Table I, and in the Southern Fields in Table II.

Jurassic

Rocks of Kimmeridgian and Portlandian age have been found in wells at Altamira, Chocoy, and Pánuco in the Northern Fields. Several outcrop localities in the Sierra Madre Oriental are referred to by Burckhardt [5, 1930]. He describes the Kimmeridgian and the Lower and Middle Portlandian bituminous shales and the Upper Portlandian limestones, referring to three wells in the Northern Fields. This is also referred to by Baker [2, 1928] and by the writer [15, 1934].

Cretaceous

Lower Cretaceous: Neocomian.

Lower Tamaulipas Limestone. Beds representing the Berriasian, Valanginian, Hauterivian, and Barremian stages are present in the wells that have been drilled to the Jurassic. They are not recorded in outcrop within the limits of the area discussed, except perhaps south-west of Tamazunchale (Fig. 1). As found in wells, rocks of these stages consist of compact grey or white limestones. *Acanthodiscus* aff. *octagonus* Uhlig was identified by Burckhardt from the Berriasian in the Chocoy well.

Beds representing the Aptian are present in wells in the Northern Fields in the form of white limestones, slightly chalky, rarely carrying a little chert.

TABLE I

Succession in Pánuco District

(Range of oil production is shown by heavy vertical line.)

		(*Note*: Eocene and Oligocene beds are present in Topila and Quebracha)
	Palaeocene? or Danian?	*Tamesi* shales 900 ft.+
		unconformity
UPPER CRETACEOUS	Maestrichtian	
	Campanian	*Méndez* shales
	Upper Santonian	800–1,000 ft.
	Lower Santonian	
	Coniacian	*San Felipe* limestones and shales 300–500 ft.
	Turonian	*Agua Nueva* limestones and bituminous shales 260–400 ft. *Inoceramus hercynicus*
MIDDLE CRETACEOUS	Cenomanian	Tamaulipas limestone, upper: White and grey dense cherty limestones 480–600 ft.
	Albian	Black shale at base. 20 ft.
LOWER CRETACEOUS	(Aptian)	Tamaulipas limestone, lower: White and light grey cherty limestone 1,000 ft.
	Neocomian	*Acanthodiscus* aff. *octagonus* Uhlig
		Probable hiatus
UPPER JURASSIC	Upper Portlandian	Limestones
	Lower and Middle Portlandian	Limestones and carbonaceous shales
	Kimmeridgian	Bituminous shales

TABLE II

Succession in Southern Fields

Middle Oligocene	*Mesón* Sandy limestones and sandy shales
Lower Oligocene	*Huasteca* Grey shales with some thin sandstones (overlaps El Abra at Dos [illegible]) *unconformity*
Upper Eocene	*Chapapote* Grey shales (surface rock from Chapapote Nuñez to Toteco)
Middle Eocene	*Tempoal* Brownish shales (thinly represented north of Toteco)
Lower Eocene	*Aagón* shales *unconformity*
Palaeocene? or Danian?	*Tamesi* (Probably represents phase of Upper Chicontepec) Grey and red shales *unconformity*
Upper Cretaceous	Upper *San Felipe*-lower *Méndez* *unconformity*
Middle Cretaceous	*El Abra* limestone (upper Cenomanian missing) *Pecten roemeri* Hill at top *Orbitolina texana* Roemer (zone fossil of facies of Glen Rose of Texas) found 7,100 ft. below top of El Abra limestone in well at Jardin, south-east of Alamo

The foregoing series of limestones is designated the Lower Tamaulipas limestone. The facies is called bathyal by Burckhardt [5, 1930].

Middle Cretaceous: Albian-Cenomanian.

Upper Tamaulipas Limestone. Grey cherty limestones (bathyal facies) of this age crop out in the Sierra Madre south-east of Tamazunchale. These beds take their name from the Sierra Tamaulipas (Fig. 1). The type locality of the Upper Tamaulipas limestone lies in the Borrega Cañon on the west side of the Sierra Tamaulipas. Flaggy and massive bedded grey and white cherty limestones are exposed, the lowest part, consisting of black limestones and shales, belonging to the base of the Albian. In wells in the Northern Fields the beds consist of grey and white dense cherty limestones. Oil production has been found from the base upwards. The total thickness of the Tamaulipas limestone (Lower and Upper) in the Northern Fields is about 1,600 ft.

El Abra Limestone. Albian and Lower Cenomanian rocks in a reef facies crop out in the Sierra Madre west of Tampico. This facies is named El Abra limestone. The top of the El Abra is equivalent to the Buda of Texas. It is a porous or cavernous, predominantly light-grey limestone built up of the remains of miliolids, rudistids, and shelly debris. Albertite is found in fossil cavities. The highest beds consist of black bituminous limestone near El Abra, the type locality (Fig. 1). El Abra limestone forms the reservoir rock in the Southern Fields (Golden Lane). It has been referred to, erroneously, as the 'Tamasopo limestone'. The Tamasopo Cañon limestone is of younger age, Coniacian (Austin Chalk), and possibly includes part of the Turonian in its lower part and the Santonian in the upper part. Except that the Upper Cenomanian is missing, the type El Abra is the time equivalent of the Upper Tamaulipas limestone. The approximate distribution of the two facies is shown in Fig. 1. A mixed type of facies, or merging of the Tamaulipas and El Abra limestones, forms the reservoir rock in the Poza Rica Field.

Upper Cretaceous: Turonian.

Agua Nueva Formation. Overlying the Tamaulipas limestone is the Agua Nueva formation [see 15, 1934] a series of black and dark-grey chert-bearing limestones with bituminous black shales containing *Inoceramus hercynicus* Petraschek and *I. labiatus* Schlotheim. These beds are characteristically recognizable both in outcrops and wells, though the colour of the limestones may be predominantly light grey in some areas (Pánuco Field) and the amount of interbedded black shale vary in the different levels in one area as compared with another. The thickness in the Pánuco area is from 260 to 400 ft. Production is found from top to bottom of the formation in the Northern Fields. It is absent in the South Fields, though it has been found in wells some kilometres east, or west, of the structure. It is present in wells in Pozo Rica.

The Agua Nueva is generally thicker in synclines than on tops of anticlines. No hiatus is present above the Tamaulipas limestone.

Coniacian and Lower Santonian.

San Felipe Formation. Overlying the Agua Nueva is a series of alternating greenish-grey, grey, and white limestones, and grey shales. Limestones are more predominant in the lower part and shales in the upper part. These beds are named the San Felipe formation [15, 1934] and are approximately equivalent to the Austin Chalk of Texas. The type locality lies west of San Felipe station on the Tampico–San Luis Potosí Railway. The San Felipe contains facies changes; in a few places it is entirely an argillaceous deposit, in others mainly calcareous. Its thickness in the Pánuco area may vary from 300 to 400 ft. Production is only found in the basal 80 ft., except in a few anomalous cases where it is encountered higher up.

A thin development of the uppermost San Felipe, not exceeding about 50 ft. in thickness, is present with overlap on El Abra limestone in the South Fields Ridge.

Upper Santonian, Campanian, and Maestrichtian.

Méndez Formation. Grading up from the San Felipe is a series of grey foraminiferal shales known as the Méndez formation. The upper part (about 40–100 ft. thick) consists of pinkish to purplish-red shales.

The Upper Méndez can be correlated with the beds near Cárdenas, State of San Luis Potosí. The Cárdenas beds are of Maestrichtian age. Hitherto the Méndez has been considered as Santonian-Campanian only and equivalent to the Taylor marl of Texas, but the Navarro is represented by the Upper Méndez; see Adkins [1, 1932]. The name Papagayos was used by Dumble [14, 1918]. It should be regarded as a group name representing an argillaceous facies of all the San Felipe and the Méndez.

The Méndez crops out in Chocoy, and extends southwards to Cacalilao. Its type locality lies 300 metres east of Méndez station on the Tampico–San Luis Potosí Railway. The Méndez has a thickness of 800–1,100 ft. in the Northern Fields. In the South Fields Ridge only a thin remnant is present.

Distribution of Cretaceous Rocks

The Tamaulipas, El Abra, Agua Nueva, and San Felipe are only found cropping out in the areas of the Sierra Madre and Sierra Tamaulipas. Elsewhere in the Tampico Embayment they are covered by younger rocks. The Méndez is found in the inter-montane valleys and on the east side of the Sierra Madre Oriental and on both flanks and the south plunging end of the Sierra Tamaulipas. South of the Río Pánuco the Méndez is covered by younger beds.

Uppermost Cretaceous or Palaeocene?

Tamesí Formation. Unconformably overlying the Méndez is a series of grey and red shales named the Tamesí formation by Belt [3, 1925]. There is a distinct palaeontological break between the two formations and a hiatus is present. The Tamesí is found overlying the Méndez on both flanks of the Sierra Tamaulipas. It crops out in the Río Pánuco near the town of the same name. It forms the surface rock in the Ebano Field and in the extreme eastern and western parts of Cacalilao. About 900 ft. of the formation have been drilled through in some wells. In the Southern Fields it is present with a thickness up to 400 ft. It is lacking on some parts of the ridge. No macro-fossils have yet been found in the Tamesí, and a statement as to age on the basis of the micro-fauna is still a matter of uncertainty. The Tamesí can be regarded as post-Maestrichtian and of earlier age than the equivalent of the Midway (Lower Eocene) of the Gulf Coast.

Tertiary

Lower Eocene.

Chicontepec Group. The name Chicontepec was referred to by Dumble [14, 1918] in describing a series of sandstones

and dark shales near the town of the same name. Around Tanlajás the part of the Chicontepec exposed is of Upper Midway age. The Wilcox (of the Gulf Coast) is probably represented elsewhere in the Chicontepec group. From Tancanhuitz south-eastwards the Chicontepec forms the foot-hills of the Sierra Madre. It is a shallow water and, in part, deltaic deposit. It is not found (*sensu stricto*) in the wells of the Northern or Southern Fields.

Aragón Formation. The Aragón shales are described by Nuttall [17, 1930]; they overlie the Chicontepec. The Aragón crops out in a few areas about 50 to 70 km. west of Túxpan and south-east of Aldama north of Tampico. It is found in wells in the Southern Fields and near Topila. Its average thickness is about 500 ft. The Aragón probably represents uppermost Midway or Wilcox of the Gulf Coast.

Middle Eocene.

Tempoal Formation. Overlying the Aragón are shales described as Tempoal formation by Ver Wiebe [23, 1924] and Belt [3, 1925]. The type locality is at the town of Tempoal. Cole [6, 1927] later used the name Guayabal for these beds. The shales are chocolate-coloured and contain ironstone nodules. A total thickness of at least 1,600 ft. is developed. The Tempoal is present in the South Fields Ridge. The Tempoal is of Claiborne age and the upper part can be correlated with the Cook Mountain of the Gulf Coast.

Upper Eocene.

Chapapote Formation. The name Chapapote formation was introduced by Cole [7, 1928]. The Chapapote shales are a deeper water deposit representing beds of nearer shore facies described as the Tantoyuca formation by Ver Wiebe [23, 1924] and Belt [3, 1925]. The Chapapote (and Tantoyuco facies) is regarded as equivalent in age to the Jackson of the Gulf Coast. It has a total thickness in excess of 1,300 ft. It is found in wells at Topila and on the South Fields Ridge.

Lower Oligocene.

Huasteca Formation. Shales of Lower Oligocene age were referred to as Alazán by Vaughan [22, 1924] and Cooke [8, 1928]. The Alazán had previously been defined as Eocene by Dumble [14, 1918].

Various authors have referred the shales in the Río Buenavista near Alazán to the Eocene, and others have referred them to the Oligocene. Beds of *both* ages occur at the locality, with overlap of the Byram marl equivalent on the Jackson. Eocene inclusions (with micro-fauna) occur in the Oligocene. Confusion is here avoided by adoption of the name Huasteca.

The Huasteca formation consisting of grey sandy clays and thin sandstones is typically exposed at Paso Comales on the road between Ozuluama and Tantoyuca. It is present at Topila and in the Southern Fields area in a deeper water facies than at Comales. The Huasteca is the equivalent of the 'Alazán' in the sense used by Cooke [8, 1928] and Nuttall [18, 1932]. The Huasteca is found in wells in the Southern Fields with a thickness up to 2,000 ft. or more.

Middle Oligocene.

Mesón Formation. Conformably overlying the Huasteca is the Mesón. The name Mesón formation was introduced by Dumble [14, 1918]. The Mesón consists of shales, sandy limestones, orbitoidal and coralline limestones. It forms a belt near the coast up to a width of about 20 km. in places. It has a thickness of more than 1,000 ft., perhaps twice that amount in some areas. In places it overlaps the Chapapote and even on to the Aragón. It is found in wells in Topila and on the South Fields Ridge. The upper part of the Mesón has been referred to as San Rafael.

Miocene

Túxpan Formation. Named by Dumble [14, 1918] from its occurrence at the town of Túxpan. It consists of beds of sandstone and sandy limestone with beds of grey shale. Its age is regarded as Lower Miocene. It overlaps the Mesón. Its occurrence is confined to a narrow strip along the coast, but in the neighbourhood of Papantla it is better developed, both in a surfacial way and as regards thickness.

Pleistocene and Recent

Beds of Pleistocene age occur in the lagoons near Tampico and are found overlying the Oligocene in places farther inland. Alluvial tracts are developed in the valleys of the Pánuco, Tamesí, and other rivers.

Igneous Rocks

Andesitic and basaltic plugs and dykes of post-Oligocene age occur frequently throughout the Southern Oilfields and in the territory between the coast and the Sierra Madre. With two exceptions intrusions in the Northern Fields are limited to the Ebano area. Diorite and gabbro are not found on the surface, but have been encountered in wells at depth in the Northern and Southern Fields and in Aguada. Syenitic rocks are intruded in the Sierra Tamaulipas. Extrusive rocks occur near Aldama (north of Tampico) and at other places.

Seepages

Asphaltic seepages (*ojos de chapopote*) occur in the Southern Fields area, and in the Ebano district. Almost invariably they are connected with igneous intrusions, plugs, or dykes, the oil having worked its way upwards along the contact of the igneous with the sedimentary rocks. The subject is fully discussed by De Golyer [12, 1915; 13, 1932].

In a few places in the Northern Fields, western Cacalilao, Garrucho, and Altamira (Los Esteros), the seepages are associated with faulting and not with intrusions.

Structural Conditions in the Oilfields

As distinct from the folding of the Sierra Madre Oriental, the Cretaceous limestones of which are often overfolded or consist of fan-shaped folds, the oilfields lie in a structural belt in which the folds can be regarded as deep seated in origin. This difference in the tectonics is referred to by Böse [4, 1927] and Staub [20, 1931].

Northern Fields. The Northern Fields, Pánuco, Ebano, Topila, &c., lie on the plunging prolongation of the Sierra Tamaulipas anticline and should be regarded as part of that large structure (see Fig. 1). South of the Tampico–San Luis Potosí Railway a dominant feature of the area is the presence of north-east trending cross-anticlines. The Ebano Field, eastern Cacalilao (Fig. 2), the southern part of Pánuco, and the Quebracha Field are situated on north-east or north-north-east trending structures, though the regional structural trend is about north 15° to 18° west. Normal faults of both north-east and north-west directions occur, besides some with a nearly north–south trend. The

faults are usually of small displacement, having a throw of 30 to 60 ft., but occasionally about 100 ft. Step faulting with a total downthrow of 360 ft. occurs in the south-east part of Cacalilao. Reverse faults occur very rarely. Production has been found at depths of 1,400–2,500 ft. below sea-level, ranging from the basal San Felipe (restricted sense) to about 600 ft. below the top of the Tamaulipas limestone.

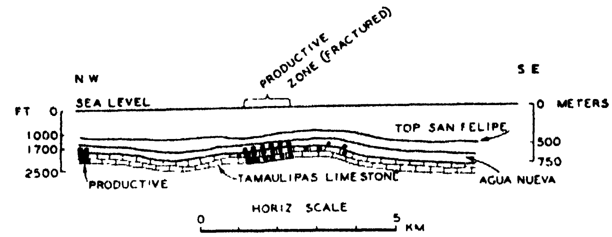

FIG. 2. Cross-section through eastern Cacalilao anticline. (Note. Relative richness of production shown by black dots.)

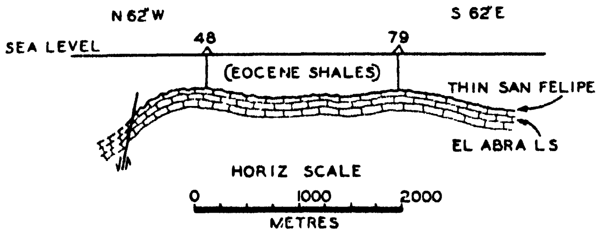

FIG. 3. Cross-section through north part of Cerro Azul.
(*Courtesy of the American Association of Petroleum Geologists.*)

Southern Fields. The South Fields Ridge is regarded as an asymmetric anticline (Fig. 3), frequently cross-faulted, though it is referred to by some as consisting of a downthrown fault [19, 1926] feature on its west flank. From Dos Bocas to Toteco the folds have a north-east or north-north-east axial trend. A change of trend occurs at Cerro Azul-Toteco, the crest maximum of the ridge. South of Potrero del Llano, from Cerro Viejo to Alamo and San Isidro the trend of folding is south-east or parallel to the Sierra Madre Oriental. The Dos Bocas–Alamo structure was subject to oscillation in level during Albian to Santonian time. During the Eocene and Oligocene it was subjected to differential movements as evidenced by the various unconformities. Production in the El Abra limestone is found at depths of 1,200 to 2,300 ft. below sea-level. The Southern Fields Ridge is covered by Tertiary beds of various stages which do not reflect the underlying structure.

Poza Rica. The Poza Rica Field, lying in the synclinal area between the Sierra Madre and the southern end of the 'Golden Lane', consists of a broad, gently folded structure. Production is found in limestone of Cenomanian age (mixed facies of Tamaulipas and El Abra) at depths around 7,200 ft. below sea-level.

Furbero Field. Oil accumulation in this field occurs in metamorphosed Eocene shales at the contact with an igneous intrusive (gabbro). The field is described by De Golyer [11, 1915–16].

Porosity in the Limestone Reservoir Rocks [15, 1934].

Northern Fields. Porosity in the dense limestones of the Tamaulipas, Agua Nueva, and basal San Felipe beds is due to fracturing of the rocks or opening of joint planes. Fracturing is associated with faults of small displacement. In some places the rocks have been shattered. In some areas good production is found on the crests of anticlines, and in others the more prolific production occurs on the flanks (see Fig. 2). The three formations mentioned form a single physical unit as regards accumulation and production of oil, communication (vertical permeability) occurring through the highly inclined fissures and joints. No dolomitization of the limestones occurs, only a trace of magnesium carbonate being found.

Southern Fields. Porosity in El Abra limestone is mainly due to fossils existing as hollow casts. Additional porosity is present due to faulting, solution enlarging the fissures. The latter features have favourably affected the permeability of the limestones, and assisted long-range drainage of the structures by single wells over distances of several kilometres; production from three wells alone is about equal to one-quarter of the total production from the entire ridge. El Abra is practically pure limestone, the proportion of calcium carbonate amounting to about 97%.

Nature of the Oil and Gas

Northern Fields. The gravity of the asphaltic oil is 12·5° A.P.I. in Pánuco, Cacalilao, and Corcovado. Eastward towards Topila the oil gradually becomes lighter, the gravity A.P.I. being from 14 to 15°. In the vicinity of Ebano oil of 11° gravity A.P.I. is found.

Gas throughout Cacalilao, Corcovado, Ebano, and Altamira is inflammable, containing about 40 to 52% methane and from 48 to 57% carbon dioxide. In Pánuco and Topila the gas is non-inflammable (except in a few rare cases), the proportion of carbon dioxide amounting to 85 or 90%. The gas in the Quebracha Field contains from 95 to 97·9% carbon dioxide.

Southern Fields. The gravity A.P.I. averages from 19 to 22°. In San Gerónimo it is 15° A.P.I. and in the Tierra Blanca pool 24° A.P.I. In Poza Rica the gravity A.P.I. is 28°. At Furbero it is 24° A.P.I.

Gas in the Southern Fields is everywhere inflammable, the amount of carbon dioxide present varying from 10·7 to 18·1%.

Analyses of gases from the Northern and Southern Fields are quoted by the writer [16, 1935].

Production

The following figures refer to the total production up to and including 31 December 1934:

Northern Fields (Pánuco, &c.)	705,800,000 bbl.
Southern Fields (Golden Lane)	986,000,000 „
Poza Rica (and Mecatepec)	5,400,000 „
Furbero	2,180,000 „
Miscellaneous Pools	2,000,000 „ .

EASTERN VENEZUELA AND TRINIDAD

By Professor V. C. ILLING, *Imperial College of Science and Technology*, and H. G. KUGLER, Ph.D., *Trinidad Leaseholds Ltd., Trinidad*

THE oilfields of eastern Venezuela lie mainly in the State of Monagas, on the flat Llanos plains of the Orinoco opposite Trinidad. Exploratory drilling is now extending westwards into the State of Anzoategui, but these areas are as yet insufficiently developed to be regarded as proved territory. On the island of Trinidad all the proved oilfields lie in the southern half and appear to belong to the same geological province as Monagas and Delta Amacuro. The main areas of production and some of the exploratory wells in Monagas and Anzoategui are shown on the accompanying map.

Oil production in these territories is largely the result of development during the last two decades. In Trinidad, it is true, development began as early as 1905, but it did not attain appreciable proportions until 1914, from which date the industry has grown steadily in importance and the production is now of the order of 2 million tons per annum. Eastern Venezuela attracted considerable attention in 1913, and some drilling was done near the pitch lake of Guanoco, but the main oil-pool of this region—Quiriquire—is entirely a growth of the last decade.

Trinidad

The general stratigraphy of the Trinidad oilfields is complicated by the occurrence of a number of different facies in the various sectors of the island. The Northern Range is largely composed of slightly metamorphosed Cretaceous or earlier rocks, and these probably represent the oldest series in the area. Most of the rest of the island is formed of Tertiary sediments, but there are exposures of Cretaceous along the axes of the major uplifts, particularly in the Central Range, and the presence of such rocks has been shown by borings and by sedimentary volcanism in the south of the island.

Outcrops of Eocene and Oligocene are confined to the cores of the major uplifts in the Central Range, Naparima area, and the Southern Range. Around these uplifts and in all the intervening territory the successive members of the post-Oligocene formations are seen. The folding is in a general ENE.–WSW. direction, crossing the island from end to end. It is logical to assume that this folding is connected with that which is known in the foot-hills of the mainland north of Maturin. Folding movements appear to have continued until quite recent times, and although it is clear that there were early movements of considerable intensity, it is noteworthy that even the Upper Miocene, and in places the Pliocene, has been extensively disturbed. The last important episode, both in Trinidad and on the mainland, was the deposition of a flat sheet of sands and clays which, in places, has completely covered the underlying folded beds, and attains considerable thicknesses in Venezuela. It is not usually thick in Trinidad.

A synopsis of the general stratigraphy is given in tabular form.

In the main the sedimentary sequence reveals the following phases:

(*a*) A Cretaceous-Eocene period of gradually shallowing water with the formation of limestones, shales, and sandstones.

(*b*) An Eocene-Oligocene period of shallow but clear water conditions with much organic deposits—occasionally foraminiferal marls, limestones, glauconitic sands, &c.

(*c*) An Upper Oligocene-Middle Miocene period of sea invasion with much terrigenous sands and clays in the south, but with clear water reef limestone periods and shallow water marls in the middle and north of the island. Strong folding movements took place during this period.

(*d*) A transformation to brackish- and finally fresh-water conditions in the Upper Miocene-Pliocene, associated with the dying down of the folding movements.

(*e*) A final deposition of the flat terrestrial sediments of the Orinoco delta over parts of the island.

So far as the proved oilfields are concerned the productive rocks are mainly in the Miocene marine development of period (*c*). In Trinidad and Eastern Venezuela there is abundant evidence of oil and gas in the Cretaceous, but no commercial production has been obtained from such rocks, although some of the oil produced from the Miocene may be migrant from the underlying Cretaceous. In the main the oil reservoir rocks are lenticular sands of varying thickness and lateral extent. This has resulted in the development of production not only on the anticlines, but deep into, and even across, the synclinal axes, as in the case of the Siparia syncline. Both folding and faulting are well displayed, and, save for the Palo Seco area, the major fields are dominantly anticlinal.

More than 90% of the oil produced in Trinidad has come from a small area between Brighton and Palo Seco. This comparative concentration may be due to interdigitation of the sandy 'Forest-cruse' facies with the clayey facies of the Naparima region, but there are other possible contributory factors such as the Pt. Fortin-Los Bajos fault, which may have acted as an oil-feeder, and also the proximity of the Central Range with its many dislocations.

The Central Range has not yet been seriously tested except on its southern margin, where a highly disturbed zone has numerous oil indications which have attracted attention. In this zone lies the **Tabaquite** field with its light oils (0·82 sp. gr.). It appears to be on a northerly dipping thrust block composed principally of Nariva sands (Miocene). The oils from these sands are aromatic, but a paraffinic oil is obtained from deeper horizons which may possibly be of Eocene age. The **Brighton** field is a gentle dome of about 1 mile radius, with the famous Pitch Lake on its crest. The uppermost beds belong to the La Brea and Moruga formations which are underlain normally by a rather clayey facies of the Forest and Cruse series. All are highly impregnated with a heavy sulphurous oil, and in earlier days the La Brea beds were exploited. An important unconformity occurs below the Cruse series, which strongly overlaps a highly imbricated Cretaceous-Eocene complex. Apparently the Brighton dome lies on the south-western prolongation of the much-disturbed southern edge of the Central Range.

East-north-east of Brighton, in the highly folded Oligocene-Miocene series of the Oropuche Lagoon and the

Naparima territory, a number of exploratory wells have proved the existence of light oil and gas sands in the Ste Croix formation without revealing any considerable field as yet. The intensity of folding appears to diminish southwards from the Central Range. This may be partly the result of smaller stresses towards the south, but it is also associated with the fact that the beds involved are younger. These conditions arise more especially in the fields which lie well to the south.

The **Vessigny** field is connected with the Vance River important unconformity at the base of the Cruse with considerable overlap on to an old ridge which appears to attain its maximum in the southern syncline. These conditions demonstrate the importance of the pre-Cruse topography, which determined the zones of basinward in-fill and caused rapid changes in thickness of the Cruse horizons against the old landscape. There are many signs that sedimentary volcanism had a strong influence on the distribution of oil and gas, not only in the Parrylands fields, but also in the general region towards Brighton.

anticline which curves round the south and south-east of the Brighton structure. Production has been obtained from the Forest sands, below which the sandy facies of the Cruse is poorly developed. Recently there have been attempts to find oil at deeper horizons, and these have shown a highly sulphurous oil, though not in commercial quantities, in the Amphistegina marls below the unconformity.

Immediately to the south lie the **Parrylands** fields. Attention was first drawn to this area by the outcropping 'Tar sands', which swing round the western plunging end of the Lot-I anticline. These beds are of Lower La Brea age, charged with migrated and inspissated oil. The early production was from Forest sands, but later developments in the underlying Cruse horizons have been much more important. The richest zone is on the southern flank which dips at 16–20° for about 2 miles to the axis of the syncline. Recent developments in the west have disclosed a rich zone on the plunging anticlinal axis, and a broad area of production on the western prolongation of the northern flank towards the Guapo area. All these developments are in Forest and Cruse horizons. Deep drilling has shown an

South of the Parrylands is the **Fyzabad** field, a series of separate domes on the Central anticline. The Forest dome is about 1½ miles long and is followed to the east by the Bernstein dome which is approximately 2 miles along the axis. The Apex field is slightly offset to the south, and occurs on a subsidiary structure on the western plunge of the Santa Cecilia anticline. The latter is a more extensive uplift which stretches towards Debe where the Ste Croix beds are exposed in the core of the fold. North-east of Apex the sandy development of the Forest-Cruse formation gives place to a clayey facies, and the prospects of oil in this area are reduced to the speculative possibilities of the pre-Cruse formations. The crestal region of the Central anticline is considerably broken by epi-anticlinal faulting. Its oil production is very irregular and is much affected by water. The northern syncline is shallow, the oil in this region is heavy and asphaltic, and is also associated with much water.

The southern flanks of this line of domes from Forest to Apex merge into a continuous monocline which extends down to the Siparia syncline, the axis of which is 2–3 miles

from the anticlinal crest. The Forest clay horizon which outcrops on the crest lies 5,000–7,000 ft. deep in the bottom of the syncline, and the flank has an average dip of 30–35°. This is the best zone of oil production in Trinidad. There is a considerable amount of block-faulting on this flank, and it is evident that the faults have played an important role in the migration of oil, gas, and water. The distribution of oil and water is markedly dependent on the fault blocks, and the character of the oil is frequently modified, apparently by having suffered repeated injection along the fault planes.

Very little production is encountered in the Moruga beds overlying the Forest clay, and the early production was derived mainly from four sandy horizons which occur in the 1,200 ft. of Forest beds. Later the deeper Cruse series was exploited. This series thickens towards the syncline where the total thickness is about 1,500 ft., and it contains some five main sandy horizons. Deeper formations have not yet been thoroughly explored.

In the Penal region east of Apex a secondary fold appears on the south flank of the Central anticline. This fold extends into the region of **Barrackpore,** and a small field has been developed on its faulted southern flank. The Cruse horizons there are almost wholly clays, and the oil production is from younger sands which, unfortunately, are partially watered.

Immediately west of the Forest field the Central anticline abuts on an important WNW.–ESE. line of dislocation, which is apparently pivotal in nature. On the western end of this line, and on the northern side, is the **Pt. Fortin** field. It is on a strong fold with its faulted northern flank dipping at 40°, and overthrust to the south. Production is obtained on the crest and the northern flank from the Forest and Cruse horizons. The field stretches about 1½ miles along the crest and is about half a mile wide.

East-south-east along the same line of dislocation the upthrown and downthrown sides are reversed, and the **Los Bajos** field is developed in the Forest and Cruse series on the upthrown southern side.

The **Palo Seco** field occupies the northern slope of the Morne Diablo structure between Erin and the eastern prolongation of the Los Bajos fault. The producing horizons are in the Forest and Cruse series, though recent developments have found oil in the Palo Seco beds below the Cruse. All the producing beds outcrop immediately to the south, and although it is true that many of the sand bodies are water-bearing, yet some carry oil, and it is remarkable that oil should be preserved under such conditions. Their productivity must be the result of lenticularity coupled, perhaps, with the sealing effects of minor faulting and asphaltization.

In the south-east of the island the Siparia-Ortoire syncline is bounded on the south by an important uplift in the Lizard Springs area. The core of this uplift consists of Cretaceous, Eocene, Oligocene, and Lower Miocene shales which were deeply eroded before the deposition of the Cruse and Forest series. A sandstone development, over 6,000 ft. thick, of Moruga and younger formations covered the entire southern area, and subsequent movements folded and fractured the rigid sandstones overlying the incompetent shales. Considerable differential thrusting and slumping was thus produced, and remarkable transformational movement of oil and gas has given some of the most outstanding examples of sedimentary volcanism in the island. The oil has impregnated broad areas of the basal Moruga series, and has been trapped on the flanks of the uplifts by strike-faulting and unconformity. Two areas of production have been developed, the most important of which lies on the faulted plunging end of an uplift at **Guayaguayre.** The oil in this region is generally asphaltic, but there are some occurrences of a lighter paraffinous oil.

Recent developments in Trinidad include an intensive programme of exploratory wells which are situated principally on the northern flank of the Central Range, the Cedros Peninsula, the Coora-Morne Diablo-Herrera segment of the Southern anticline, the Penal area, and at Rio Claro.

Eastern Venezuela

The present area of development at Quiriquire, and especially the regions of exploratory drilling, are covered by the Llanos formation—a thick blanket of Pleistocene and Recent deposits. Exposures of older rocks are seen only in the extreme north and south. In the north the hills of the Caribbean Range project through this blanket of Llanos and show, in the main, well-folded Cretaceous and Eocene beds with a strip of folded Miocene on the edge of the foot-hills. In the south the first exposures of the basement rocks are only seen along the banks of the Orinoco. These consist of metamorphic schists, quartzites, and plutonic rocks, and are covered immediately to the north by a blanket of Llanos deposits which thickens northwards as the basement gradually plunges in that direction. Our knowledge of this region is based entirely on the results of geophysical work and of a few exploratory wells. It appears that the basement plunges northwards in a series of undulating slopes and terraces, and that successive members of the Miocene are overlapped southwards by the gently dipping Pliocene and Recent deposits. The northerly plunge continues for about 60 miles to a deep basin south of Maturin, and it is only in this general region that true folding can at present be substantiated.

The geological sequence is not so well known as in Trinidad for the Oligocene and younger formations, and the tentative classification shown in the Table is suggested.

The main episodes in the geological history of this area are as follows:

(*a*) The deposition of an extensive Cretaceous series of grits, limestones, and shales, followed by thick sandstones of Eocene age.

(*b*) A possible but not fully proved episode of clear shallow water of Upper Eocene-Lower Oligocene age.

(*c*) Extensive but gradual depression of the main basins with depositional overlap of the Upper Oligocene and Miocene. It is probable that a considerable folding movement separated stages (*b*) and (*c*) in the north.

(*d*) The later stages of in-filling were associated with a more sandy facies with extensive subsidence in the north and the formation of thick masses of sandstone and shales, followed by folding movements in the northern area.

(*e*) The whole basin was covered with a blanket of Llanos deposits of terrestrial origin. These deposits consist largely of alluvial cones formed at the edge of the foot-hills, but grade southwards into great sheets of alluvial clays and sands over the main Llanos.

(*f*) The final stage consisted of a considerable upward movement associated with a partial dissection of the Llanos deposits near the foot-hills.

The Guayuta shales, where freshly exposed in the foothill regions, show considerable evidence of petroleum, and where they have been covered by sands of younger age they have impregnated the latter with asphaltic oil. The Guanoco oil is almost entirely Cretaceous, but its production is not commercial.

The exploited area at **Quiriquire** trends N. 70° E. for about 6 miles and is 3 miles wide. The productive Quiriquire formation is correlated with the La Brea beds of Trinidad, and attains a thickness of about 3,300 ft. in the south of the field. Inspissated oil is found throughout the Quiriquire formation, but the main production is from the lower 600 ft. in irregular sand bodies within silts and at times in conglomerates, capped by clays. These beds rest unconformably on Lower Miocene and Oligocene black shales. Towards the north they overlap petroliferous Eocene and Cretaceous. The oil is almost certainly migrant, and may have been derived from the Cretaceous or alternatively from Miocene or Oligocene beds farther down the flanks of the main basin.

The structure appears to be a monocline dipping SSE. at about 10°. At the northern edge of the field a strike fault with southern downthrow occurs, and cross-faults are frequent. These are marked by oil seeps, hard asphalt dykes, and the occurrence in places of shallow oil production near them. A slightly saline edge-water under considerable head bounds the field on the south. The wells range from 1,800 to 3,300 ft. in depth, and the maximum thickness of the productive zone is 750 ft. The oil is a dark green asphalt-base crude and has a gravity of 13–24·4° API.

About 7 miles WSW. of Quiriquire several wells have been drilled in the **Orocual** area, and it appears that continuity of the producing formations between the two areas may be expected. At Orocual productive beds, which may be equivalent to the Forest-Cruse formation, are known below the Quiriquire formation.

Four wells have been drilled at **Pedernales** into the Forest-Cruse beds and oil in commercial quantities has been proved. The tectonic complexities in this area are comparable to those of the Cedros Peninsula in Trinidad.

With the exception of the depths attained few data are available concerning the many exploratory wells (see sketch-map for locations). Despite this lack of information there is a belief that oilfields comparable to Quiriquire are present also in the State of Anzoategui and in southern Monagas.

COLOMBIA AND THE MARACAIBO BASIN

By V. R. GARFIAS and THEODORE CHAPIN
Foreign Oil Department, Cities Service Company

Geographical Distribution

Physical Features.

THE dominating topographic and structural feature of north-western South America is the Andean chain of mountains which extends across Colombia and Venezuela in several distinct north-easterly trending branches. In Colombia these ranges are known as the Cordillera Occidental, Cordillera Central, and Cordillera Oriental. Upon reaching the Venezuelan border, the latter range divides into the Sierra de Perijá and the Sierra de Merida. The Sierra de Perijá extends northerly and north-easterly towards the Goajira Peninsula, while the Sierra de Merida trends north-easterly, and then nearly easterly across Venezuela towards Trinidad. The Cordillera Central and the Cordillera Occidental are not sharply differentiated in northern Colombia and merge to form a single range which trends north-westerly into the Panama range.

In northern Colombia and the Maracaibo Basin the highland areas and the intervening depressions form the following geographic divisions:

Cordillera Occidental.
Cordillera Central.
Cordillera Oriental.
Sierra de Merida.
Sierra de Perijá.
Sierra Nevada de Santa Marta.
Maracaibo Basin.
Magdalena Valley.
Cauca Valley.
Atrato Valley.
Pacific Slope.

Petroliferous Areas.

The present production is confined to the Maracaibo Basin and the Magdalena Valley, but oil-bearing formations and evidences of petroleum are more widespread. The entire Maracaibo Basin is covered with formations which, under favourable structural conditions, might be oil bearing. The Colombian production is all drawn from the upper Magdalena Valley in the State of Santander. Nearly all of it is from the De Mares concession. Petroliferous rocks, however, are present in the lower Magdalena Valley, whence some production has been drawn. Oil and gas seepages, mud volcanoes, and other evidences of petroleum are numerous in a zone extending from the lower Magdalena Valley south-westwards to the valley of Rio Atrato. The location of the producing fields is shown in the Map.

Geological Distribution

The oil-bearing and oil-generating beds of Colombia and the Maracaibo Basin comprise a series of sediments over 25,000 ft. thick which extend from the Cretaceous to the Pliocene in which nearly every major division is petroliferous.

The underlying beds comprise Early Cretaceous or pre-Cretaceous red beds and partially metamorphosed sediments which are apparently non-petroliferous. The basement rocks, however, have yielded locally a small production. Heavy oil seeps from basalt at Cachirí in the western part of the Maracaibo Basin, and in the Totumo field in the District of Perijá the production is drawn from igneous and metamorphic rocks.

During Early Cretaceous time both the Maracaibo Basin and north-eastern Colombia in common with much of northern South America became submerged by an epicontinental sea in which were deposited large bodies of limestone. Before the close of the Cretaceous, however, this depositional period was closed by a gradual general emergence, accentuated along the axes of the present sierras.

Following a long erosional period, the Tertiary sea again invaded the area, occupying partially separated basins lying between highland areas, which became depositional basins and remained so more or less continuously throughout the Tertiary epoch.

The basal Eocene deposits rest unconformably on Cretaceous and older rocks, and are the result of a depositional phase that extended on into the Oligocene and with some interruptions through the Tertiary. In the Maracaibo Basin this phase was brought to a temporary close by widespread uplift and erosion, but during the Middle Oligocene the region was again submerged, and this depositional cycle extended on into the Early Miocene. In Colombia the Oligocene emergence may have been more important, as in places the entire Oligocene section is missing and the Miocene rests directly on the Eocene and older deposits.

This Miocene submergence was followed by relative elevation and mountain folding which culminated in the Pliocene or at its close. This continued uplift restricted the depositional basins more and more and furnished the detritus for the accumulating sediments which were laid down as continental, estuarine, and marine deposits.

The Cretaceous sequence of the Maracaibo Basin is given in Table I.

TABLE I

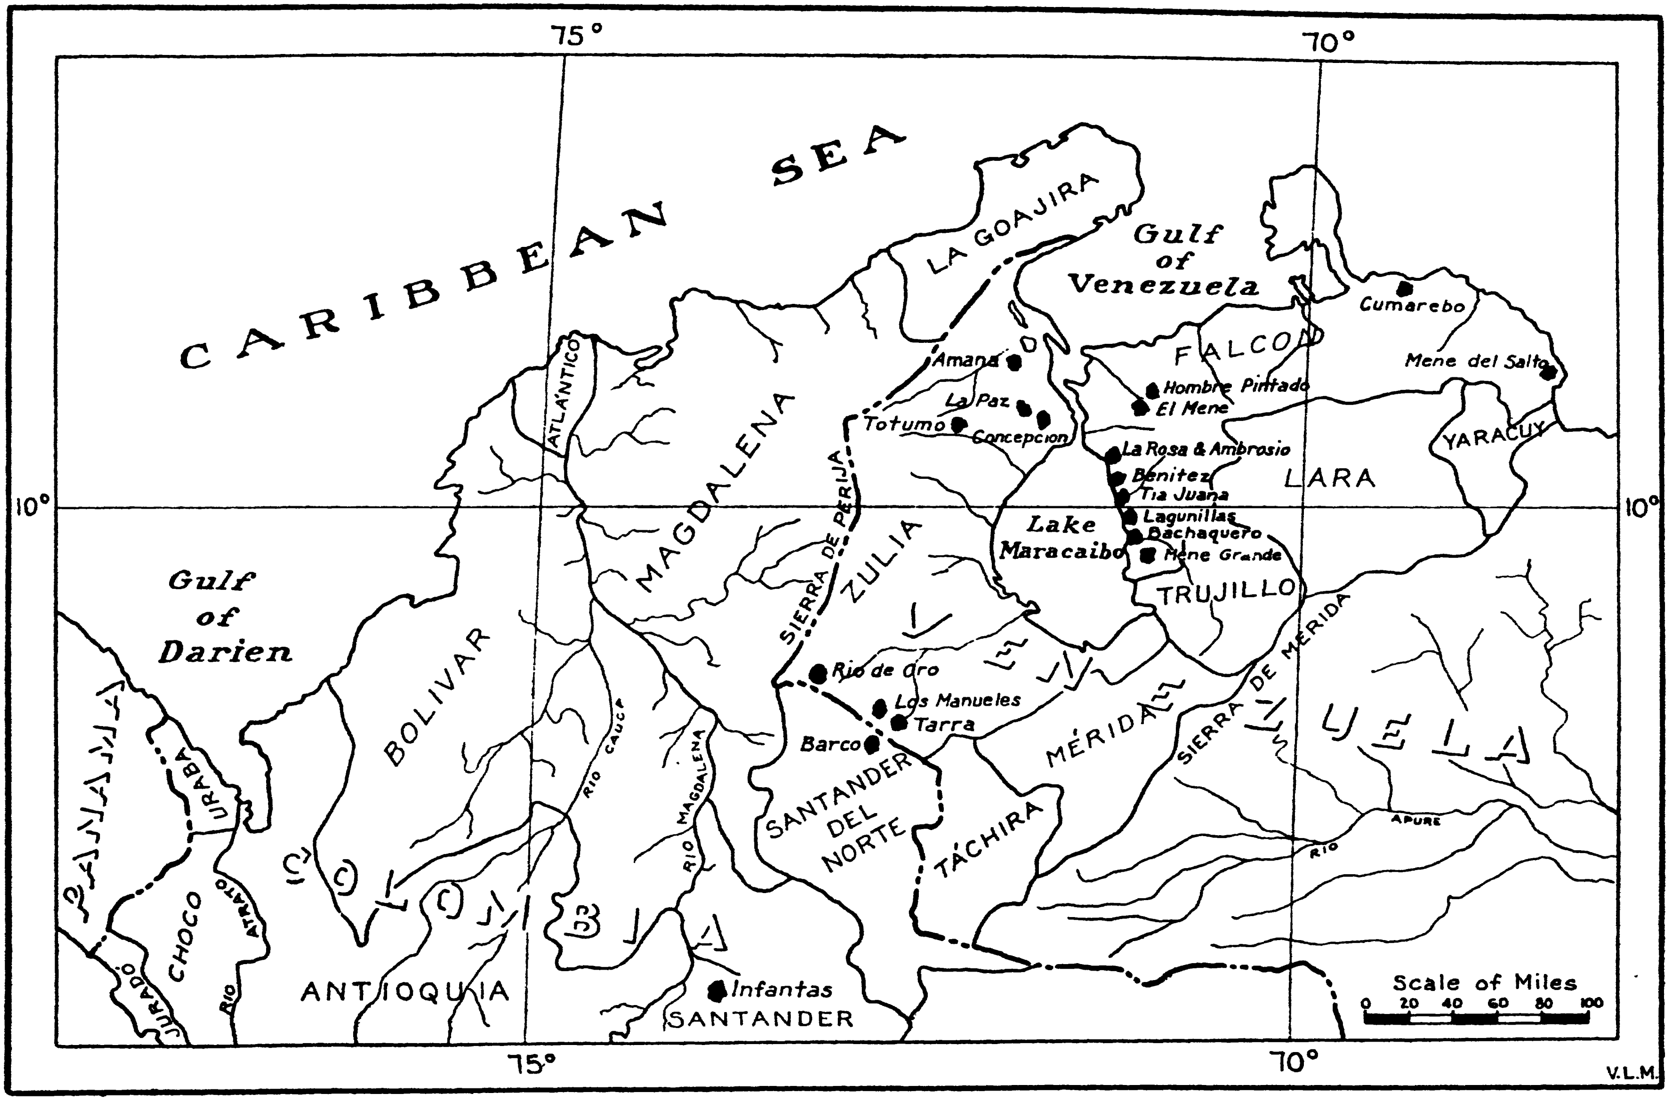
Cretaceous Sequence, Maracaibo Basin.

Tertiary sediments.
Unconformity.

Upper Cretaceous.
Colon shale—Petroliferous, dark-grey, foraminiferal shale with thin beds of hard grey sandstone and limestone concretions; 2,000–3,000 ft., Ammonites abundant.

Middle Cretaceous.
La Luna formation—Dark grey to black carbonaceous and petroliferous limestone; 2,000 ft., Megafossils rare but microfossils abundant, mainly *Foraminifera.*

Lower Cretaceous.
Cogollo limestone—Light grey limestone, petroliferous in fractures, but lacking in bituminous organic material. *Exogyra* abundant, but few pelagic *Foraminifera*; 1,500 ft.
Rio Negro conglomerate—Conglomerates and coloured sandstone with lenses of limestone and thin shales; 4,000 ft.
Unconformity.



Sketch-map of northern Colombia and the Maracaibo Basin, showing location of producing oilfields.

Rio Negro Conglomerate. The basal member is the Rio Negro conglomerate which was formerly called both the Lagunillas conglomerate and the Basal Cretaceous conglomerate. The formation consists of 4,000 ft. of non-fossiliferous conglomerates, red, yellow, and greyish coarse sandstones, limestone lenses, and shales. The conglomerate rests with marked unconformity on the eroded edges of red beds and older formations, and is correlated with the Barranquin formation of north-eastern Venezuela.

Cogollo Limestone. The type locality of the Cogollo limestone is the Rio Cogollo in the Sierra Perijá. It overlies the Rio Negro conglomerate conformably, although in places it overlaps pre-Cretaceous rocks. Liddle [6] in 1928 described it as hard, massive, grey or buff fossiliferous limestone and intercalated dark grey to black shales, 1,000 to 1,500 ft. thick. Locally it is nodular and cherty.

Hedberg [4] in 1931 published some petrographic details. It is typically grey or light grey. Molluscs, echinoid fragments, and bryozoans are common, and in places the rock is almost entirely composed of poorly preserved *Exogyra*, although it is almost entirely lacking in pelagic foraminiferal remains. Some beds are seemingly composed chiefly of calcareous algae, and algal remains are characteristic of the formation in general. In places it is sandy and phosphatic, but it is notably lacking in bituminous organic material.

The Cogollo limestone is petroliferous, but the oil is confined chiefly to fractures and is not diffused through the rock. The contained oil was probably derived from the overlying beds, and the Cogollo is not regarded as either a source or a reservoir rock.

The most common fossils are *Gryphea*, *Exogyra*, and *Ostrea*. It is correlated with the El Cantil formation of north-eastern Venezuela, of Lower Cretaceous age, the equivalent of the Aptian and Albian.

La Luna Formation. The La Luna formation is named from its typical exposure at Quebrada La Luna on the eastern flank of Sierra Perijá. It comprises the lower part of what has sometimes been included in the Colon shale and probably also the upper part of the section included in the Cogollo limestone. It was defined by Hedberg [4] in 1931 as a formation distinct from the Colon shale on account of its lithological character and from the Cogollo limestone on the basis of the marked faunal and lithological differences. He says that two distinct types of Cretaceous limestone exist which he terms a La Luna type and a Cogollo type. These can be clearly differentiated, but at most places no definite line of contact can be drawn between them because of the interbedding of the two types, but the Cogollo type is predominant in the lower part and the La Luna in the upper part.

'The La Luna limestone in typical development is dark grey to black. The formation is characteristically more thin-bedded than the underlying Cogollo limestone and is in many places finely laminated. It is particularly characterized by black, ellipsoidal, limestone concretions ranging from a few inches to several feet in diameter. Many of these concretions, when broken, show well preserved mollusk shells as nuclei. Megascopic fossils are in general rare, although a profusion of fish scales is characteristic of parts of the formation. When freshly broken, some of the limestone has a strong petroleum odor. Black chert is common as seams and nodules. The total stratigraphic thickness of the formation may be as much as 2,000 ft. in this area, but exposed thicknesses are markedly different because of faulting....

'Under the microscope the black La Luna rock is seen to be composed almost entirely of tests of small pelagic *Foraminifera* (*Globigerina*, *Globorotalia*, *Globotruncana*, *Guembellina*, et cetera). . . . Large fossils are almost completely absent, and there is little or no coarsely crystalline calcite. There is very little sand impurity.'

As already noted, the La Luna limestones are more or less petroliferous throughout, the oil being uniformly diffused and probably indigenous to the formation. The foraminiferal test cavities are generally filled with clear crystalline calcite, and the surrounding matrix is composed chiefly of dark grey or black carbonaceous and bituminous matter.

It is correlated with the Villeta formation of Colombia of Middle Cretaceous age, and with the Guayuta formation of eastern Venezuela.

Colon Shale. The type locality of the Colon shale is the District of Colon in the western part of the Maracaibo Basin, where the beds crop out on the eastern flanks of the Sierra Perijá. It consists of 2,000 to 3,000 ft. of dark grey foraminiferal shales with thin beds of hard grey sandstone and limestone concretions. The Colon shale conformably overlies the La Luna formation with which it was formerly grouped. It is the equivalent of the upper part of the Guayuta formation of eastern Venezuela.

It contains *Exogyra*, *Enallaster*, *Cucullaea*, *Ostrea*, *Cardita*, *Astarte*, *Cythera*, *Baculites*, *Schloenbachia*, and other forms. Liddle [6] in 1928 said that the great number of ammonites and pelecypods found in these shales indicates that they are Upper Cretaceous, including at least the Cenomanian and Turonian. The uppermost Cretaceous is not known.

The Colon shale is a productive horizon. Its outcrop produces many active seepages, and within the limestone concretions many fossils are found, in the body-cavities of which liquid asphaltic oil is common.

Cretaceous of Colombia. The Cretaceous of Colombia consists of 20,000 ft. or more of sediments of which no complete conformable sequence has been established. The sequence suggested by Anderson [1] in 1926 is given in Table II.

TABLE II

Cretaceous Strata in Colombia

By F. M. ANDERSON

Tertiary sediments.
Unconformity.

Upper Cretaceous.
Guadalupe group—Sandstone and sandy shales; dark clay shales, usually hard; siliceous shales or cherts, with *Foraminifera*, but with few fossil molluscs; contain locally lignitic or carbonaceous beds; 4,000 ft.

Middle Cretaceous (Aptian and Albian).
Villeta group—Grey or dark clay shales and sandstones; thin-bedded limestones, more or less bituminous; marls sometimes sandy, with echinoids, *Asterias*, and near-shore molluscs; locally richly fossiliferous shales and limestones; 1,500–2,000 ft.

Barremien and Hauterivien.
Suarez group—Red sandstone, locally very thick; thin-bedded limestones and marls, with *Crioceras*, *Hoplites*, *Puzosia*, &c.; 1,500–2,000 ft.

Lower Cretaceous.
Jiron group—Red sandstones and variegated sandy shales without fossils; white sandstones, often in thin beds; local conglomerates; 10,000–12,000 ft.

Jiron–Suarez Groups. Neither the Jiron nor the Suarez group appear to be probable oil horizons.

Villeta Group. The bituminous limestones and seepages of asphaltic oil in the Villeta have led to statements that it is a source rock of oil. Actual production from it has not been obtained, although its equivalent, the La Luna limestone, is a probable source rock.

Guadalupe Group. The Guadalupe group composed of sandstones, sandy shales, and white siliceous shales also contains bituminous strata and seepages of oil.

Tertiary.

Tertiary rocks are widespread over the Maracaibo Basin and northern and western Colombia. The Maracaibo Basin deposits are limestone, sandstone, and shale of marine, estuarine and lacustrine origin, representative of all the major Tertiary divisions. The condensed section is shown in Table III.

TABLE III

Tertiary Stratigraphic Section, Maracaibo Basin

Pliocene.
El Milagro beds—Micaceous and ferruginous sandstone and arenaceous shales with petrified wood
Mene Grande series—Mottled clays and petroliferous sandstone; 12,000–4,800 ft.
Unconformity.

Upper Miocene.
La Villa beds—Conglomerates, clay shales, and sandstones; Guayabo formation—Arenaceous and argillaceous beds with seams of coal; 2,500 ft.

Middle Miocene.
Damsite formation, Palmarejo beds, Los Ranchos beds, Upper Shale horizon—Greenish to greyish selenitic clay shales and interbedded marly fossiliferous limestone; 1,500–4,000 ft.

Lower Miocene.
First Coal horizon—Lignitic sandstone, shale, and calcareous beds; 2,000 ft.
Cerro Pelado formation—Flaggy sandstone and shale; 4,000 ft.

Upper Oligocene.
Agua Clara formation—Light grey, concretionary, fissile, petroliferous shale and limestone; 1,300 ft.

Middle Oligocene.
San Luis formation—Massive coraline limestone with conglomeratic sandstone and conglomerate; 1,000 ft. thick; *Lepidocyclina* and other fossils.

Upper Eocene.
Paují formation—Massive grey to black fissile shale and hard buff and grey sandstone; 3,000 ft.
Unconformity.
San Pedro formation—Hard, steel-grey, foraminiferal limestone; few feet thick; *Orthophragmina, Lepidocyclina.*
Unconformity.

Middle Eocene.
Mirador sandstone—Conglomeratic to fine-grained, hard, massive, buff sandstone with shale and coal; *Halyminites, Venericardia, Turritella, Ostrea*; 2,000 ft.

Lower Eocene.
Third Coal horizon—Nearly pure shale with lenses of fossiliferous limestone and in the basal part sandy beds with coal; 1,200 ft.
Unconformity.

Cretaceous sediments.

The Colombian Tertiary also includes a variety of sediments of marine-, brackish-, and fresh-water origin, the marine section occurring along the coast and becoming progressively less marine in character towards the highlands. Condensed stratigraphic sections are shown in Tables IV and V.

TABLE IV

Tertiary Stratigraphic Sequence, Lower Magdalena Valley and Sinu Valley

Pliocene.
Coral limestone and sandstones; *Cyprea, Pecten, Codakia,* oysters, gastropods.
Probable unconformity.

Upper Miocene.
Galapa–La Popa group—Sandy shale, clay marl, calcareous sandstone; 1,500 ft.; *Pecten, Dosinia, Cardium.*
Possible unconformity.

Middle Miocene.
Tubera group—Fossiliferous sandstone and sandy shale.

Lower Miocene.
Las Perdices group—Clay shales, sandy shales, sandstone, siliceous beds; Mollusca, *Foraminifera.*

Oligocene.
Poso series—Fossiliferous sandstone and shale.
Unconformity.

Eocene.
Carmen group—Fossiliferous marine beds with intercalated coal deposits; *Operculina, Lepidocyclina, Nummulites.*

TABLE V

Tertiary Stratigraphic Sequence, Upper Magdalena Valley

Pliocene.
Honda beds—Sandstone, clay, and tuffaceous sediments; 800 ft.
Unconformity.

Miocene.
Oponcito-Barzalosa beds—Red conglomerate, tuffaceous sandstone, carbonaceous shale; 3,000 ft.
Unconformity.

Eocene.
Guaduas beds—Fossiliferous coal-bearing sandstone and shale; 10,000 ft.
Unconformity.

Eocene.

Misoa-Trujillo Formation. The Misoa-Trujillo formation is named from the sierras in the eastern part of the Maracaibo Basin. Its two members, the Third Coal horizon and the overlying Mirador sandstone, take their names from the District of Colon in the south-western part of the Maracaibo Basin.

The basal Eocene member is the Third Coal horizon, which unconformably overlies the Cretaceous sediments. It is composed of about 1,200 ft. of almost pure shale which becomes sandy towards the base, where it contains workable coal seams. Locally it contains lenses of impure fossiliferous limestone, and pyritic and ferruginous bands. The overlying Mirador sandstone member, separated from the Third Coal horizon on lithology, consists of 2,000 ft. of conglomeratic to fine-grained, hard, massive, buff sandstone with interbeds of shale and coal.

Venericardia planicosta Lamarck and *Turritella mortoni* Conrad are characteristic index fossils of the shale horizon, and *Ostrea bellovacina* Lamarck, *Calyptrahorus trinodiferus* Conrad, and *Ostrea alabamensis* Lea also occur. On the island of Toas in Lake Maracaibo an oyster reef in calcareous sediments contains *Ostrea crenulimarginata* and other forms. The Mirador sandstone member is practically barren of fossils, but locally has yielded *Halyminites.* It is correlated with the Midway, Wilcox, and probably also the Claiborne, and is the probable equivalent of the Ortiz and Aragua formations of eastern Venezuela, which have yielded a large fauna.

The Misoa-Trujillo formation is widely distributed in the Maracaibo Basin. It produces seepages of high-grade

oil and is a productive horizon at Mene Grande, Tarra, La Paz, La Concepcion, Punta Benitez, and several fields on the north-eastern shore of Lake Maracaibo.

San Pedro Formation. The type locality of the San Pedro formation is the Rio San Pedro in the eastern part of the Maracaibo Basin. It consists of only a few feet of hard, steel-grey, foraminiferal limestone lying unconformably on the Mirador sandstone. It contains abundant *Orthophragmina* and *Lepidocyclina*, also other *Foraminifera*. It is regarded as Jackson, and is correlated with the Soldado formation of eastern Venezuela.

Paují Shale. The term Paují shale was first applied to beds in the Rio Paují in the eastern part of the Maracaibo Basin, where it is apparently conformable on the San Pedro formation. It consists of 3,000 ft. of massive grey to black, fissile, micaceous shales, locally calcareous or gypsiferous, alternating with hard, fine-grained, buff to grey sandstone with local quartz or calcite stringers. Ironstone and pyritic concretions weather into characteristic red splotches. It is a productive horizon at Mene Grande and other fields.

The Paují shale is widespread over the Maracaibo Basin, in the south-western part of which it is known as the Sandy Shale horizon, a term which may include also overlying beds including Lower Miocene.

The Paují shale is correlated with similar deposits throughout Venezuela. It has been regarded as lower Oligocene, but on the basis of its *Foraminifera* it was stated by Nuttall [7] in 1935 to be Upper Eocene.

Carmen Group. In the lower Magdalena Valley and the west coast, Eocene formations which Anderson [1] in 1926 referred to locally as the Carmen, Arjona, and Tofeme-Coloso groups, and the San Sebastian cherts, consist of fossiliferous marine beds with intercalated coal deposits. He gives the following section at El Carmen on the Lower Magdalena.

TABLE VI

Eocene Sediments, Lower Magdalena

By F. M. ANDERSON

Clay shale, sandy clay shale, white siliceous shale, probably organic (not known to be the top)	1,000 ft.
Concretionary sandy shale, sandstone, &c., with molluscan fossils, *Foraminifera*, petrified wood, &c.	600 ,,
Yellow, thin-bedded sandstone, weathering red	400 ,,
Whitish shale, with lenses and thin beds of limestone, sandstone, &c. (Tofeme group, with thin beds of lignite and carbonaceous matter near bottom)	800 ,,
Earthy or hard, thin-bedded, siliceous shale, marly shale with limestone, containing molluscan fossils	800 ,,
Yellow concretionary sandstone	500 ,,
Heavy beds of sandy conglomerate (near Cansona)	400 ,,
Total	4,500 ,,

This section is the part equivalent of the strata described in 1921 by Beck [3] as the Palmito limestone, and by Werenfels [9] in 1926 as the Arroyo Seco formation and the Toluviejo series. The Arroyo Seco is described as conglomerate overlying black shale, and the Toluviejo as snow-white massive limestone with *Helicolepidina*, *Lepidocyclina*, *Nummulites*, and *Operculina*.

Guaduas Beds. Estuarine and lacustrine deposits in the central and upper valley of the Magdalena correlated with the marine Eocene, although possibly in part Oligocene, include the Guaduas beds named by Hettner [5] in 1892, and equivalent strata. They consist of 10,000 ft. of fossiliferous coal-bearing sandstone, shale, and eruptive rock which rest unconformably on the Guadalupe formation. The estuarine phase contains *Ampularia graduasensis*, n.sp., *Melanella magdalenensis*, n.sp., *Corbula Hettneri*, n.sp., *Cyrena Karsteni*, n.sp., and numerous plant remains.

Both the marine and non-marine Eocene formations contain much organic material and are highly petroliferous, containing numerous oil and gas seepages, asphaltic residues, mud volcanoes, and bituminous sands. It is the productive horizon and probably also the source rock at Las Infantas and other fields.

The Colombian Eocene is correlated with the Wilcox and Claiborne, and is the probable equivalent of the Third Coal horizon and the Mirador sandstone of the Maracaibo Basin. It lies unconformably on the Cretaceous and older rocks.

Oligocene.

San Luis Formation. The type locality of the San Luis formation is Sierra de San Luis in the State of Falcon. In the Maracaibo Basin it conformably overlies the Paují shale. It consists of massive, steel-grey, coralline limestone, dark shale, and coarse, grey, conglomeratic sandstone and conglomerate. It is widely distributed in the eastern part of the basin, where it has a maximum thickness of about 1,000 ft., but pinches out towards the west. The Maracaibo Basin exposures form the western part of a coral reef which reached its best development in the State of Falcon. Besides the abundant corals, it contains many *Lepidocyclina* and other fossils. It is regarded as Middle Oligocene, and is correlated with the Tamana formation of Trinidad.

Agua Clara Formation. The Agua Clara shales were named from their typical exposures near Santa Clara in the State of Falcon. In the Maracaibo Basin it is apparently conformable on the San Luis formation and is known from widely distributed outcrops and from well cuttings. It consists of 1,300 ft. of light grey, concretionary fissile, gypsiferous shales alternating with hard, flaggy, light grey, fossiliferous limestone of upper Oligocene age.

The Agua Clara formation is very petroliferous, and is the most important oil horizon of the basin. It contains two important horizons about 200 ft. apart known as the Santa Barbara and La Rosa sands, which are the producing horizons in most of the fields.

Poso Series. The Oligocene of Colombia is probably best known by the name of Poso Series, a term applied by Anderson [2] in 1929 to the entire sequence lying between the Eocene and known Miocene, including strata previously described as the San Juan group of the Magdalena Valley and the Bombo shales of the Rio Sinú. The term was suggested by the fact that this assemblage was being tested for petroleum. The type locality is the general region of the Rio Sinú at which place they unconformably overlie the Eocene, but in other places the Oligocene is missing entirely. Their thickness and character are shown in Table VII.

TABLE VII

Stratigraphic Section of Poso Series, Rio Sinú, Colombia

By BRUCE G. MARTIN

Alternating, hard, coarse sandstone and medium-grained sandy shale	1,000 ft.
Medium-soft, fine-grained, bluish-grey sandstone and clay, with some concretionary limestone lenses	1,500 ,,
Medium-coarse, hard, grey sandstone and medium-soft, blue or grey sandstone	900 ,,
Total	3,400 ,,

Unconformity.
San Sebastian cherts, &c. (Eocene).

He gives the following section in the Palomas Range, where the sediments show a more shaly facies.

An upper shale and sandstone member	1,500 ft.
A sandstone and grit member	2,000 „
A basal shale member	1,500 „
Total	5,000 „

The Poso series are not very fossiliferous, but their general stratigraphic position indicates that they are post-Eocene and in part or altogether pre-Miocene. They are the source of numerous seepages of oil and gas and of mud volcanoes.

Miocene.

Cerro Pelado Formation. The term Cerro Pelado is applied to an assemblage of rocks typically exposed in the eastern part of the Maracaibo Basin and in the State of Falcon. They conformably overlie the Agua Clara beds and include 4,000 ft. of thin, alternating, reddish-brown, flaggy, micaceous sandstone and mudstones in the upper part and massive, cross-bedded sandstones in the lower part. Their equivalent in the western part of the Maracaibo Basin has been included in the lower part of the Sandy Shale horizon.

Socorro Formation and First Coal Horizon. The Socorro formation of Falcon occurs in the eastern Maracaibo Basin. It lies conformably above the Sandy Shale horizon into which it grades, and consists of 2,000 ft. of micaceous, ripple-marked, and cross-bedded, lignitic sandstones, grey and brown micaceous shales, and a few calcareous beds. Its equivalent in the western part of the basin is included in the First Coal horizon which is productive in the Tarra and Los Manueles fields.

Damsite Formation. The Damsite formation was named from its typical exposure at a dam site on the Rio Coro in the State of Falcon. It is predominantly greenish and grey selenitic clay shale with interbeds of marly, fossiliferous, yellow to bluish-grey limestone, and is gradationally conformable on the Socorro formation.

Equivalent beds in the western and south-western part of the Maracaibo Basin are the Palmarejo beds, the Los Ranchos beds, and the Upper Shale horizon. The Palmarejo beds crop out on the western shore of Lake Maracaibo. They consist of 2,000 ft. of grey micaceous shales, arenaceous shales, and hard, grey, ferruginous sandstones. The Los Ranchos beds exposed on the eastern flank of the Sierra Perijá are made up of 4,000 ft. of conglomerates, conglomeratic sandstones, grey and brown, ferruginous, mottled sandstones, and clay shales. The Upper Shale horizon is a series of soft arenaceous shales and carbonaceous sandstones which crop out in the south-western part of the basin. The stratigraphic relationships of these beds are obscure, but the Upper Shale horizon, the Los Ranchos beds, and the Palmarejo beds are all probably the part equivalent of the Damsite formation.

La Villa Beds. The type locality of the La Villa beds is the town of that name in the western part of the Maracaibo Basin. They are apparently gradationally conformable on the Los Ranchos beds and together are sometimes referred to as the Arimpia formation. The La Villa beds consist of 2,500 ft. of conglomerates and vari-coloured mottled clay shales and cross-bedded and poorly consolidated sandstones. Their probable equivalent in the south-western part of the basin is known as the Guayabo formation, named from the Guayabo hills. It is locally unconformable on the Upper Shale horizon. Lithologically it resembles the La Villa, but contains several seams of coal.

Magdalena Valley. The Miocene of north-western Colombia also occurs in marine, brackish, and fresh-water facies. A marine section occurs along the coast and the lower Magdalena Valley, but becomes progressively less marine in character towards the highlands.

These strata have been described by various names with local significance. Beck [3] in 1921 described the basal Miocene as the Huertos limestone series consisting of limestone and sandstone, and the upper part as the San Antonio Sandstone formation. To the same section exposed at Toluviejo, Werenfels [9] in 1926 applied the names Cerrito formation and Savana sandstone.

The known Miocene of the lower Magdalena Valley was later divided by Anderson [2] in 1929 into two sections to which he assigned the names Las Perdices and Tuberá groups, and included with them as probably Miocene with the overlying Galapa–La Popa group.

Las Perdices Group. The Las Perdices group comprises 1,000 ft. of strata which appear to be in the basal part of the lower Magdalena Miocene. It consists of clay shales, sandy shales, and hard cherty, or siliceous beds and some sandstone, and contains a few Mollusca and many *Foraminifera.* This same horizon at Toluviejo and Sincelejo contains notable amounts of sandy limestone.

Locally the lowest known Miocene shows an unconformable relationship to the Pozo series, although it is not certain that this unconformity occurs at the contact of the Oligocene and the Miocene, or that it is general or important.

Tuberá Group. The term Tuberá group was used for the overlying sequence which crops out typically in the vicinity of Tuberá. It consists of 2,650 ft. of incoherent sandstones and sandy shales, and constitutes the most widely distributed and the more usual facies of the Colombian Miocene. It overlies the Las Perdices group with apparent disconformity. It is highly fossiliferous. Many of its fauna have been figured and described by Anderson who correlates its middle upper part with the Gatun formation.

Galapa–La Popa Group. Overlying the Tuberá group with apparent conformity is a sequence of beds, portions of which have been termed the Galapa, La Popa, Arbolete, and Escondido groups, usually regarded as Pliocene. Anderson [2] in 1929 considered them as probably Upper Miocene, in part at least, and conformable on the Tuberá group. They consist of sandy shales, clays, marls, and calcareous sandstone, 1,500 ft. or more thick, and carry an abundant marine fauna with *Pecten, Dosinia,* and *Cardium.*

Barzalosa Beds. The non-marine Miocene of the central upper parts of the Magdalena Valley were named the Barzalosa beds in 1918 by Scheibe [8]. They and their probable equivalent, the estuarine Oponcito series, consist of red conglomerate, tuffaceous sandstone, and carbonaceous shale, in places 3,500 ft. thick. They are unconformable on the older formations. In places the entire Oligocene is absent, and they rest upon the Eocene.

The Miocene beds of Colombia are low in organic content and are not important as source rocks. They are, however, petroliferous in places and appear to be possible reservoir sands where favourable structural conditions obtain.

Pliocene.

Maracaibo Basin. The early Pliocene appears to have

been a period of uplift and erosion, followed by marine and fluviatile deposition. In the Maracaibo Basin the Mene Grande series has a thickness of 1,200 to 4,800 ft. and unconformably overlies the Miocene and older formations. It consists of mottled clays with a few lenticular bodies of sand, non-fossiliferous except for a few *Foraminifera*. The overlying El Milagro beds are ferruginous, sandy, micaceous clay and loosely consolidated, cross-bedded sands with silicified wood.

Lower Magdalena Valley. In Colombia the Pliocene consists of marine and non-marine deposits which are apparently unconformable on all the older formations. Near Barranquilla and Cartegena they are represented by coralline limestones and sandstones. Anderson [2] published the following sequence in 1929.

TABLE VIII

Pliocene Strata between Puerto Colombia and Salgar, near Barranquilla

By F. M. ANDERSON

Upper coral limestone	250 ft.
Incoherent sandstones	350 „
Lower coral limestone	160 „
Sandy clay shales	150 „
Total thickness	910 „

The limestones contain corals and mollusca including *Cyprea*, *Codakia*, *Pecten*, oysters, and gastropods.

Honda Beds. The Honda beds are composed of greenish-grey andesitic tuff, tuffaceous sandstone, clay, and conglomerate which unconformably overlie the Barzalosa and older formations in the Upper Magdalena Valley. Their stratigraphic position suggests that they are Pliocene.

The Pliocene strata are in places highly petroliferous. The Honda beds contain bituminous sands and oil seepages, and oil and gas seepages with sulphurous water are found also in the Pliocene deposits of the coast. The Mene Grande series is petroliferous and has produced some oil.

ECUADOR

By H. G. BUSK, M.A., F.G.S., M.Inst.P.T.

Geologist

PETROLEUM in commercial quantities has been proved to exist in Ecuador on the west coast in the Santa Elena Peninsula, on the western side of the great estuary of the River Guayas (Fig. 1). It occurs in rocks of the same age and of similar lithology as those of Peru, namely, in Eocene and Oligocene clays and sandstones. Exact correlation, even for short distances, is extremely difficult, owing to the shattered and crushed nature of the country, the rocks of which may be regarded as forming a great tectonic breccia, the geological units of which may be of microscopic size or up to 3 and 5 miles across. This is further complicated in Ecuador by the intrusion of dolerites during the time that these disturbances were taking place.

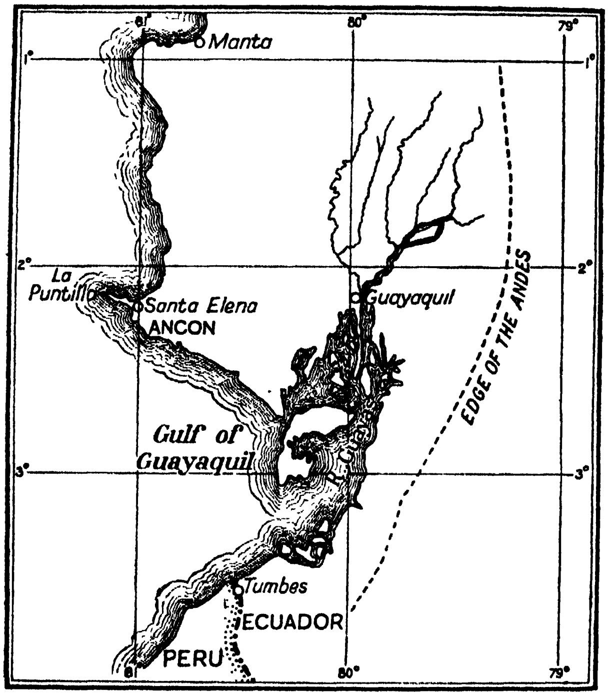

FIG. 1.

The Peninsula of Santa Elena, from which petroleum is at present being successfully produced, may be divided into two parts (Figs. 2 and 3):

(1) The southern part, which is occupied by rocks whose dips are generally less than 10° at the surface, but which are none the less greatly disturbed by tear faults and low-dipping planes of movement.

(2) The northern part, in which dips are seldom less than 70° (generally in a southerly direction), and where intruded dolerite is involved intimately with the disturbed beds, and is itself crushed and brecciated.

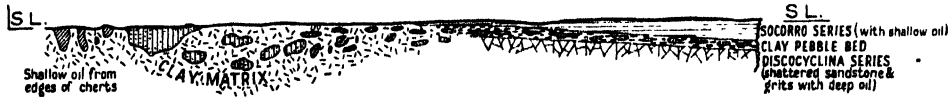

FIG. 3. General section through the Santa Elena Peninsula. The fragments of sandstone in the clay matrix of the northern area are believed to be mostly of Oligocene age, while the Socorro Series is Eocene. The exact relationship between the northern and southern areas is still obscure.

In the *southern part* of the peninsula, occupied by the Ancon oilfield, commercial oil, varying between 36° and 42° Beaumé, and containing between 30% and 70% gasoline, is found in two zones.

'Shallow oil' is found from the surface to 1,000 ft. in a series of alternating clays, silts, and sands (Socorro Series, Upper Eocene). Fossils are rare, apart from abundant *Foraminifera*, the chief of which are: *Lepidocyclina peruviana, Helicolepidina polygyralis* [8, 1932], *Operculina oculana*. The oil found in these rocks has a naphthene base, and is termed 'low cold test', being rich in lubricants. This property is ascribed to the oil's proximity to the ground surface.

'Deep oil' is found from 2,500 ft. to 3,500 ft., and is produced from a series of massive non-porous sandstones and grits, of which over 1,000 ft. have been proved. The oil is contained in fissures in the sandstones, which are shown by the core-taker to be highly brecciated. The age of this series, which at the top yields abundant *Foraminifera* is probably Upper, but may be Middle Eocene. Two

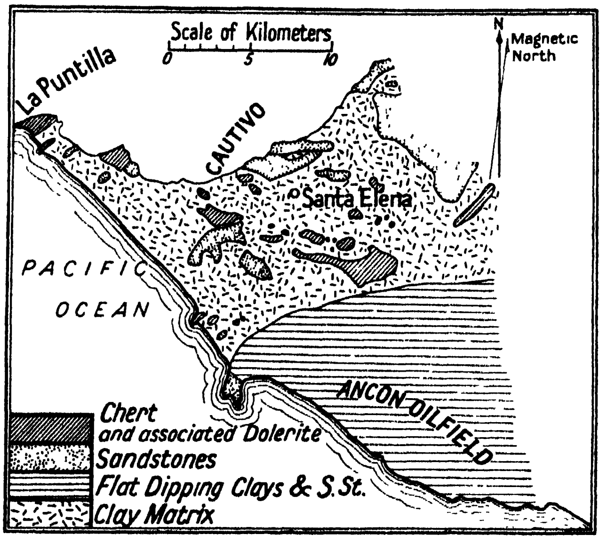

FIG. 2. Map of the Santa Elena Peninsula, showing distribution of sandstones and cherts in the clay matrix of the northern area, and the extent of the flat dipping rocks of the Ancon oilfield.

species of *Discocyclina*, *D. anconensis* and *D. sheppardi*, which do not occur elsewhere [8, 1932], have led to the adoption tentatively of the term 'Discocyclina Series' for these rocks. The oil is 'high cold test' and has a paraffin base.

Between these two series is a formation known as the 'clay pebble bed', whose origin has given rise to considerable controversy. It is barren of oil, and separates sharply the 'low' and 'high cold test' types of the shallow and deep zones. It varies rapidly in thickness, in one place from 100 to 1,300 ft. in less than a kilometre, and consists of a matrix of formless compacted clay, which breaks across slickensided surfaces; this matrix contains pebbles of many kinds, but chiefly of quartzite or of clay, the latter being well rounded and with a slickensided or shiny surface. There is no doubt that this rock resembles an old surface landslip breccia, but from the widespread occurrence of similar rocks, both in a lateral and a vertical sense, and both in Ecuador and Peru, and from its general environment, it is beginning to be agreed that the formation is a breccia, lying between two series, which have moved relatively the one to the other.

The clay pebble bed contains fossils identical with those of the Socorro Series, with the addition of *Operculina wilcoxii*, and, in places, a fauna, associated with the beds immediately below it, appears 50 ft. above its base. It seems that the Socorro and Discocyclina Series may be regarded as tectonic units in the great coast breccia, and that the clay pebble bed is a modified form of the general matrix.

In the *northern part* of the peninsula an attempt has been made to separate the main sandstone units of the great crush breccia, the intervening material being classed together as 'clay matrix'. It is to be noted, however, that 'units' can be separated from the matrix right down to the size of pebbles and much smaller. The intrusions of dolerite, too, or the hot vapours associated with them have given rise to great masses of chert, which are now proved to be thermally altered clays of Tertiary age. These cherts and dolerites were also involved in the movements, which created the breccia.

The petroleum in the northern part of the peninsula is closely associated structurally with the dolerite intrusions and the cherts, though there is no evidence to show that they are connected with its origin. It appears that, as the dolerites were intruded, the petroleum was vaporized near the hot nucleus, and condensed on the edges of the zone of metamorphism. Thus it may be found in productive quantities in porcellanites, which are an intermediate form of alteration round the edges of the cherts. Wells drilled round these chert masses yield petroleums of great variety, some of 42° Beaumé with 60% gasoline, and others of a heavy type, but rich in lubricating fractions. The occurrence of petroleum is, however, again greatly complicated by the earth movements, and no case has yet been proved in the peninsula where a dolerite or a chert can be shown to be in its original place of contact with a clay or a sandstone. A very common form of contact between the dolerites and the clay is, for instance, where fragments of the harder rock have been stripped off and rolled into the clays in the form of boulders.

The Tertiary rocks of the whole area are largely masked by raised sea terraces, known as Tablazos, and little could have been worked out without some knowledge of the Peruvian coast, near the Negritos and Lobitos oilfields.

It is natural that, in a region so complicated, there should have been and still is considerable controversy regarding both stratigraphy and structure. Thus Cunningham Craig [4, 1920] regarded the cherts of the peninsula as 'oceanic strata' of Cretaceous age', and inferred from this a striking illustration of the downward migration of petroleum. Later observers are agreed that the cherts are altered Tertiary shales [5, 1926; 7, 1923]. Barrington Brown and Baldry in an original survey regarded the clay pebble bed as a tectonic breccia [1, 1925], while Sheppard regards this formation as a true clastic [6, 1927]. A general comparison with Peru is desirable. Bosworth gives a clear picture of the crushed and brecciated state of the oilfields region of that country. 'The land surface', he says [2, 1922], 'is divided up into long triangles and elongated quadrilaterals outlined by faults of considerable displacement. The larger blocks are further cut up into many parts by smaller faults.' And he adds [3, 1922]: 'There is no folding in the Tertiary, but the earth's crust is so intensely broken up by faults as to resemble a giant crush breccia.'

Recent research in the two countries may well provide a number of new theories on tectonics, which may also be applicable to the oilfields of the North American continent of the Pacific Coast.

THE ARGENTINE REPUBLIC

By ENRICO FOSSA-MANCINI, Ph.D.

Buenos Aires

I. General

OUR knowledge of the distribution of petroleum in the Argentine is necessarily incomplete and imperfect. The Argentine has an area more than twelve times greater than that of Great Britain, whilst Great Britain has almost four times as many inhabitants as the Argentine. Until 12 or 15 years ago, most of the geological studies were carried out during long journeys on horseback and had mainly the character of preliminary reconnaissance work.

The thick mantle of Quaternary deposits which covers nearly one-half of the country, the subtropical and tropical forest in the north-east, the predominance of continental conditions since Carboniferous times, the rather uniform facies of the continental formations, their scanty fossil content, and, moreover, the frequent lack of a sure correlation of such fossils with the well-known faunas and floras of the northern hemisphere are some of the difficulties encountered in exploratory work.

II. Geographical

Politically the Argentine is a Federative Republic, composed of fourteen States called 'Provincias', which enjoy a certain autonomy, and ten territories, called 'Territorios Nacionales' or 'Gobernaciones', which depend directly upon the federal Government.

The names and the disposition of these provinces and territories are shown in Fig. 1.

Actually there are producing oilfields in the provinces of Salta and Mendoza and in the territories of Neuquén and Chubut: in the province of Jujuy and in the territory of Santa Cruz, oil and gas have been found by drilling. In the territory of Rio Negro wells drilled near an oil seepage have not found oil in commercial quantities, whilst in the territory of La Pampa an interesting oil seepage is known.

In the province of Santa Fé, without any surface indication of petroleum, two wells have found small shows of oil at considerable depths.

The most southerly indications of petroleum in this continent have been found in the Chilean territory of Magallanes, in the neighbourhood of Punta Arenas, nearly midway between two Argentine territories (Santa Cruz and Tierra del Fuego). Wells were drilled there and it was reported that they gave gas and a little oil.

The highest surface indication of oil in the Argentine is the oil seepage at Barro Negro de Tres Cruces (also known as Tejadas) in the Puna of Jujuy, more than 10,000 ft. above sea-level. The highest producing oilfields are those of the Mendoza province (4,000 to 5,000 ft.) and that of San Pedro y San Pablo in the province of Salta (about 3,200 ft.).

The lowest producing oilfield is that of Comodoro Rivadavia, where the deepest oil-producing horizons have been found nearly 2,500 ft. below sea-level. The deepest oil traces have been found in this oilfield at about 5,500 ft. below sea-level.

The approximate geographical location of the proven or prospective oilfields and of some exploratory wells and oil seepages of major importance are given below:

	Province or territory	*Latitude*	*Longitude*	
Lomitas-Vespucio-Tranquitas	Salta	22° 33′–22° 40′	63° 53′–63° 59′	producing oilfield
Deshecho Chico	,,	22° 41′	62° 26′	oil seepages
Aguas Blancas	,,	22° 44′	64° 20′	producing oilfield
Rio Pescado Y.P.F. 3	,,	22° 54′	64° 27′	oil-well
Barro Negro de Tres Cruces	Jujuy	22° 56′	65° 39′	oil seepage
Santa Cornelia	,,	23° 45′	64° 26′	oil seepage
Y.P.F. JE. 1	,,	23° 48′	64° 26′	exploratory well
Laguna de la Brea	,,	23° 50′	64° 26′	oil seepage
Garrapatal	,,	24° 5′	64° 55′	oil seepages
San Pedro FF.CC.E. 1	,,	24° 8′	64° 54′	abandoned oil-well
San Cristobal Y.P.F. 1	Santa Fé	30° 18′	61° 14′	exploratory well
Cacheuta	Mendoza	33° 5′–33° 7′	69° 4′–69° 6′	productive oilfield
Tupungato Camp	,,	33° 20′	69° 3′	new oilfield

Ñirihuau Y.P.F. 2	Rio Negro	41° 17′	71° 11′	exploratory well
Comodoro Rivadavia	Chubut	45° 40′–45° 54′	67° 22′–67° 50′	producing oilfield
Pampa del Castillo T. 2	,,	45° 47′	68° 4′	exploratory well
Cañadón Lagarto L. 4	,,	45° 42′	68° 10′	exploratory well
Cerro Abigarrado A. 4	,,	45° 49′	69° 3′	oil-well
Sierra San Bernardo A. 5	,,	45° 57′	69° 32′	exploratory well
Pampa Maria Santisima A. 1	Santa Cruz	46° 1′	69° 20′	gas-well
Chenque Bayo N. 1	,,	46° 18′	69° 6′	exploratory well

Some of these localities are shown (with the limitations imposed by so small a scale) in Fig. 2.

III. Stratigraphical

It is known that continental conditions prevailed generally throughout geological time on that part of the earth's crust which corresponds to the territory of the Argentine Re-

public. However, these continental conditions were interrupted by marine transgressions of moderate extent, during which the sea invaded one or another region (never extending over the whole country) in several epochs of the Older Palaeozoic and Devonian (northwestern Argentine), the Late Trias, Jurassic, and Older Cretaceous (Salta, Jujuy, southern Mendoza, Neuquén, western parts of Chubut, and Santa Cruz), the Newer Cretaceous (southern Mendoza, southwestern Pampa, north-eastern Neuquén, Rio Negro, eastern parts of Chubut and Santa Cruz, northern Tierra del Fuego), and the Middle Tertiary (certain parts of Santa Fé, Corrientes, Entre Rios, Buenos Aires, Rio Negro, Chubut, Santa Cruz, and Tierra del Fuego).

Some of these marine transgressions are of doubtful age, the marine fossils of the 'Horizonte Calcáreo' of Salta and Jujuy having been referred to the Triassic, to the Jurassic, and to the Cretaceous by different authorities.

In the Argentine petroleum is found in rocks of various ages, younger than the Devonian. The following are several examples:

Quaternary, continental: oil seepages in alluvial deposits of Santa Cornelia, Laguna de la Brea, Laguna Llancanelo.

Upper Tertiary, continental: oil-bearing sands of Tupungato.

Middle Tertiary (or older), continental: oil seepage of Ñirihuau, many beds with shows of oil and gas penetrated by the two deep holes drilled there.

Lower Tertiary or Upper Cretaceous: oil and asphalt of Cerro Alquitrán.

Upper Cretaceous, marine: oil seepage and bituminous outcrops of Barda Baya. Upper productive horizons of the Comodoro Rivadavia oilfield.

Upper Cretaceous, continental: oil seepages of Challacó; asphaltite veins of Aucá Mahuida; main productive horizons of the Comodoro Rivadavia oilfield; oil-bearing beds penetrated by exploratory wells in Pampa de Castillo, Cerro Abigarrado, Pampa Maria Santísima, and Chenque Bayo.

Lower Cretaceous, marine: some of the oil seepages of Rio Barrancas.

Upper Jurassic, marine: oil seepages of Ranchitos and Cerro Lotena.

Upper Jurassic, continental: oil-producing horizons of Plaza Huincul.

Lower Jurassic, marine: oil seepage of Barro Negro de Tres Cruces and Garrapatal, productive horizons of well

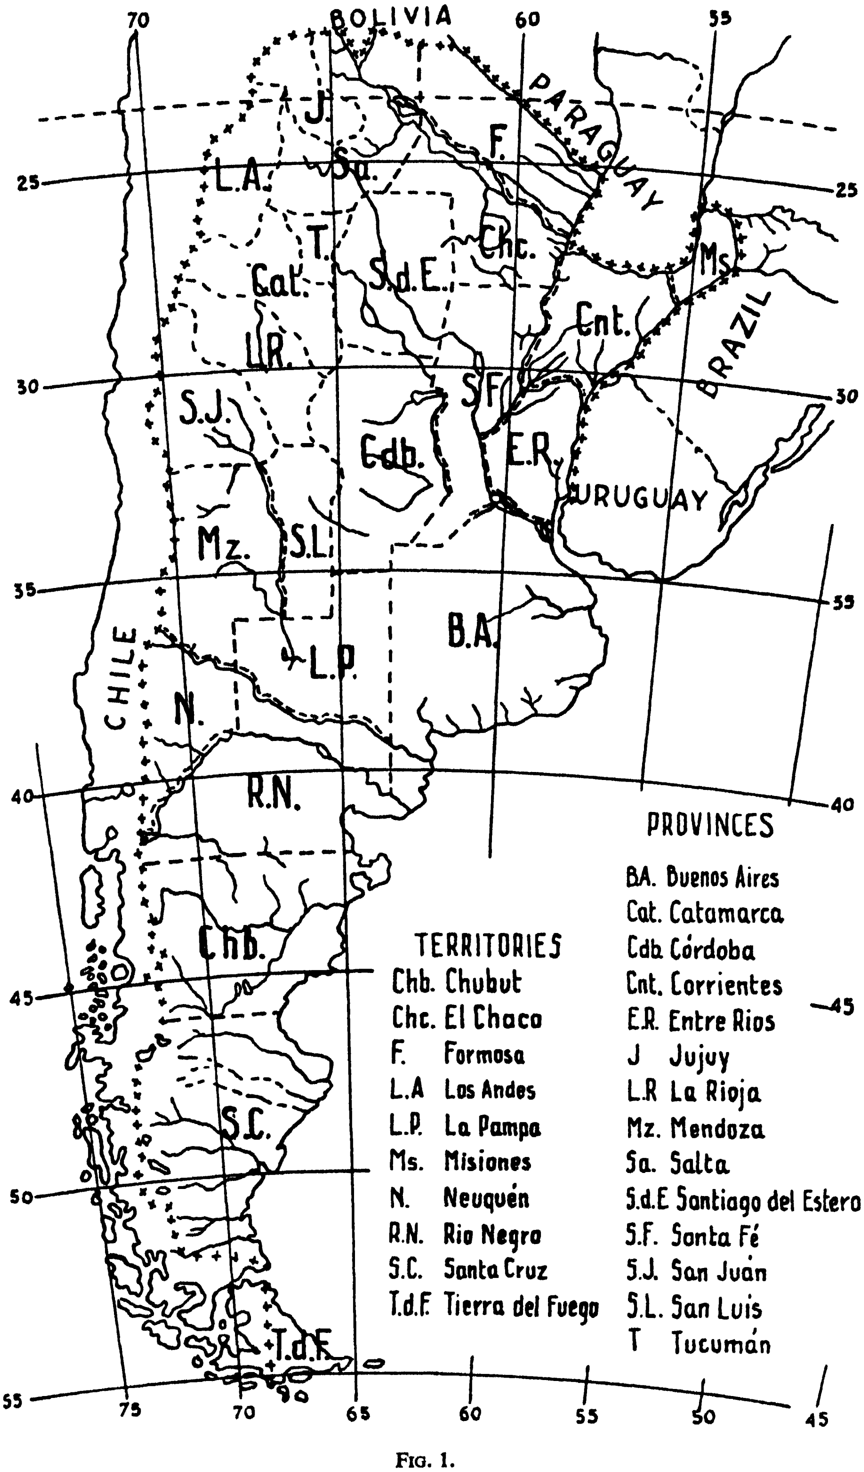

FIG. 1.

Y.P.F. JE. 1, uppermost oil-bearing beds of Tranquitas, oil seepage in the Mina Matilde.

Uppermost Triassic (*Rhaetic*), continental, lacustrine: productive horizons in the oilfield of Cacheuta.

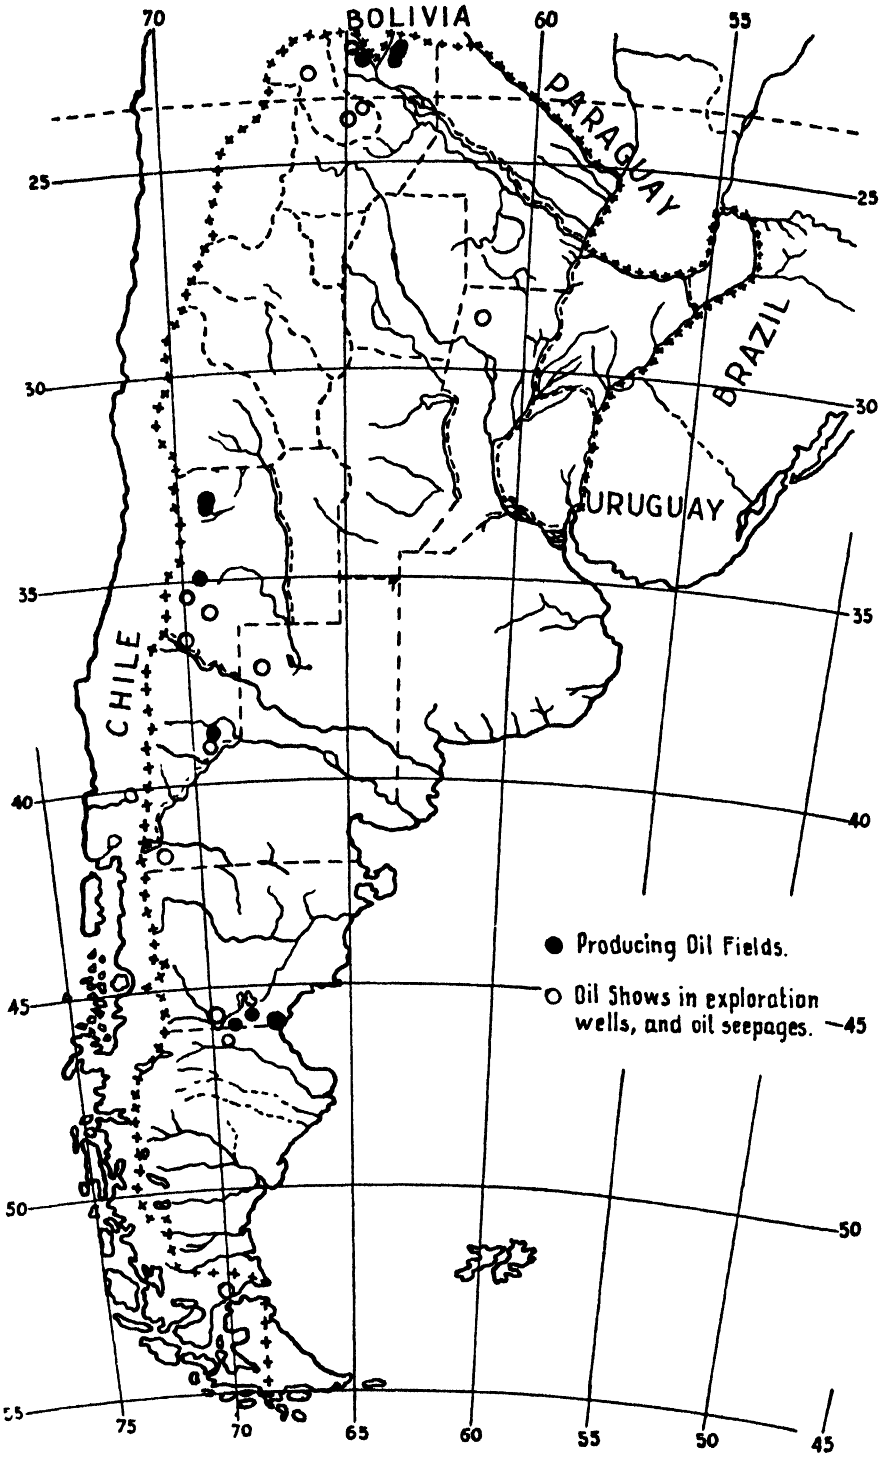

FIG. 2.

Triassic, continental: light oil-shows found in the wells of San Cristobal.

Triassic, continental, and *Permian*, continental and partly glacial: main productive horizons in the oilfields of Salta province.

It is apparent that in the Argentine oil is found chiefly in continental beds. In the oilfield of Cacheuta and in its surroundings no marine formation is known; the Rhaetic bituminous shales with *Estheria*, considered as the probable source rock, may have been deposited in a desert lake or in a coastal lagoon, whose salinity approached or even exceeded that of the oceans.

In the oil-bearing continental formations of Comodoro Rivadavia and Plaza Huincul, petrographers have found a few horizons with dwarf *Foraminifera* which seem to indicate estuarine conditions.

In the small Cerro Alquitrán oilfield, oil accumulations are intimately associated with intrusive magmatic bodies (andesite, supposed of Early Tertiary age). Also in several other regions (La Pampa, Rio Negro, Chubut, and Santa Cruz) accumulations or indications of petroleum have been found very near to intrusive magmatic masses, dykes, and sills.

The stratigraphical sequence is often difficult to determine because of the vertical uniformity and the horizontal variability so common in continental formations. Another common feature, cross-bedding, not infrequently obscures the true attitude of the strata, so that it can be, and has been, a serious source of error.

There are large gaps in the stratigraphical sequence and, therefore, there are many unconformities and disconformities; these render especially difficult the work of the petroleum geologists in the Plaza Huincul oilfield, where there are at least three marked unconformities between the surface of the ground and the oil-bearing beds.

IV. Lithological

In the oilfields of the Argentine, limestones are very poorly developed and volcanic tuffs are very abundant; sometimes these tuffs have been altered to bentonites, but almost always they behave physically as shales.

Sands are mostly medium or fine-grained, often somewhat clayey; in some oilfields the reservoir rock is a rather well cemented sandstone.

V. Structural

Simple anticlines or simple domes: the writer knows of no example of these among the Argentine petroliferous structures. Certain assumptions of simple folded structures, made at an early stage of the development of the oilfields of Salta and Chubut, have since proved to be

erroneous as a result of more information obtained by drilling.

Faulted anticlines: all the producing oilfields of the province of Salta; the anticlines of Tupungato, Ñirihuau, Pampa Maria Santísima, &c.

Faulted monoclines: Cacheuta oilfield; surroundings of the Barda Baya de Puelén.

Faulted tabular structures: Comodoro Rivadavia oilfield.

Complex structures with magmatic intrusives: Cerro Alquitrán oilfield.

Complex structures with buried hills: Plaza Huincul oilfield.

Obscure tectonic conditions, probably related to faults bounding a tectonic trough: Garrapatal.

VI. Production

From 1887 to date more than 4,000 wells have been drilled for oil in the Argentine; the proportion of dry holes has been very low, but few wells have yielded a high initial production, say, of more than 500 bbl. a day even at the commencement. On the other hand, several wells of moderate initial production have had rather long lives, so that their total production has been satisfactory.

In the province of Salta development began in 1925; at the end of 1934 there were 258 holes drilled, with a total production of about 6,150,000 bbl.; production for the year 1934 was a little more than 2,000,000 bbl.

In the province of Mendoza production began in 1887, but data were not available until 1926; the production from 1926 to 1934 was nearly 200,000 bbl.; production for 1934 was about 53,000 bbl., and the total number of wells drilled was more than 60.

In the territory of Neuquén 450 wells had been drilled up to 1934, and the total production from 1918 to 1934 was about 10,000,000 bbl.; production for the year 1934 was a little more than 1,000,000 bbl.

In the territory of Chubut the number of holes drilled between 1907 and 1934 exceeded 3,100, and the total production for this period was nearly 106,000,000 bbl.; the production for the year 1934 approached 11,000,000 bbl.

Up to the end of 1934 the total production of the Argentine oilfields had exceeded 120,000,000 bbl.

Oil-producing Companies.

Dirección General de Yacimientos Petrolíferos Fiscales (Argentine Government Oilfields, locally known as 'Y.P.F.'), in Salta, Mendoza, Neuquén, and Chubut.

Standard Oil Company of Argentine and its subsidiaries: in Salta and Neuquén.

Astra: in Neuquén and Chubut.
Rio Atuel Company: in southern Mendoza.
Diadema Argentina: in Chubut.
Compañía Ferrocarrilera: in Chubut.
Compañía Industrial y Comercial: in Chubut.
Compañía Solano: in Chubut.

Exploration in search of Oil.

Dirección General de Y.P.F. Geological and geophysical surveys: in Salta, Jujuy, Mendoza, Neuquén, and Chubut. Geological only: in Tucuman, Catamarca, La Hioja, San Juan, La Pampa, Rio Negro, Chubut, and Santa Cruz. Geophysical only: in Santa Fé; exploratory wells in Salta, Jujuy, Santa Fé, Mendoza, Neuquén, Rio Negro, Chubut, and Santa Cruz.

Oil Companies (so far as is known to the writer). Geological and geophysical surveys in Salta, Jujuy, and Neuquén; geological surveys in Tucuman, Mendoza, Neuquén, Chubut, and Santa Cruz; exploratory wells in Salta, Jujuy, Tucuman, Mendoza, Neuquén, Rio Negro, Chubut, and Santa Cruz.

AUSTRALIA

By W. G. WOOLNOUGH, D.Sc., F.G.S.
Geological Adviser to the Commonwealth of Australia

THE continental mainland of Australia is roughly elliptical in shape and has an area of 2,948,366 square miles. It lies between 11° and 38° south latitude, and 113° and 154° east longitude, approximately. Tasmania is south of the mainland and embraces an area of 26,215 square miles. New Guinea, the eastern half of which is under the control of the Commonwealth, lies to the north of Australia.

Broadly speaking, the geological structure of Australia is marked by the existence of three 'oldlands' separated by two geosynclines filled with little altered sediments of Later Palaeozoic, Mesozoic, and Tertiary age. Of course, each of these units is composite, geosynclines including minor 'oldland' elements and vice versa. Fig. 1 gives a highly generalized idea of the distribution of these structural elements.

At the time of writing (December 1934) the production of petroleum products in Australia is commercially negligible. The search for oil and gas has been carried on with more or less vigour for some 25 years, and minor discoveries have been made.

The great world belt of alpine folding, along which are found many of the world's oilfields, misses Australia completely. Passing through the Malay Peninsula, Dutch Indies, New Guinea, and New Zealand, it swings round Australia like the grain in a board swings round a knot in the timber.

The Australian Tertiaries are very little disturbed and altered, precluding the possibility of discovery of oilfields of the Californian–Central European–East Indian type on the mainland. This does not, however, in any way lessen the probability of the existence there of other fields of the types met with in the mid-continent region of U.S.A., in Argentina, and in the Ural Mountains.

Since the alpine folding passes through New Guinea and Papua, the possibilities of the discovery of Tertiary fields in those Territories are high.

Tectonically, the mainland of Australia has experienced no considerable orogenic movement since the close of Palaeozoic time, and only in the coastal portions of Queensland has mountain building been noteworthy since early Palaeozoic time. Generally speaking, orogeny has been progressively more recent from south to north and from west to east. In the southern and western regions even pre-Cambrian formations are little mineralized and metamorphosed. In eastern Australia all rocks older than Carboniferous (with some exceptions) are altered and mineralized and do not enter into consideration as potential source or reservoir rocks for oil.

Although in the western half of Australia the latest granitic injections are not newer than earliest Cambrian, and although Proterozoic formations are lithologically and structurally very little altered, the probability of the existence in them of petroleum is very remote. In Elcho Island (136° E., 12° S.) and in some other parts of the Northern Territory inspissated oil has been met with on shore-lines filling joints in Proterozoic sediments. Its autochthonous origin is, however, very unlikely.

Fossiliferous Cambrian sediments, marked by considerable thicknesses of limestone, are widely distributed chiefly in South Australia and the Northern Territory. Earth movement and consequent alteration in South Australia have removed these formations from the category of potential oil producers, and, even in the north, their high geological antiquity leaves room for grave doubts as to the possibility of oil retention, even though, from the points of view of structure, lithology, and organic content, they compare more than favourably with many of the producing formations in other continents.

In the Ord River region of Western Australia and the Northern Territory (about 129° E., 17½° S.) there is an extensive Cambrian basin within which the rocks have suffered so little compression as to leave the richly fossiliferous argillaceous members almost unconsolidated. Sub-horizontal Proterozoic sediments containing obscure fossils are overlain by a thick series of basalts, most or all of which appear to have been surface lava flows. The fossiliferous Cambrian sediments rest on these lavas. Along the northern edge of the basin the topmost highly vesicular member of the basalt series has its pores filled with impsonite which has been proved by Simpson to be unquestionably inspissated asphaltic petroleum. Reports of the occurrence of *plastic* bitumen have not been objectively confirmed by submission of samples to official investigation.

A bore sunk in this area failed to bring to light any definite evidence of petroleum. This is not regarded as conclusive negative evidence, since aerial observation suggests that the drilled area was less suitable, by reason of faulting, than it appeared to be from ground survey alone. Reconnaissance aerial observation shows that there exist within the Cambrian geosyncline quite promising gently domed structures. These are worthy of closer investigation, even allowing for the hoary antiquity of the formation.

The origin of the bitumen has been variously explained. Blatchford has suggested that it was formed by distillation from the Proterozoic (or Cambrian) sediments underlying the basalts. Wade and Mahony believe that it is derived from the overlying fossiliferous Cambrian formations. The writer, during a single brief and rudely interrupted visit to the locality, saw at least one dyke or sill intrusive into the Cambrian limestones, and suggests that the very local development of the bitumen has been caused through distillation by a very late and very local basalt intrusion into the limestone material very soon after its deposition.

An enormous development of fossiliferous Cambrian sediments, little affected by earth movement, is met with in the Barkly Tableland of eastern Northern Territory and north-western Queensland (136–9° E., 18–23° S). The region is very sparsely settled and little geological investigation has been carried out. Sub-artesian water has been struck by drilling without any indication of oil coming to light. The age of the formation is against its being petroliferous, but lithologically and structurally it calls for some further investigation.

developed in eastern Australia, have mostly been extensively metamorphosed and mineralized, constituting the country rocks of the goldfields to a large extent. In the south-eastern corner of the Northern Territory there is known to exist a considerable extent of little disturbed and highly fossiliferous Ordovician formation. While it does not seem very probable that these very old formations are likely to be petroliferous in areas where they have been exposed for long geological periods, the freedom from alteration of the Cambrian and Ordovician formations in the western portion of Queensland may have an important bearing on the presence of oil and gas in the Mesozoic formations which overlap them over vast areas to the east and south-east. Such a condition is closely analogous to the structure of the producing fields of parts of Oklahoma and Texas.

In the Burdekin River Basin of Queensland (145° E., 190° S.) a major development of fossiliferous Devonian beds, although mostly too much indurated and altered for oil development, may repay investigation. Similar rocks must be expected to form part of the basement of the Great Artesian Basin, and, as suggested for the Cambrian and Ordovician, may contribute their quota to the oil indications encountered in the Mesozoic beds there.

Carboniferous formations in eastern Australia are mostly excluded from consideration as potential source beds by reason of their induration and folding.

It is, however, with the Permo-Carboniferous series (Kamilaroi Series) that we encounter conditions which may be regarded as distinctly favourable for oil genesis and retention. Comprising great thicknesses of marine sediments, intercalated with fresh-water coal-measures and, at certain horizons, with glacial formations, the rocks of this system occupy wide and deep geosynclines especially in parts of Western Australia, Queensland, and New South Wales. In many places the edges of these geosynclines are overlapped by fresh-water Mesozoic strata, so that the extent of the potentially petroliferous Kamilaroi system must be regarded as much greater than is indicated by its outcropping positions.

In south-eastern Queensland and north-eastern New South Wales rocks of this age have been considerably folded and mineralized; but usually alteration and contortion are moderate or negligible. Developments of this formation in Tasmania, Victoria, South Australia, and southern Western Australia, though highly interesting and economically important in many ways, may be omitted from detailed consideration in the study of potential oil areas.

The most extensive, and probably at the moment most promising, area of Kamilaroi rocks is that constituting the 'Desert Basin' in north-west Western Australia (121–8° E., 17–23° S.). The bulk of it is entirely unexplored, but some of the most intensive oil search in Australia has been concentrated in its north-eastern corner, along the valley of the Fitzroy River. Numerous bores have been sunk and blebs of bitumen and small amounts of oil have been obtained in several of them, just sufficient to suggest that the formations are definitely petroliferous. Ground surveys and aerial photographic survey have proved the existence of many domal structures, some of them of large dimensions, and it is anticipated that there will be a renewal of active prospecting operations in the near future.

The stratigraphical correlations of the various stages in this region with those in the better known areas of eastern Australia are incomplete. There appear to be a lower limestone series and an upper sandstone series. Most of the drilling has been done, on the cores of domal structures, in the sandstone members. Few adequate cover rocks have been encountered.

A second extensive basin of Kamilaroi rocks in Western Australia occupies portions of the basins of the Lyndon, Minilya, Gascoyne, Wooramel, and Murchison Rivers (114–16° E., 23–8° S.). The region is an arid one, difficult of access, and has not been examined in any detail, for the most part. An area on the Wooramel has been closely surveyed, but appears to be too limited and too much faulted to offer much promise of commercial success. It is noteworthy that a bore sunk here for water yielded brine under a hydrostatic head of about 1,800 ft., pointing to the competence of the cover rocks.

A smaller basin on the Irwin River (116° E., 29° S.) reveals an anticlinal structure, but has not given any evidence of being petroliferous. Here again sub-artesian waters are saline.

All the Western Australian Kamilaroi basins have contemporaneous glacial boulder beds strongly developed.

Kamilaroi formations in the Northern Territory have not been examined at all exhaustively, but do not appear very attractive from the point of view of oil search.

Kamilaroi basins in Queensland are extensive and important. Smaller trough faulted structures like several in Cape York Peninsula, may be neglected for present purposes. Larger geosynclinal areas, however, are of outstanding importance in relation to oil possibilities.

Reid has shown that, east of a line running roughly parallel with the coast, and approximately through the intersection of 151° E. and 26° S., newer Palaeozoic and older Mesozoic formations are considerably compressed and indurated. While it yet remains to be proved, it seems likely that earth movement in this sector has been somewhat too severe to favour retention of oil supplies. West of what may be called 'Reid's Line', earth movement has been much less intense, and lithology and structure are much more favourable than they are farther east.

The whole of south-western Queensland, the north-western part of New South Wales, and a section of north-eastern South Australia are occupied by the geosyncline of the Great Artesian Basin, filled with Mesozoic sediments. On the eastern border of this basin, *and disappearing beneath it*, are some of the most important of the Kamilaroi basins. Special attention may be drawn to the Dawson and Mackenzie River Basin (147–50° E., 21–6° S.) and the Springsure Basin (148° E., 23½–5° S.). In both of these a full suite of marine and fresh-water sediments is developed, richly fossiliferous, and in the former case coal bearing; lithologically they are eminently suitable as source and reservoir rocks for oil. Except in their coal-bearing portions these formations have not been adequately prospected, though they have been geologically surveyed in considerable detail. No seepages or other evidences of the presence of oil have been brought to light in their outcropping portions up to date.

Although crossed by considerable faults, the Springsure area has been shown to possess highly promising domal structures, and test drilling is called for. Of still greater importance, however, is the fact that this anticlinal axis plunges southwards under the mantle of Mesozoic formations in the Great Artesian Basin, and, if continued, must pass not far from Roma (146° E., 29½° S.), where the most outstanding evidences in Australia of gas and oil have been met. There is no reason to deny the probability that similar geosynclines of Kamilaroi sediments form part of

the basement of the Great Artesian Basin in other places, and there is strong presumption that such covered basins, analogous to the deeper structures of Oklahoma and Texas, may be the source of the petroleum definitely recognized in bores in the Great Artesian Basin.

A very extensive and important Kamilaroi geosyncline extends along the New South Wales coast from Port Stephens (152° E., 33° S.) to near Bateman's Bay (150¼° E., 35¾° S.) and back in a general north-north-westerly direction towards Gunnedah (150° E., 31° S.) It certainly extends much farther inland than this, but is hidden beneath Mesozoic formations. This basin includes the productive coalfields of New South Wales, and contains a thick series of glacial, marine, and fresh-water formations. Some slight evidences of natural gas have been encountered, and some drilling for oil and gas has been carried out, so far unsuccessfully. The potentialities of this basin are, however, scarcely yet touched, and much further prospecting is called for.

In eastern Australia the latest Palaeozoic marine transgression occurred about the middle of Kamilaroi (Permo-Carboniferous) time. Upper Kamilaroi sediments are of epicontinental origin, as also are those of Triassic and Jurassic age. Only in Lower Cretaceous time was there a further marine incursion. On the west coast of Western Australia narrow selvages of marine formations of Jurassic and Cretaceous age are encountered, but in the north-eastern portions of that State the Jurassic formations, like those of eastern Australia, appear to be of fresh-water origin.

These fresh-water Mesozoic beds occupy huge geosynclines closely related structurally with those of the preceding era, and the oldlands of Australia were almost or completely isolated from one another by fresh-water seas. One of these occupied the greater part of what is now Queensland, northern New South Wales, and north-eastern South Australia, and in it were deposited the aquifers and cover rocks of the Great Artesian Basin. It is in the *basal* beds of the *fresh-water* Jurassic formation, notably about Roma (146° E., 29½° S.) and Longreach (144° E., 23½° S.) that the most noteworthy discoveries of gas and oil in Australia have occurred. In every instance, so far, the petroliferous products have been encountered in sands either in immediate contact with granitic or metamorphic bedrock, or within a very short distance above the latter. There are very strong reasons for doubting the competence of the Jurassic (locally known as Walloon) beds as mother rocks of oil. The distribution and striking variations in character of the oil and gas encountered, particularly in the Roma district, point strongly, it is believed, to derivation of the hydrocarbons from hidden, truncated domes of Kamilaroi (Permo-Carboniferous) rocks, under conditions closely analogous to those of many of the oilfields of Oklahoma and Texas. So far, drilling has not been sufficiently close to determine conclusively whether accumulation is governed by domal development. The gas and oil sands lie at depths of approximately 4,000 ft., and are overlain by the full thickness of the Walloon Series and by considerable thicknesses of Cretaceous as well in many places. It is not absolutely proved that there is complete conformity between these two formations, though this is generally regarded as being so. Superficial rock decomposition is profound and complete, and geological survey is greatly hampered in consequence. Recently the discovery of a small closed structure east of Roma (Warooby Creek) was followed by drilling and the development of a gas well, pointing to anticlinal control. In some parts of the region, as about Longreach, it has been demonstrated that aerial photographic survey is capable of yielding structural information completely unobtainable by ordinary geological survey methods.

As mentioned above, Kamilaroi rocks, the probable source rocks, disappear beneath the eastern edge of this basin. On the western side Cambrian and Ordovician formations are similarly situated and are at least as favourable, lithologically and organically, as the older Palaeozoic formations exposed on the flanks of the Arbuckle Mountains of Oklahoma would appear to be. It may be presumed, then, that any favourable structure discovered at the surface within the limits of the Great Artesian Basin is worthy of testing by deep drilling. The lower Mesozoic basins of eastern Australia, including the coal basins of south-eastern Queensland, the Clarence Basin of north-eastern New South Wales, the Sydney Basin of New South Wales, the Cape Otway and Cape Liptrap Basins of Victoria, and considerable developments in Tasmania, being entirely fresh-water in character, are not very attractive, though some rather desultory drilling has been done in some of them. In the Clarence Basin a bore for water at Grafton (153° E., 29¾° S.) encountered a gas flow containing traces of ethane.

The narrow coastal basin of marine Jurassic sediments near Geraldton, Western Australia (115° E., 29° S.), though probably too limited in extent to be attractive, shows gentle doming. Water bores have encountered saline supplies in places, but no systematic oil prospecting has been carried out.

The greatest extension of Cretaceous rocks is in the Great Artesian Basin of Queensland, New South Wales, and South Australia, and their possible relation to the known petroleum indications in that basin has been described above. Near Longreach the superficial Cretaceous beds present evidence of exceedingly unstable shore-line conditions of deposition, richly fossiliferous patches being closely associated with lagoonal lenses containing fossil plant stems encased in pseudomorphs after halite. In one place small amounts of unquestionable, plastic, inspissated oil have been obtained; but, apparently, there is not sufficient bulk of such saliferous Cretaceous formations to yield much promise of oil production in quantity.

The extent and thickness of marine upper Cretaceous formations actually exposed in the coastal portions of Western Australia are limited, and the search for oil in them has not been seriously entertained. It is likely, however, that similar beds have a considerable extension under the Tertiary and Recent formations of the Perth Coastal Plain.

Very recently extended field work in the peninsula west of Exmouth Gulf, Western Australia (114° E., 22° S.), has brought to light an extremely important palaeontological suite extending from Cretaceous to Oligocene; the first time that true Eocene beds have been recognized in Australia. These formations are somewhat folded, dips in the neighbourhood of 30° having been recorded. It is understood that further investigation is being carried out by oil interests, and that testing of the area by drilling is being considered. So far as is known, no seepages or other surface indications have been encountered.

With this exception the marine Tertiary formations of Australia have been exceedingly little disturbed. At most they show very gentle dips, and there is a total absence of the acute alpine folding which characterizes the majority of the oilfields in Tertiary areas.

Three major Tertiary geosynclines occur along the south coast of Australia; the Gippsland basin centring about Bairnsdale (148° E., 38° S.); the Murray basin of South Australia extending from the mouth of the Murray River (139° E., 35½° S.) to Portland (142° E., 38° S.) and sweeping inland beyond Mildura (142° E., 34° S.); and the Nullarbor Plain extending north of the Great Australian Bight from 124° E., 34° S. to 133° E., 32° S., and inland for an unknown distance into the unexplored desert interior probably at least to 127° E., 29° S.

Minor basins are met with near Albany (118° E., 35° S.) (the Plantagenet Basin), and to the north-east of this area.

The Gippsland Basin possesses the distinction of having supplied small amounts of petroleum continuously for over four years from pumping bores situated towards the eastern margin of the basin. This discovery has led to the expenditure of large amounts of money in oil prospecting, with a consequence that no part of Australia has been so intensively drilled nor so systematically examined palaeontologically. Unfortunately the fossiliferous Tertiary formations are almost completely masked by a 'blanket' of Pleistocene sands and gravels which entirely prevent any extensive geological or aerial survey. Geophysical (magnetometric) survey suggested the existence of anomalies within the basin, but scout drilling failed to confirm the promise so given.

The results of such geological work as has been possible, supplemented by the somewhat extensive, though rather sporadic drilling, have shown that there is a general monoclinal structure within the basin, with a nearly uniform south-westerly dip at low angles. Towards the western edge there is a change of facies in the Oligocene and Miocene formations from marine to fresh-water, so that the brown coals which are developed to so spectacular an extent in western Gippsland correspond with the petroliferous series of the eastern basin.

The basin is an artesian one, and the oil encountered has been met with in the basal beds of the Oligocene, where it rests on a granitic bedrock, and in association with artesian water, from which, so far, it has not been possible to effect a separation. In spite, then, of the unequivocal proof of the petroliferous nature of the marine Tertiaries in this region, natural obstacles have prevented the development of a commercial oilfield.

In the Murray Basin of south-eastern South Australia, overlapping into western Victoria, the evidences of the existence of oil are far less convincing than they are in the Gippsland Basin. The formations are, however, of the same general age and nature, and there seems no good reason why they may not be petroliferous. As in the Gippsland Basin, most of the surface is hidden under Pleistocene deposits, and outcrops are too scattered for structural features to be determined by geological survey. West of Mount Gambier, however, aerial reconnaissance shows that the Pleistocene covering is so far removed as to render possible delineation of many of the structural features by aerial photography.

One anticlinal structure within this area, exposed in a railway cutting and mapped on the ground, has been drilled. Although the lowest sand encountered at a depth of 2,013 ft. contained microscopic globules of inspissated bituminous material, drilling was abandoned, and the test cannot be regarded as conclusive. A considerable amount of other drilling has been carried out from time to time, but the results cannot be said to be at all convincing.

Farther inland, where the Melbourne to Adelaide railway line crosses the Ninety Mile Desert, the Tertiary formations of this basin are artesian, and yield much-needed water supplies in abundance. There has been no suggestion of the occurrence of oil indications in any of these artesian bores.

The Nullarbor Plain and Plantagenet Basins have not proved of any importance in the search for oil.

It is unquestionably a fact that, since the colonization of Australia, large and small masses of 'bitumen' varying in consistency from soft sticky oil to hard asphaltic glance have been encountered all along the southern coast lines from about Perth to the west coast of Tasmania. Such masses come ashore still, perhaps more abundantly after storms. When first cast on beaches in a soft 'tacky' condition, the material will just float on sea-water. On exposure it rapidly hardens and darkens, and becomes so heavy as to sink in sea-water. Naturally such material is responsible for the constant recrudescence of 'oil discoveries' even in places where the coast consists of Archaean granites and crystalline schists.

Since similar material is met with on the coasts of Chile and New Zealand, and probably also in Kerguelen Island, an extra-Australian source, probably Antarctic, is suggested.

The onshore drift of the scourings of bilges of oil-carrying and oil-burning ships is responsible for some of the phenomena in places like Perth.

There is also a curious alteration product formed from accumulations of marsupial guano in caves and other protected situations which is recurrently responsible for new 'oil discoveries'.

NEW GUINEA

By B. K. N. WYLLIE, B.Sc., F.G.S., F.R.G.S., M.Inst.M.M.

THE island of New Guinea has an area of some 300,000 square miles, a large part of which is geologically little better than *terra incognita.* The main feature is a sinuous central backbone of high mountains, frequently exceeding 10,000 feet in altitude [1, 1929]. These mountains are built up of crystalline rocks, sedimentary rocks of various ages, ranging up to Neogene in the highest peak [3, 1927], and young volcanic rocks. On the southern side the sea lies close to the central range at either end, but in the middle a broad strip of low-lying country extends southwards towards the northern part of Australia. Granite outcrops on the south coast at Mabaduan, and a large part of this southern lowland is probably floored at shallow depth by similar rocks. On the northern side the central range is flanked by a great trough, extending for nearly the whole length of the island (McCluer Gulf to Huon Gulf). To the north of this trough lie a number of more or less isolated mountain masses (Van Rees, Gautier, Cyclops, Torricelli, and Finisterre Mountains), all of which appear to be built up essentially by crystalline rocks.

Attempts have been made to interpret the geological structure of New Guinea in terms of alpine tectonics. These are certainly premature, and probably misleading. From the point of view of the oil-prospector, the most important datum appears to be the fact, that strong orogenetic movement took place late in Palaeogene time, so that Neogene sedimentation was concentrated in a number of distinct basins or foredeeps and ran in normal cycles, beginning with deposition of fine-grained, open-sea, largely planktonic materials and ending with shallow-marine, littoral and lacustrine beds. In late Neogene time a further outburst of orogenetic activity caused compression, folding, and elevation of these sediments, a large part of which erosion has since returned to the sea. The problem for the oil-prospector is to discover areas of adequate size within these basins of Neogene deposition, where deformation has not been too intense and where erosion has not already removed those parts of the sedimentary cycle in which oil and gas could most readily be accumulated and preserved.

In the Dutch section of the island, the most important published account of geological investigation in a potential oil-region is that given by Zwierzijcki [2, 1921], who distinguished the following subdivisions of the Neogene sediments in the coastal belt lying to east, south, and west of the Cyclops Mountains:

5. Brown-coal beds.
4. Fossil horizon.
3. Sandstones.
2. Globigerina marls.
1. Conglomerates.

According to Zwierzijcki [2, 1921; 3, 1927], the whole of the Neogene of the northern coast is intensely folded. The anticlines are generally of small amplitude, and usually show cores of the conglomerate or marl subdivisions, in at least one instance exposing the crystalline rocks of the basement.

Conclusions regarding oil prospects were pessimistic. Only two seepages were found, both on anticlines with steep cores, one consisting of rocks of the sandstone group, the other of globigerina marls. Later exploration, of which no scientific details have been published, appears to have yielded more hopeful results.

In the Australian sector (Papua and the Mandated Territory of New Guinea) oil-prospecting efforts up to 1929 were described in some detail in a comprehensive report by the Anglo-Iranian Oil Company to the Commonwealth Government [4]. The main centres of activity were Aitape, on the northern coast, and Upoia in the south.

Near Aitape the oil-seepage at Matapau led to shallow drilling followed by a brief geological inspection, more drilling, then a regional geological survey which produced results corresponding fairly closely with those recorded by Zwierzijcki in the adjoining Dutch territory. No commercial production has been obtained.

Oil seepages were discovered near Upoia in 1911–12. Geological mapping and drilling were carried on by the Commonwealth Government from 1913 to 1920, when the management of the work was entrusted to the Anglo-Iranian Oil Company. Regional geological investigation showed that the immediate neighbourhood of the seepages was structurally unfavourable for oil-accumulation, but suggested that effort might more profitably be expended on well-defined structures lying to east of the Lakekamu River. Attempts to drill one of these structures (the Popo Anticline) were continued at intervals until 1929, but without success. The final report of the Anglo-Iranian Oil Company's geologists tended to the view that exploration should be directed westwards from Upoia, especially to the region of the Purari River, where an early reconnaissance showed signs of the preservation of strata much higher in the Neogene cycle of deposition.

THE EAST INDIAN ARCHIPELAGO

By Dr. H. SCHUPPLI

Bataafsche Petroleum Mij.

As shown on the accompanying map, the producing oilfields in the East Indian Archipelago are confined to the following areas:—

1. East Java (Rembang, Surabaya).
2. South Sumatra (Palembang, Djambi).
3. North Sumatra (Atjeh, Langkat).
4. South-east Borneo (Koetei).
5. North-east Borneo (Tarakan).
6. North-west Borneo (Sarawak, Brunei).
7. East Ceram (Boela).

With the exception of the oilfields of Sarawak and Brunei (6), these oil-producing areas are situated in the Dutch East Indies.

The oil-bearing formations of the important producing areas of Java, Sumatra, and Borneo situated in the western part of the archipelago, belong exclusively to the Tertiary. In the eastern part of the archipelago oil indications also occur locally in a Mesozoic (mainly Triassic) Flysch series, and the production of the rather unimportant Boela field (Ceram), obtained from Pliocene sands, is probably genetically connected with this Mesozoic series.

As the Tertiary oil is of paramount importance, the geological history of the Tertiary formations is briefly outlined here.

In the beginning of the Tertiary or during lower Tertiary time a number of geosynclinal basins came into existence along the marginal part of the Asiatic continental block, which had been stabilized by pre-Tertiary orogenesis. During the Tertiary these basins maintained a subsiding tendency of an oscillating character, and thick series of marine, lagoonal, and non-marine sediments were accumulated there. This subsidence seems to have been most pronounced during the Miocene, when deposits, partly bathyal and of particularly great thickness, were formed, followed in Pliocene time by a predominantly near-shore and continental sequence, representing the final filling up of these basins.

The total thickness of the Tertiary deposits ranges between 6,000 and 10,000 metres in the central parts of the oil-bearing basins of Sumatra. In the various basins of Java and Borneo the figures are even higher, ranging around or exceeding 10,000 metres.

The main folding of these basins occurred in Plio-Pleistocene time as far as Java, Sumatra, and southern Borneo are concerned. It took place somewhat earlier, i.e. at the end of the Miocene, in the northern part of Borneo (Sarawak and Tarakan basin), followed by less important Plio-Pleistocene movements.

Generally speaking, the primary richness of the oil-bearing series in the East Indian Archipelago does not seem to have been particularly great, at least compared with the oil basins of California, Trinidad, Roumania, for example. This must be concluded from the fact that only anticlines with very favourable conditions as regards structure, size of collecting area, &c., yield oil accumulations of economic importance.

Production is confined to sands and sandstones of Miocene and Pliocene age. The Miocene is by far the most important oil-producing series for all basins, with the exception of Tarakan, where most of the oil is derived from Pliocene beds.

The producing structures are, as a rule, confined to the regions of weak to moderately strong folding. Steeply folded and complicated anticlines, even when situated in areas of favourable facies and rich in oil indications, generally have not yielded paying production. Many of the best oilfields are on asymmetric structures, one flank being flat, the other steep, or even overturned. Sometimes slight thrusting is associated with these steep and overturned flanks.

The depths of the producing sands exploited up to now are relatively shallow. In most of the oilfields they range from 500 to 1,000 metres, whilst depths exceeding 1,500 metres are exceptional.

The importance of the individual oil-producing areas may be seen from the following list giving the respective productions during the last 10 years:

The figures in parentheses represent the share of the total production which was obtained by the Koloniale Petroleum Maatschappij, a subsidiary of the Standard Oil Company of New Jersey, which holds some very important fields in South Sumatra and obtains a small production from East Java. All other production belongs to subsidiaries of the Royal Dutch Shell Group.

BURMA AND ASSAM

By G. W. LEPPER, B.Sc., A.R.C.S., F.G.S., M.Inst.P.T. and P. EVANS, B.A., F.G.S., M.Inst.P.T.
The Burmah Oil Company Ltd.

I. Distribution of Petroleum in Burma and Assam

THE oil-bearing region of Burma and Assam lies in the angle between the Eastern Himalaya on the north and the Shan Plateau on the east, and is divided into two parts by a group of hill ranges which include the Arakan Yoma, Chin Hills, and Naga Hills. This group of hills divides the main portion of Burma from the Arakan–Bengal–Assam region, and separates two geological provinces.

There are five areas in which oil seepages are numerous: on the eastern side of the Arakan Yoma–Chin Hills ranges are a very large number of oil-shows in the Thayetmo, Minbu, Magwe, and Pakkoku Districts (this area including the main oilfields belt and the foot-hills of the Arakan Yoma), and farther north are the Indaw oilfield and neighbouring oil-shows of the Chindwin Valley and Shwebo District; on the western and north-western side of the hills are the Arakan oil-shows in the south, those of the Surma Valley some 300 miles to the north, and the Assam Valley seepages with the Digboi oilfield rather more than 300 miles north-east.

Gas occurrences are common throughout the region of the oil-shows and many gas seepages associated with saline springs occur to the south of the oil-shows in the Prome and Henzada Districts of Burma. There are also gas seepages and salt springs in the Chittagong District, the Chittagong Hill Tracts, and Hill Tippera (Tripura), linking up the Arakan and Surma Valley shows.

Throughout this note, as far as possible, places are mentioned in geographical order from south to north.

II. General Geology

A. Stratigraphy.

All the known oil-shows occur in Tertiary rocks, which both in Burma and Assam attain an immense thickness.

Pre-Tertiary rocks of various ages make up the greater part of the Eastern Himalaya on the north of the oil-bearing region and occupy a large area to the east of the Irrawaddy, Chindwin, and Sittang Valleys. The Arakan Yoma and Chin Hills, between the two main oil-bearing regions, also include a considerable breadth of pre-Tertiary rocks, mainly metamorphosed argillaceous sediments with ultra-basic intrusions.

Burma Tertiary Stratigraphy. The Burma Tertiaries are divisible as follows:—

Mio-Pliocene	Irrawaddy Series Unconformity	Up to 10,000 ft.
Miocene	Pegu Series (Upper Part) Unconformity	„ 10,000 „
Oligocene	Pegu Series (Lower Part)	„ 10,000 „
Eocene	. . . . . .	Probably 30,000 „

The Lower Eocene beds include a very thick argillaceous group, the Laungshe Shales, which, however, is associated, particularly in the lower part, with sandstones and conglomerates. This is overlain by the Tilin Sandstones, the Tabyin Clays, the Pondaung Sandstones, and the Yaw Stage. The argillaceous Yaw Stage has a rich fauna of Upper Eocene age and includes a variety of rocks, amongst which are carbonaceous shales and coal seams. The Oligocene beds are alternations of sandstones and shales; in the upper part grits and conglomeratic sandstones are common and indicate the early stages of an unconformity which is more pronounced in Assam than in Burma. The Miocene beds are, in general, very similar to the Oligocene, but contain characteristic fossils of Lower and Middle Miocene age. The uppermost Pegu beds are frequently missing owing to the unconformity between the Pegus and the Irrawaddies.

The Pegu succession has been described in several publications of the Geological Survey of India and by Dr. Stamp. Dr. Stamp considers that in a broad way the palaeontological stages cross the lithological divisions, a lithological division in the south being younger than the corresponding lithological division farther north, but this view is at variance with the evidence obtained by the Burmah Oil Company's geologists. Their mapping suggests that as each member of the Pegu succession is traced northwards, it passes from a marine to a non-marine facies, and that lithological units do not show any marked transgression of palaeontological divisions. In the more southerly outcrops the Pegu series contains a large number of marine fossils, but north of the main oilfields area fossils are less abundant, and brackish water forms appear, marine fossils being very rare.

The Pegu beds are overlain by a great thickness of continental deposits, the Irrawaddy Series—mainly yellow and white grits, sandstones, quartz pebble conglomerates, and subordinate, brightly coloured clays. Fossil remains of terrestrial and aquatic vertebrates have been found. The unconformity is often marked by a reddish-brown earthy layer which may rest on any horizon from the Eocene to high in the Miocene.

Arakan–Assam Tertiary Stratigraphy. The subdivisions characteristic of the Tertiaries of the main Burma area cannot be recognized either in the Arakan region of Burma or farther north in Assam. It is evident that conditions of deposition were somewhat different on the two sides of the Arakan Yoma–Naga Hills ranges, and the paucity of fossil remains makes it very difficult to correlate the Assam succession with other areas. A local classification of the Assam rocks has recently been extended to include the Arakan region of Burma; the main divisions are given in the following table, but it is necessary to emphasize that the ages indicated for the Assam and Arakan rocks are at present to be regarded as tentative suggestions.

Mio-Pliocene	Dihing Series	Up to 5,000 ft.
Probable unconformity		
Miocene	Tipam Series and Surma Series	„ 25,000 „
Important unconformity		
Eocene to Oligocene	Barail Series	15,000 „
Eocene	Jaintia Series	2,000 „
	and Disang Series	Over 10,000 „

The lowest Tertiary beds of Assam, the Disang Series, are mainly dark-grey splintery shales. These are thought to be

equivalent to the Laungshe shales of Burma, but may include some Cretaceous beds. In the north-western part of Assam (Garo Hills to Mikir Hills) the Disang Series is not found and its place in the succession is taken by the Jaintia Series, which includes fossiliferous limestones and is of Middle or Lower Eocene age. The Barail Series includes sandstones, shales, and carbonaceous shales, and in the extreme north-east of Assam is marked by a development of thick coals near the top of the series; these may possibly be correlated with the Yaw Stage of Burma, but fossils are extremely rare and badly preserved.

The unconformity which separates the Eocene-Oligocene succession from the Miocene has resulted in the complete removal of the Barail Series in some parts of Assam; in other localities the Surma Series is missing, and the Tipam beds rest directly on the Barails. The Surma Series consists of impure shales and sandstones with frequent ferruginous conglomerates; a few fossils occur which show the series to include beds of Lower Miocene age. This series is very poorly developed in Upper Assam, is well developed throughout the Surma Valley, and reaches a very great thickness in the Arakan coastal region of Burma, where the rocks are rather finer in grain. The overlying Tipam Series includes ferruginous sandstones and, in the north, mottled clays; fossils are very rare, except in Arakan, and there is some doubt about the age of the series as some fossils have been thought to suggest the presence of Upper Miocene or even Pliocene beds. Different views have been expressed regarding the correlation of the Tipam Series with the Burma succession; the apparently conformable passage from the Surma Series into the Tipam Series and the unconformity believed to occur above the Tipam Series make it probable that this series does represent the uppermost part of the Pegu succession, but this tentative correlation must await confirmation or revision. The highest Tertiaries of Assam, the Dihing Series, are pebble beds which appear to be equivalent to some part of the Irrawaddies of Burma.

B. Structure.

From the remarks in the opening paragraphs it will be appreciated that the Tertiary beds of Burma and Assam lie in two large geosynclines, one stretching from the Arakan Coast of Burma northwards through the Surma Valley into Upper Assam, and the other occupying the Irrawaddy–Chindwin Valley of Burma. Throughout the two regions the general lines of folding are roughly parallel to the boundaries of the main synclinal areas, and a large part of the Tertiary tract has been thrown into a series of long narrow folds which in many places have been severely overthrust. There are naturally occasional divergences from the general trend of folding, and small areas, such as the North Cachar Hills in Assam, and especially the synclinal tracts, show fairly broad stretches of nearly horizontal beds. The overthrusting is possibly most strongly developed in the Naga Hills ranges to the south-east of the Upper Assam Valley. The principal overthrust fault of this area is known as the Haflong–Disand fault, and this forms a structural line which has been traced for 400 miles.

III. Stratigraphical Distribution of Petroleum

In Burma oil seepages occur throughout the range Upper Eocene to Middle Miocene. Gas and salt-water springs and mud volcanoes are also numerous, being associated with beds ranging from Middle Eocene to Miocene. In the Yenangyaung oilfield the principal production has come from Upper Oligocene and Lower Miocene sands. Some lower horizons are productive in the Minbu group of fields, and the production of the Singu–Lanywa–Yenangyat fields comes from the Oligocene, the Miocene beds being exposed.

In the Arakan–Assam geosynclinal tract oil seepages range from Eocene to high in the Miocene, being prominently associated with the upper part of the Barail Series and the lower part of the Surma Series, but in Upper Assam extending into the Tipam Series. Mud volcanoes, gas-shows, and saline springs are numerous, both in the highest Barail beds and in the Surma beds. Oil indications are thus very closely connected with the Oligocene unconformity.

IV. Structural Distribution of Petroleum

In Burma most of the oilfields lie on the eastern rim of the main synclinal tract which runs roughly along the line of the Irrawaddy–Chindwin valley. To the south of this elongated basin are the Pyaye dome with gas, and the small Padaukpin field. Farther north, and on the western side of the main axis, is the small oilfield of Yenanma. On the eastern side of the syncline is the northerly pitching Tagaing structure which had a short-lived production. Northwards come the central oilfields; Petpi, Yethaya, Palanyon, and Minbu form the southernmost group (Minbu line of folds), then 20 miles to the north is Yenangyaung, and 30 miles farther north is the group which includes Singu, Lanywa, Yenangyat, and Sabe. All these fields of the central region lie immediately east of the axis of the main geosyncline. The only other oilfield is at Indaw, situated about 150 miles farther north, and also lying just east of the main axis. Although there are many other folds in the oil belt, production on a commercial scale has been obtained only from those anticlines which lie along the edge of the main synclinal area.

In the Arakan–Assam region there is no main structural synclinal line closely corresponding to the Irrawaddy–Chindwin geosyncline of Burma. There is presumably a major synclinal axis beneath the Bay of Bengal, with the seepages and mud volcanoes of the islands of the Burma coast (Cheduba, Ramri, Baronga) to the east of it. This axis probably continues northwards under the Bengal alluvium and swings north-eastwards into the Surma Valley, at the head of which are many oil-shows. The Badarpur field, which has given a small production of oil, lies in this area. The synclinal axis pitches out in an east-north-easterly direction in the Naga Hills. In Upper Assam there is another major synclinal axis somewhere beneath the Dhansiri–Brahmaputra alluvium, and the Digboi field lies near the north-eastern end of this syncline on what is probably the first fold to the south-east. The numerous seepages of the Naga Hills occur on the south-eastern side of the Upper Assam syncline.

Structure of the Oilfields.

All the oilfields of importance in Burma and Assam and many of the seepages lie on anticlinal folds. The seepages of the 'western outcrops' of Burma and the 'northern outcrops' of the Surma Valley are exceptions; so, too, is the small accumulation of oil in the Yenanma field where the structure is apparently monoclinal. The Minbu line of folding is rather sharp, the eastern flank being the steeper. The small dome of the Yethaya field is close to, but east of, the main Minbu line of folding. The Yenangyaung field

is a comparatively gentle elongated dome, slightly asymmetrical; the eastern flank is more gentle, and drilling in recent years has led to an eastward extension of the productive area. The Singu and Lanywa oilfields lie on a markedly asymmetric fold which, like the Minbu line of folding, has a steep eastern flank. Almost on the same line is the Yenangyat–Sabe flexure which is similarly very strongly asymmetric. The isolated Indaw field is on an elongated dome.

On the western side of the Arakan Yomas the seepages are associated with compressed folds; very small productions have been obtained from shallow wells drilled near seepages in Ramri Island and in Eastern Baronga Island. Farther north the oil- and gas-shows of the south-eastern side of the Surma Valley are all on asymmetric, often overthrust, anticlines. The Badarpur structure is a small dome with an overthrust eastern flank. In Upper Assam most of the oil-shows occur along or in close association with the strike-faults which are such a distinctive feature of the Naga Hills structure. Near Digboi the overthrusting is less severe, and the Digboi oilfield is situated on a sharp asymmetrical fold with a steep and faulted northern flank.

V. Origin of Oil in Burma and Assam

The conditions favourable for the formation of oil persisted from the Middle Eocene to the Middle Miocene. In Burma the deposition appears to have been in a gulf into which sediment was carried mainly from the north, but also from the east and west. From the facies of the Pegu strata outcropping round the edges of the main synclinal basin and from numerous cores of the strata of the oilfields it is inferred that the bulk of the sediments in the broad synclinal area are of shallow marine facies. During late Oligocene times there appear to have been considerable local interruptions in sedimentation.

In Assam there is an intimate association between the occurrence of oil-shows and the Oligocene unconformity. Oil is also closely associated with the coal-bearing beds in north-eastern Assam and with the Tipam beds, whose lithology there suggests a definitely non-marine type of deposition. Since the Tipams are petroliferous only where they rest on petroliferous Barail beds, and in view of the intimate connexion between the coal-bearing beds and the oil sands, it seems likely that extensive migration has taken place, presumably from the geosynclinal area beneath the Brahmaputra alluvium.

VI. Bibliography

The most important source of information regarding the Burma and Assam Oilfields for the period prior to 1912 is Dr. Pascoe's memoir (*Mem. Geol. Surv. Ind.* **40,** parts i and ii (1912, 1914)). Later references to Burma are to be found in the Geological Survey Records and in other publications; a full list is included in Dr. H. L. Chibber's *Geology of Burma* (Macmillan, 1934). The occurrence of oil in Burma has been discussed in several papers by Dr. Dudley Stamp: 'The Conditions governing the Occurrence of Oil in Burma' (*J. I.P.T.* **13,** 21 (1927)), 'The Connection between Major Structural Features and Commercial Oil Deposits' (ibid. **14,** 28 (1928)), and 'The Oilfields of Burma' (ibid. **15,** 300 (1929)). These papers also contain a bibliography.

The most recent discussions of the oil distribution of Burma are contained in the paper by G. W. Lepper published in *Proc. World Petr. Cong.* **1,** 15 (1933), in Dr. Chibber's book referred to above, and in a contribution by Dr. Stamp to Dr. Chibber's *Mineral Resources of Burma* (Macmillan, 1934) in which he summarizes his earlier papers.

There has been very little published on the oil geology of Assam since Dr. Pascoe's memoir, but the general stratigraphy is given in 'Explanatory Notes to accompany a Table showing the Tertiary Succession in Assam' (P. Evans, *Trans. Min. Geol. Inst. Ind.* **27,** 155 (1932)), which contains a full list of references. The distribution of oil is discussed in G. W. Lepper's *World Petroleum Congress* paper.

LANYWA OILFIELD, UPPER BURMA

By E. S. PINFOLD, M.A., F.G.S.
Attock Oil Co., Ltd., India

THE Singu oilfield is truncated at its northern end by the left bank of the Irrawaddy River and the surface geology indicates a continuance of the fold beneath the river-bed to the right bank where the Singu structure, pitching to the north, appears to lie *en echelon* with and somewhat to the west of the southern end of the Yenangyat anticline. Production from wells on the right bank of the river was obtained by the Indo-Burmah Petroleum Co. Ltd. in 1921, and since that date a portion of the river-bed has been reclaimed by means of a stone and brick-faced embankment, 2 miles in length, and of sufficient height to withstand a seasonal variation in river-level of over 40 ft. The area behind the embankment has been filled to above high-water level by material dredged from the river-bed. Before the filling was complete the wells were surrounded by water for 6 months in the year and all work was carried on from raised platforms connected by bridges.

Oil sands at 1,700, 1,900, and 2,500 ft. have so far been exploited, and additional sands are now known to exist. The structure is regular, and the oil sands show little lateral variation. Throughout the area worked there is a low pitch to the north, which is but little disturbed by cross-faults. Sixty-seven wells had been drilled, and a total production of 3,414,934 bbl. recovered from the Lanywa field to the end of 1935.

NORTH-WEST INDIA

By E. S. PINFOLD, M.A., F.G.S.
Attock Oil Co., Ltd., India

THE petroleum occurrences of the Punjab and North-West Frontier Province are described by Dr. (now Sir Edwin) Pascoe in *Mem. Geol. Surv. India*, 40, pt. 3 (1920), and a full bibliography to 1919 is given in this work. A later paper by R. Van Vleck Anderson (*Bull. Geol. Soc. Amer.*, 38, 665) contains a detailed description of the geology of the Punjab oil region.

Surface oil-shows are numerous and occur over a wide area from north-east of Rawalpindi to northern Baluchistan. Mud volcanoes occur on the Mekran Coast, 90 miles north-west of Karachi; one of these, Chandragup, is a mud-cone over 300 ft. high. The oil is believed to have originated in Eocene times during alternations of marine and inland sea conditions, and a large proportion of the seepages are associated with gypsiferous marls overlying massive nummultic limestones. The Eocene rocks are overlain unconformably by fresh-water sandstones and shales of Oligocene to Pleistocene age, and a large number of oil-seepages occur at the outcrop of the plane of unconformity; in these cases the oil is believed to reach the surface by migration along the plane of unconformity. E. Parsons (*J. I.P.T.* 12, 439 (1926)) suggests that migration has taken place along fault-planes.

The Eocene and younger rocks have been affected by the orogenic movements of late Tertiary times which gave rise to the Himalayan Mountains and associated ranges. Immediately under the hills the compression has been severe, but away from the hills the folding becomes more open, and it is from anticlines in this structural zone that oil-production has so far been obtained.

The earliest well drilled for oil in the Punjab was put down near Jafar in 1869, and in the early seventies an oil expert, F. W. Lyman, was engaged by the Punjab Government to report on the known oil localities. Borings were put down on his recommendation, but no production was obtained. In 1890 a government-aided syndicate managed by the Townsend brothers carried out prospecting on a considerable scale and a number of wells were put down at Chharat and Jaba in the Attock district, Punjab, at Kundal in the Trans-Indus Salt Range, at Khattan in Baluchistan, and near Sukkur in Sind. Small quantities of oil were obtained from the first four of these localities, and oil from Jaba was used for many years at the Rawalpindi gas-works. In 1912 yet another unsuccessful test was drilled at Golra near Rawalpindi.

The Attock Oil Company commenced drilling at Khaur, 45 miles south-west of Rawalpindi, in 1914, and production was obtained from shallow sands in 1915. A refinery was constructed in Rawalpindi and commenced working in 1922. To the end of 1935, 228 wells had been drilled and a total production of 2,945,448 bbl. recovered from the Khaur oilfield. Oil occurs in fissures in the Murree sandstones from the surface to depths of over 5,000 ft.; and recently oil has been obtained at still greater depths in the Eocene limestone. Fluid conditions have been irregular and drilling has been difficult, due to heaving formations and high-pressure gas and water sands. A special technique was devised to meet these conditions, and this is described in a paper by C. E. Keep and H. L. Ward (*J. I.P.T.* 20, 990 (1934)).

In 1935 oil was discovered by the same company in the Dhulian anticline, 10 miles south-west of Khaur. Oil occurs there in the basal beds of the Murree and in the Eocene limestones at a depth of 7,500 ft.

Unsuccessful test-wells have been drilled by various companies at Kabakki and Gabhir on the Salt Range, Meyal, Jhatla, and Chharat in the Attock district, the Marwat Range, Trans-Indus, on the Sukkur dome, south of Rohri, in Sind, and on the Mekran coast near Chandragup.

CHINA

By FREDERICK G. CLAPP, S.B., F.G.S.A., F.A.G.S.
Consulting Geologist

A LARGE part of the Chinese Republic consists of rocks of types and ages in which no possibility of commercial oil deposits exists. Some parts of the country, however, have seepages and other surface indications or structures of suitable types in sedimentary basins.

Among the regions where oil is known to exist is the Shensi Basin, situated in northern Shensi Province, touching western Shansi, eastern Kansu, and a bit of Inner Mongolia. The length of this basin is about 450 miles from north to south and 250 miles from east to west, and it therefore contains more than 100,000 square miles of sedimentary rocks of suitable age to hold commercial fields. Anticlines are conspicuous on the borders of the basin, but they become gentler as the centre of the basin is approached, so that the greater part of that vast area is underlain by rather flat to gently dipping strata in which 'closed' structures are rare. The surface sandstones are of various 'Permo-Mesozoic' or Mesozoic ages, whereas underlying shales, sandstones, and limestones range from Carboniferous down to Cambrian.

Oil seepages at Yenchang (Shensi Province) were mentioned more than 200 years ago in the *Ta Min I Tung Chih*, or *Chronicle of the Great Ming Dynasty*. The later *Chronicle of the Great Ming Dynasty* also mentions petroleum, as does the *Fang Yu Chi Yao*, or *Concise Geography* by Ku Chu-yu, the Prefectural Record and District Record of Yenchang. In a geological study of the Province the writer and his associates found and proved sixty-three actual seepages [2, 1926] all of about the same size.

Drilling commenced in April 1907, when an outfit was purchased in Japan by the Imperial Government on the advice of Mr. K. Inami of Wuchang. The first discovery was in October of that year just outside the gates of Yenchang, where an initial yield of 60 bbl. per day was found at a depth of 230 ft. A small refinery was then constructed and is operated to this day, the oil coming also from three wells within a few hundred feet of the original one and from a depth of about 370 ft. No materially abnormal structure exists at the locality except small terrace or ravine-like deviations from the normal westward dip of one or two degrees.

Later test wells were drilled by the Standard Oil Company of New York in conjunction with the Chinese Government at several points in Shensi Province, but little additional oil was found at depth. The following figures are given by Chu [1, 1924] (errors of location corrected).

No.	*Locality*	*Depth, ft.*
1	Yenchang	2,770
2	Yungpingchen, 35 miles NW. of Yenchang	2,000
3	2½ miles NE. of Yenanfu	3,000
4	2 miles SW. of Tientou, district of Chungpu	3,545
5	5 miles SW. of Tientou	2,500
6	13 miles NW of Tungkuan	2,800

In 1917 the oil produced amounted approximately to 2,582 bbl. The last-mentioned well was located on an anticline, No. 5 was on a weak dome, Nos. 3 and 4 on structural terraces, and the first two in proximity to seepages, since suitable anticlines or domes were not known at that time.

Another great structural basin is situated in Szechuan Province, where the central region consists of Carboniferous, Permian, and Mesozoic strata. There is said to be a good anticlinal structure, the lateral dips ranging from two to eight degrees. All the drilling was in search of salt-water, the production and evaporation of which constitutes an extensive industry in western China, just as it did in Pennsylvania before the days of oil discovery there. The following records of groups of wells are given by Chu:

No. of locality	*Name of locality*	*Depth, ft.*
1	Niuhuachi	2,000–2,400
2	Chukantan	1,500–1,710
3	Between Chukantan and Faeshanching	250–1,650
4	Faeshanching	1,400–1,600

More than 1,000 wells have been drilled, about one-fifth of which had some oil and gas. The deepest test holes are said to be about 4,000 ft. deep, and in 1918 about 300 bbl. of oil were obtained from these wells.

Besides the Szechuan and Shensi basins oil seepages are reported in the Lingwu, Chengchen, Kuyuan, and Huating districts of eastern Kansu Province and in Yungchang, Zuechuan, Yumen, and Toukwang districts of western Kansu. Petroleum is also reported in sixty-five springs in Wusu, Kuchu, Suilai, Dihua, and Taecheug districts of Sinkiang Province, but no detailed geological studies have been made and no known prospecting has taken place.

THE GEOLOGY OF THE OILFIELD BELT OF IRAN AND IRAQ[1]

By G. M. LEES, Ph.D, F.R.G.S., F.G.S.
Chief Geologist, Anglo-Iranian Oil Company, Ltd.

I. Introduction

THE oilfield belt of southern and south-western Iran and of Iraq lies within a sector of the Alpine mountain system. The Dinaric limb of this system swings south-eastward through the Balkans and thence in a series of great arcs to the neighbourhood of Alexandretta in Syria. Between this point in Syria and Mosul in Iraq, the dominant strike swings gradually from north-east to south-west through east to west to a north-west to south-east direction. From Mosul to Bandar Abbas at the entrance to the Persian Gulf, a distance of 1,000 miles, the general north-west to south-east strike is maintained and the magnificent mountains of this sector, the Zagros Ranges, as they are called, form the subject of this article. East of Bandar Abbas structural complications set in. One branch of the fold-system swings southward into Oman in south-eastern Arabia, while another branch, of very different structural and stratigraphical composition, continues eastward along the Mekran and Baluchistan coastal zone.

The Zagros Ranges between Mosul and Bandar Abbas show, in general terms, a remarkable uniformity, though naturally differences in detail are numerous. Structurally the ranges form an almost ideal example of a fold-system. The direction of movement was from the north-east towards the south-west, and the intensity of folding shows a gradual diminution in this direction. In the north-east are great overthrusts. The geology of the overthrust zone is not dealt with in this article. For a more complete account of the structural conditions see *The Structure of Asia* (de Böckh [2, 1929]). In front of these lies a belt of tightly packed folds and fault-structures giving an imbricate pattern and exposing Palaeozoic and Early Mesozoic rocks, which form mountain ranges of up to 15,000 ft. in height. This is followed to the south-west by a zone of long regular fold-mountains in which Cretaceous and Palaeogene limestones are the dominant feature-forming rocks. The mountain belt is flanked on the south-west by a foot-hill zone composed almost exclusively of thick Neogene deposits. As the plains are approached the interval between anticlines increases and the broad synclines are filled with Pleistocene and recent alluvial deposits. Finally, the broad synclinal zone occupied by the plains of Iraq and south-western Iran and the Persian Gulf is still, throughout much of its extent, slowly subsiding and being filled by the deposits of the great rivers, the Tigris, the Euphrates, the Karun, and their tributaries.

Stratigraphically, the Zagros Mountains may also be regarded as one large unit and, in general terms, the uniformity of depositional conditions throughout their length is most remarkable; a noteworthy feature is the dominance of limestones or marlstones throughout the sequence from Permian to Palaeogene. (The term marlstone is used to describe a calcareous rock containing up to 40% of argillaceous material which is hard and brittle in its physical character.) Our knowledge of older Palaeozoic rocks is limited to relatively few outcrops; between the Cambrian and the Permian the geological record is scanty, but there are no angular discordances. From the Permian onwards, however, sedimentation was continuous and very uniform over wide areas.

The first orogenic movements of importance occurred in the Upper Cretaceous along the north-easterly margin of the geosynclinal zone. In depressions adjacent to the mountains formed by those movements thick sandstones and conglomerates were deposited during the Maestrichtian and the Lower Eocene, but farther to the south-west uniform marine sedimentation of marlstones and limestones continued without a break.

The dominance of calcareous sedimentation ended with the Lower Miocene and was succeeded by a lagunar phase. Local and temporary concentrations of the sea-water had resulted in some gypsum deposits at intervals throughout the Mesozoic and Early Tertiary, but these are of small importance. During the Early Miocene chemical sedimentation became very widespread and great thicknesses of anhydrite and salt were deposited. This formation, the Lower Fars Series, is of great economic importance, as it provides an excellent impervious cover for the oil-reservoirs in the limestones immediately beneath it. During later Miocene and Pliocene times thick detrital deposits, sandstones and shales, and finally massive conglomerates, formed the concluding phase of the cycle. The orogenic movements which gave their present form to the Zagros Ranges commenced in the Early Miocene and culminated in the Late Pliocene.

II. Stratigraphy

1. Pre-Cambian.

No exposures of pre-Cambrian rocks have been found throughout the autochthonous zone of Iran or Iraq. Crystalline schists and eruptive rocks of granitic character, sometimes gneissic in texture, are known in the zone of nappes, but these may be partly or wholly of Palaeozoic, possibly even Mesozoic age.

2. Palaeozoic.

Palaeozoic strata appear at the surface only in areas of considerable tectonic disturbance, either in faulted anticlines or in salt-plugs. The sequence is thus often obscure or defective, and some of the major divisions have not been recognized. It is fairly certain that, over much of the region, marine sediments assignable to Silurian, Devonian, and all but the uppermost part of the Carboniferous are absent.

(*a*) **Cambrian.** Normal exposures of Cambrian occur at the base of the great fault-slices in the Bakhtiari Mountains and in Kuh-i-Dina. Lower Cambrian consists of chocolate-coloured shales with black and variegated leached dolomite, overlain by red sandstones, red and green shales, and some bedded gypsum, with signs of the former presence of bedded rock-salt. Flakes and crystals of haematite are common in many of the shales.

Upper Cambrian consists of greenish-brown shales and thin micaceous sandstones with dark limestones containing Lingula, Billingsella, Hyolites, and various trilobites. Locally, reefs of limestone contain abundant, large, Orthis-

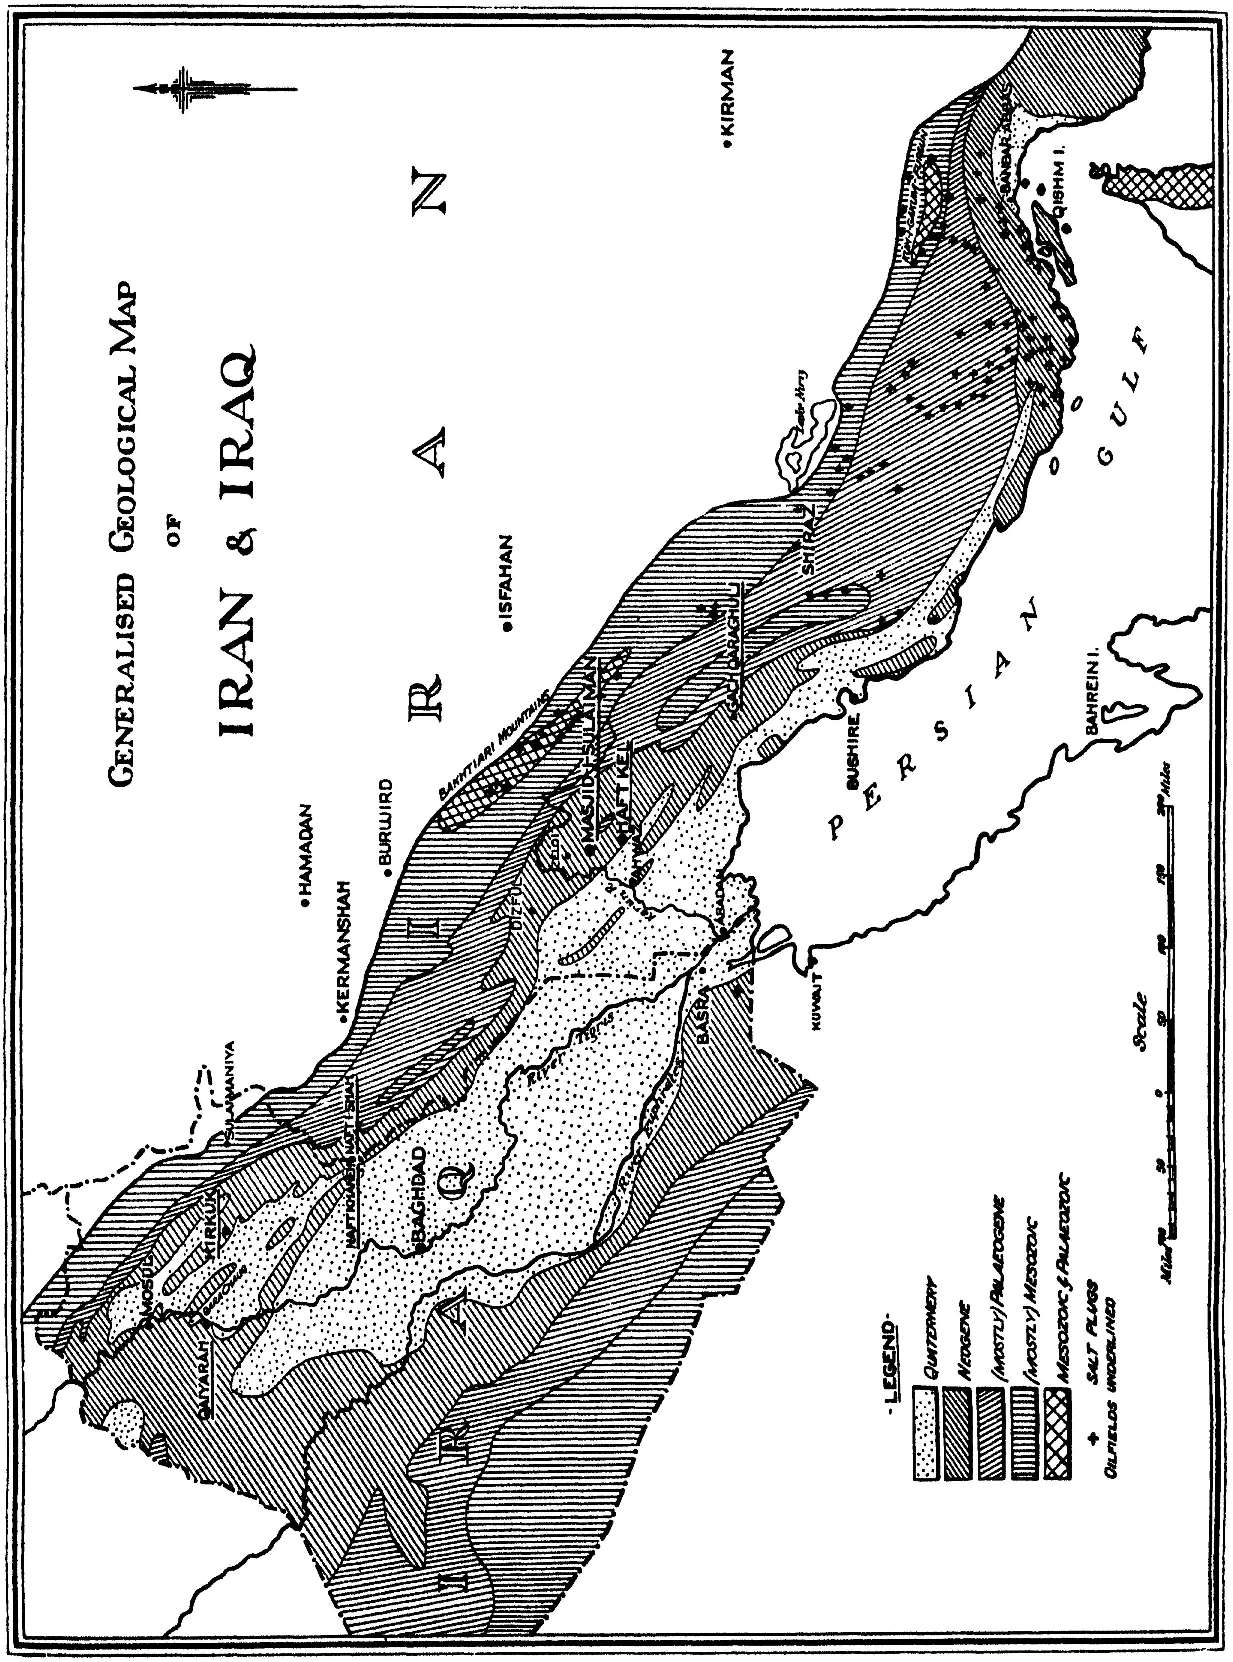

FIG. 1. Outline geological map of Iran and Iraq.

like brachiopods. The total thickness of Cambrian may be as much as 7,000 ft.

Salt-plugs. In addition to normal exposures, Cambrian rocks reach the surface through the mechanism of intrusive salt-bodies at numerous points in southern and south-western Iran and in the Persian Gulf. To date 130 of these salt-plugs have been discovered. The salt with its associated rocks was first named the Hormuz Series by G. E. Pilgrim [14, 1908], but no clue as to its age was forthcoming until 1924, when Middle Cambrian trilobites were discovered in shales and limestones associated with the salt-mass of Al Buza. The stratigraphy and structure of the salt-plugs were described by J. V. Harrison [4, 1930], to which work reference is made for further detail. These salt-masses are spectacular phenomena, but their effect on the concentration of oil is inconsiderable compared with that of the well developed normal anticlines among which they occur. It may even be negative in many instances.

The salt-plugs form intrusive stocks with an average diameter of about 4 miles and a subcircular cross-section; exceptionally they may emerge along fault-lines and have an elongate form. The salt-intrusions reach the surface through rocks of various ages from Cretaceous onwards. Some occupy the cores of anticlines, but most show no direct connexion with the normal folding, appearing on flanks or pitching ends of anticlines or even in synclines. Where the salt bursts through massive limestones there is little disturbance of the limestone around its periphery; but soft sediments, such as those of the Miocene and Pliocene, are steeply upturned around the edge of the salt-body. The salt carries up with it great detached masses of Cambrian rocks, purple-red and green shales and sandstones, buff and grey limestones and dolomites, black laminated foetid dolomites, and much anhydrite. The presence of the latter and of sandstones carrying salt-'pseudomorphs' point to an original association of these rocks with the salt, and the contained fossils give their age. (Many geologists hesitate to believe in a salt formation of such a great age and various attempts have been made to evade the issue. Krejci-Graf [9, 1928] suggested a Miocene age by assuming, with complete disregard for actual facts, great overthrusts; and more recently Kossmat [8, 1936] would prefer some such explanation. There is also a reluctance on the part of many geologists of the Indian Geological Survey to accept a Cambrian age for the salt of the Salt Range.) In many cases actual salt is not exposed, but its presence underground may safely be inferred from the abnormal appearance of this residual jumble of strange rocks occurring as a circular inlier surrounded by normal sediments; in other cases the plugs form mountains of bare glistening salt, reaching heights of as much as 5,000 ft. above the surrounding plains and forming the highest physical feature of the vicinity (Fig. 1). In these cases the salt is probably in a state of isostatic equilibrium and the yearly removal of material by rainfall is compensated by an equal rise of the salt-mass, thus maintaining its height above the surrounding limestones on its flanks. Harrison [5, 1931] and Lees [11, 1931] have shown that if the original position of the bedded salt is 20,000 to 30,000 ft. below the surface the greater specific gravity of the ordinary sediments can account for a column of salt rising to 4,000 ft. above surface-level.

The age of the salt movement ranges from Upper Cretaceous to Recent. Some of the plugs formed islands in the Upper Cretaceous sea, others in the Eocene and later seas, as is shown by the presence of conglomerates with 'Hormuz' detritus immediately surrounding the plug, whereas normally such conglomerates are absent. The salt-plugs which show evidence of early rise belong to a time before the present fold-system had developed, the later ones were in movement during the folding, while the intrusion of the youngest is subsequent to the folding and, in some cases, subsequent even to the development of the present topography.

(*b*) **Ordovician-Silurian.** The overthrust folds of Kuh-i-Furgun and Kuh-i-Gahkun, north of Bandar Abbas, expose some 200 ft. of dark, fissile shales with badly preserved graptolites (Monograptus, Diplograptus, and Climacograptus), provisionally assigned by G. L. Elles to Lower Valentian. The section is very imperfect; but the shales appear to be underlain by about 60 ft. of white quartzite, followed by 500 ft. + of sericitic shales, interbedded with thin quartzitic sandstone, full of fucoids and worm-tubes and frequently ripple-marked. The fucoid beds may be of Ordovician age.

Elsewhere in Iran where early Palaeozoic is exposed Ordovician and Silurian are absent.

(*c*) **Devonian.** The Silurian of the above localities is overlain by some 400 ft. of white, quartzitic sandstone with bands of green and dark shale, but fossil control of their age is lacking. They are followed by Upper Carboniferous limestones and so may represent the Devonian.

(*d*) **Carboniferous.** Marine Upper Carboniferous is probably represented in Kuh-i-Gahkun by limestones containing rugose corals, crinoids, and a productid fauna. In Bakhtiariland fossiliferous Permian overlies a group of brown-weathering sandstones and shales from which A. C. Seward [16, 1933] has identified *Sigillaria persica*, of age not greater than Westfalian and possibly Lower Permian. These beds lie without sign of angular unconformity on strata of Cambrian age.

(*e*) **Permian.** A thick series of dominantly calcareous strata extends from the Iranian-Iraq frontier near Halabja to Kuh-i-Furgun, north of Bandar Abbas. Locally, fossils (productids, fusulinids, corals) are fairly abundant in the lower half, but the upper limit of the strata assignable to the Permian cannot be determined.

3. Mesozoic.

(*a*) **Triassic.** Permian limestones pass upward without a break into the Triassic, which is represented by thick-bedded limestones and dolomites with, locally, subordinate hard calcareous or siliceous shales and some gypsum beds. Fossils are extremely scarce, but some species of *Myophoria* and *Pseudomonotis* (cf. Werfener Schiefer of the Alps) have been identified. In Kuh-i-Mungasht, east of Masjid-i-Sulaiman, a Middle Triassic (Carnic) fauna, containing *Gervillia socialis* and *Coenothyris vulgaris*, has been identified by J. A. Douglas, while south of Shiraz Upper Triassic is indicated by the occurrence of *Myophoria seranensis* and *Spiriferina altivaga*. For the most part the upper and lower limits of the Triassic are indeterminate, but the beds tentatively assigned to that age have a thickness of 2,000–3,000 ft.

In the zone of nappes the Triassic is present as a massive limestone formation carrying in its upper part abundant large megalodons reminiscent of the Dachsteinkalk of the Eastern Alps. These massive limestones are overlain, north-east of Kermanshah, by yellow and grey rubbly limestones and shales carrying an Upper Triassic Myophoria fauna and also the foraminifer *Orbitopsella*. This limestone-shale group passes upward into the thick series of red and green radiolarian cherts and shales which range

FIG. 2. Kuh-i-Namak Salt-plug. The salt extrudes through Cretaceous limestone, and the flow of salt downhill at either side of the plug can be seen

FIG. 6 View of the edge of the Turkidiz syncline at Masjid-i-Sulaiman showing the steep upturning of the Lower Fars. Tul-i-Bazun is on the right (see Section 1, Fig 4)

in age from, and perhaps include in part, the Upper Triassic through Jurassic into Lower Cretaceous.

(*b*) **Jurassic.** In the north-western half of the mountain-belt of Iran and Iraq the Jurassic is represented by a group of bituminous limy shales and thin limestones with chert bands, with a thickness varying between 250 and 1,000 ft. The limestones carry an abundant, though poorly preserved, fauna of small ammonites and are also rich in *Posidonomya*.

In Iraq, north-east of Zakho, Upper Jurassic has been recognized on the basis of the following determinations by Pringle and Chatwin:

Lithacoceras ardescicus
Virgatosphinctes vimineus
Ataxioceras?
Perisphinctes guentheri
Mytilus morrisi.

Farther to the south-east, Upper Jurassic appears to be absent but Middle and Lower Jurassic have been recognized throughout from Zakho to near Kermanshah. The thin-bedded limestones carry an Upper Bajocian fauna with *Stephenoceras* (of *coronatus* type), *Parkinsonia* sp., *Oppelia* sp., *Sonninia* sp., *Sphaeroceras* sp., *Morphoceras* sp. (determinations by Spath).

In the south-eastern half of the mountain zone the Jurassic is present as one component of a continuous thick-bedded limestone-formation which extends from Triassic into the Cretaceous, and in consequence of the scarcity of fossil-control the upper and lower limits of the Jurassic are indeterminable. A problematical shell at the base of the Jurassic is a thick shelled oyster-like organism which has been referred to *Lithiotis*, a form derived from the Lias of the Southern Alps and Croatia.

In the zone of nappes the Jurassic is represented by a thick series of red and green radiolarian cherts, red shales, and oolitic limestones; associated with them are great masses of green igneous rocks.

(*c*) **Cretaceous.** The Cretaceous may be divided lithologically into two groups, a lower with massive limestones predominating, and an upper with marlstones. The limestone division embraces the Lower and Middle Cretaceous up to the Cenomanian, and the marlstone division the Senonian and Maestrichtian, but for the most part it is uncertain to which group the Turonian should be assigned.

The Middle and Lower Cretaceous are represented as limestones throughout the entire length of the mountain-belt. In type, the limestones range from massive and thick-bedded neritic limestones or dolomites, carrying locally a rich fauna of oysters, large gasteropods, orbitolinas, and in its upper part rudists, to a thinner-bedded bathyal type, rich in microforaminifera and usually more or less bituminous. Subordinate developments of bituminous limy shales occur at different horizons, and, as a rule, yield abundant ammonites. In the north-west end of the mountain-belt, in Iraq, the Neocomian is composed of such limy shales and thin limestones, while the Aptian, Albian, and Cenomanian are continuous limestones. Farther south-east, in Iran, the more shaly zones are usually of Aptian or Albian age.

The Middle and Lower Cretaceous limestones are important feature-forming rocks, and they are responsible for most of the highest ranges. Where the limestones are hard and thick-bedded, strong features and heavy steep scarps result, while the thin-bedded bathyal facies tends to form smoother and more rounded hills. The thick-bedded limestones are folded into large simple units, whereas the thin-bedded type frequently crumples into a complex pattern of steep minor folds.

The upper lithological division of the Cretaceous is dominantly marly. Throughout the whole area the Senonian is almost uniformly represented by dark-coloured bituminous marlstones which on exposure weather light-blue, with some subordinate groups of thin-bedded limestones. The marlstones contain 60% or more of calcium carbonate and, although they crumble into small splinters on weathering and have the appearance of a soft formation, they are found to be hard and brittle and physically not unlike pure limestones when freshly exposed or where met in wells.

In Pusht-i-Kuh and at Imam Hassan, near Qasr-i-Shirin, the Senonian marlstones carry a rich fauna of oysters, echinoids, &c., the most prominent forms being *Gryphaea* (*Pycnodonta*) *vesicularis*, *Lopha dichotoma*, and various species of *Hemiaster*, *Iraniaster*, and *Epiaster*. The fauna indicates a Santonian or Campanian age. Elsewhere macrofossils are scarce but microfossils are very abundant, typical and diagnostic forms being *Globotruncana linnei*, *Globorotalia cf. globulosa*, *Globigerina* spp., *Anomalina* spp., &c.

The upper stages of the Upper Cretaceous, i.e. Maestrichtian and Danian, are, in the south-westerly zone, similarly represented by marlstones and thin marly limestones, but in the more north-easterly zone the effect of the Senonian movements still farther to the north-east is shown by the appearance of coarse detrital matter among the marls. (Danian is undoubtedly present, but fossil control of its limits is lacking.) The sands and conglomerates are formed almost exclusively of chert, felspar, and green minerals, which impart a dominantly green colour to the sediments. The Maestrichtian thickens up from about 1,500 ft. in the marly zone to about 5,000 ft. in this sandy zone. The sandy development carries a rich fauna including *Loftusia persica*, *Loftusia morgani*, *Omphalocyclus macropora*, *Cyclolites* spp. and numerous rudists. Locally reef-limestones composed of rudists are developed. Red shales and some gypsum beds are occasionally present.

4. Kainozoic.

(*a*) **Eocene.** The Upper Cretaceous deposition of marly sedimentation, alone or with sandy intercalations, continues into the Lower Eocene in much of the south-westerly zone. In a large area south-east of Shiraz the Lower Eocene is represented by a thick series of gypsum-beds and red marls (this may extend downward into the Upper Cretaceous).

Throughout much of the mountain-zone, particularly in the north-east, strong limestones, locally very rich in nummulites, commence with the Lutetian and continue through the Upper Eocene. Locally red marls are developed in the Middle and Upper Eocene.

In much of the south-westerly zone of Iran, as, for example, at Asmari Mountain and at Masjid-i-Sulaiman, the Middle and Upper Eocene are represented by thin-bedded marly limestones and marlstones with some bituminous beds, but in the equivalent zone in Iraq the Upper Eocene is present as nummulitic limestone and is important as forming part of the oil-reservoir rock of the Kirkuk oilfield.

(*b*) **Oligocene and Lower Miocene.** The uniform conditions of sedimentation which persisted in the Cretaceous and Lower Eocene throughout most of the Zagros belt were complicated in the Middle and Upper Eocene by the

local development of lagunar conditions and of limestone reefs. This process reached a maximum during the Oligocene and Lower Miocene, when areas of thick anhydrite deposition and areas of reef-limestone or of normal limestone form a complex pattern.

In the south, near Bandar Abbas, the Oligocene Khamir Limestone is a porous reef-development of nummulitic limestone and dolomite about 1,200 ft. in thickness, and the Lower Miocene is a gypsum-series. On Qishm Island, only 15 miles distant from Khamir, a well drilled through the Oligocene encountered a mixed shale- and anhydrite-series, but no limestone. In the country south-east of Bushire the Oligocene is represented by only about 50 feet of limestone with *Nummulites intermedius-fichteli*; the Lower Miocene is present as gypsum and shale.

From the Bushire–Shiraz road to Pusht-i-Kuh the Oligocene and Lower Miocene show a fairly uniform development as the Asmari Limestone—a limestone which has become famous as the reservoir-rock of the Iranian oilfields. It is described in detail in a later section.

In the frontal ranges of Pusht-i-Kuh, lagunar conditions prevailed, while in the more north-easterly ranges the Asmari Limestone facies continued. At Naft Khaneh the oil-reservoir rock consists of a limestone, locally known as the Kalhur Limestone, some 250 ft. in thickness, and this is underlain by about 400 ft. of anhydrite, salt, and thin limestones. The latter group is regarded as the time-equivalent of the anhydritic group of the middle section of the Asmari Limestone.

From the Iran-Iraq frontier near Chia Surkh to the Kirkuk oilfield the Lower Miocene has a conglomeratic development indicating pene-contemporaneous erosion. The components of the conglomerate are of local derivation and are cemented by limestone. The Oligocene is present as a porous dolomitic reef-limestone and in the case of Kirkuk, the Upper Eocene, also very porous, forms part of the so-called 'Main Limestone' reservoir rock of the Kirkuk oilfield.

(*c*) **Miocene and Pliocene.** Late in Burdigalian times the lagunar conditions, which had hitherto only had local development, became widespread, and the salt- and anhydrite-deposits of the Lower Fars were laid down in an immense gulf which stretched from the present Turkish frontier, north-west of Mosul to the Persian Gulf.

The Lower Fars is composed of anhydrite-beds associated with grey, greenish, or red marls, and a highly variable amount of bedded rock-salt. Further, the succession shows a number of thin limestones, some oolitic, some foraminiferal, and towards its basal part a few thin bands of bituminous shale. North-westwards, at Naft Khaneh and in Iraq, the limestone bands are much more numerous, and the lower part of the Lower Fars Group becomes a transition series to a dominantly anhydritic formation from a uniformly calcareous group beneath.

Economically, the Lower Fars is of great importance in forming the effective 'cap-rock' series to the reservoir limestone immediately beneath it, and for this reason it has been studied in a considerable amount of detail. In Iraq Lower Fars problems are comparatively simple. The salt-zone has allowed some independent movement of the upper strata over the lower in the axial regions of steep anticlines, such as Kirkuk, but the structural details can be controlled by good limestone-marker-beds at intervals throughout. Conditions in the main oilfield belt of Iran are rendered much more complex by much greater original thicknesses of Lower Fars and a greater development of salt, combined with more intense compression. The result is that there is in many places complete disharmony between the surface rocks and the more rigid Asmari Limestone beneath. A further difficulty in the past has been the absence or rarity of characteristic marker-beds throughout many thousands of feet of apparently uniform anhydrite, shale, and salt, but recently it has been found possible to use the microscopic texture of the anhydrites themselves for diagnostic purposes with notable success (Strong [17, 1937]). Certain minute mineral-inclusions are constant within individual anhydrites over long distances and different horizons in the Lower Fars are characterized by inclusions of various carbonate minerals, quartz or chalcedonic silica.

The Lower Fars has been subdivided in Iran into three stages. Stage I at the base consists of grey marls, anhydrites, and much salt, with some thin oil-shales and locally some limestones in the lower part. The cap-rock anhydrite at Masjid-i-Sulaiman and Haft Kel carries thin stringers of foraminiferal limestone, which facilitate its recognition and thus enable precautions to be taken before drilling into the reservoir limestone immediately below. The thickness of Stage I is exceedingly variable. Over part of the Masjid-i-Sulaiman field it is absent, presumably by non-deposition, while at Zeloi, 15 miles to the north-west, a well commenced in Stage I, reached its base at 10,680 ft., this amount being, of course, due to tectonic accumulation of an originally thick development.

Stage II is more regular in its thickness and behaviour. It consists of red and grey marls, anhydrite, and locally some salt, and has an average thickness of about 500 to 700 ft.

Stage III consists of anhydrite and grey marls with some shelly limestones. Structurally it conforms with the overlying Middle Fars rather than with the lower stages of the Lower Fars.

The Middle Fars is best developed in the area between Bushire and Ram Hormuz, where it includes up to 2,500 ft. of pale-greenish or grey marls and marly limestones containing an abundant molluscan fauna, conspicuous amongst which are large oysters of *Ostrea virleti* and *O. gingensis* types. It also includes huge masses of reef-limestones composed of calcareous algae and bryozoa with some foraminiferal and coralline layers. The group shows transitions to the chemical series below (interbedded gypsum, oolitic limestones) and the detrital series above (interbedded sandstones). In the neighbourhood of Masjid-i-Sulaiman the whole group is only about 600 ft. thick, and in Iraq a separate Middle Fars Group has not been distinguished.

The Upper Fars Group is composed of reddish, brownish, or greenish marls, separated at close intervals by 20–40-ft. bands of grey or brownish sandstone. Originally the name was confined to the lower 3,000 ft. of the detrital series, while the thousands of beds above, which are generally somewhat paler in colour, less coherent, and more or less pebbly, were called the Lower Bakhtiari Group. It now appears doubtful whether this distinction has anything more than conventional value. Deposition was continuous, and the transition from finer to coarser detritus was a gradual one, corresponding with a gradual uptilting of the north-eastern edge of the region, from which the materials came. The great break occurs at the end of the Lower Bakhtiari deposition, when the mountain-building revolution reached its culmination and the coarse Upper Bakhtiari conglomerates were deposited on the bevelled folds.

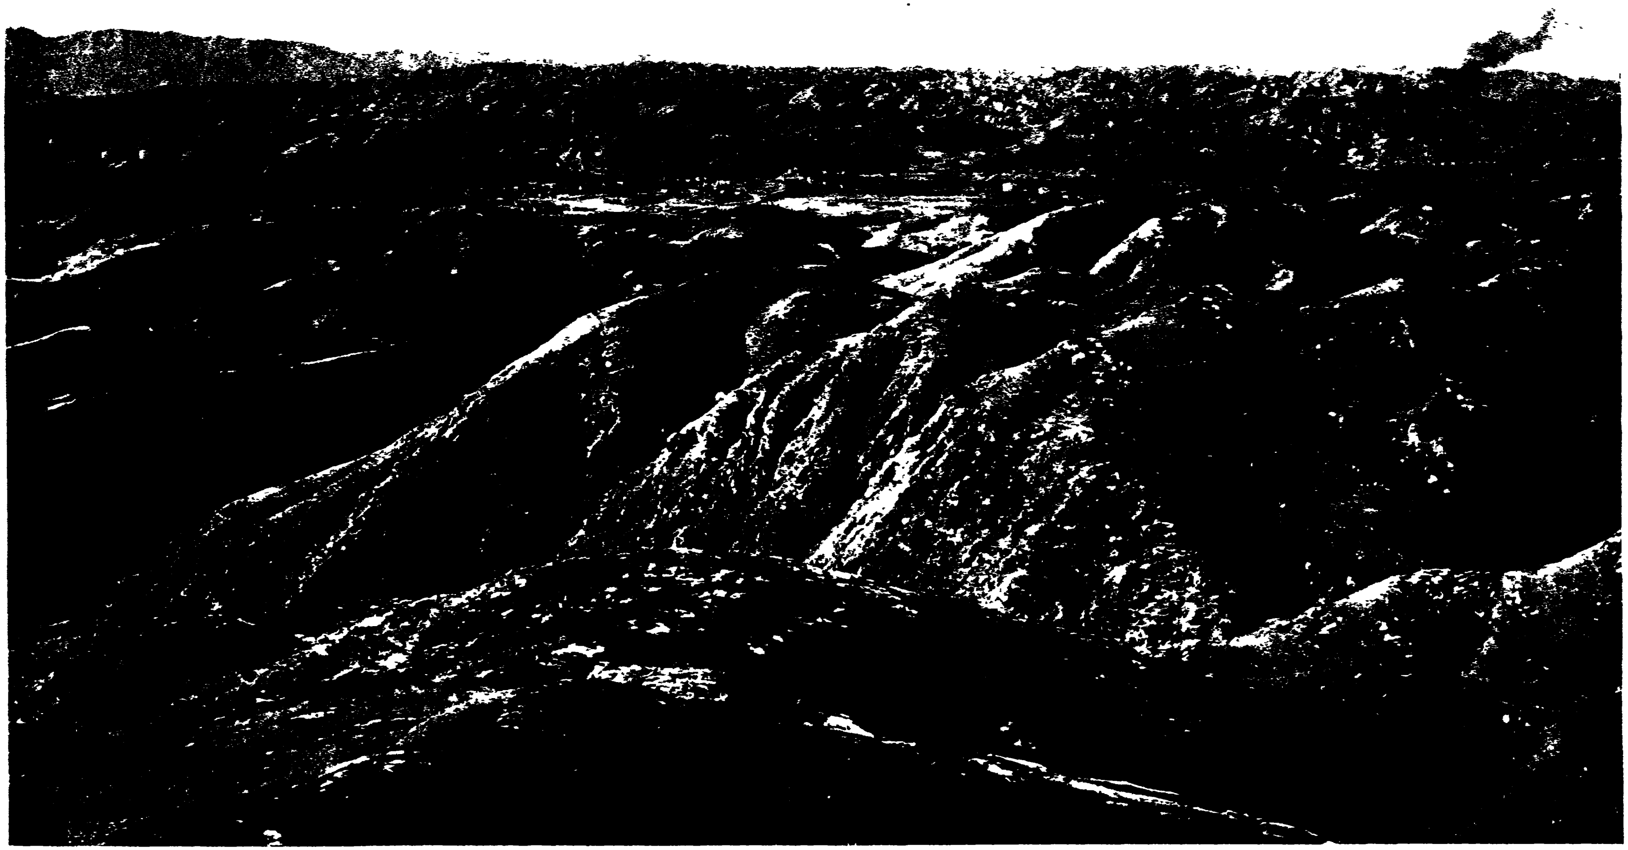

FIG. 5 View of the central part of Masjid-i-Sulaiman oilfield showing dissected Lower Fars landscape

Between Bushire and Agha Jari marine intercalations are present in the basal 2,000 ft. of the Upper Fars, and some horizons carry abundant large oysters (*Crassostrea gryphoides*) and, more rarely, a mixed fauna of echinoids and lamellibranchs. Farther north, however, the Upper Fars is completely unfossiliferous, and to place the boundary of the Miocene and Pliocene exactly is impossible.

Bakhtiari Conglomerates. As already stated, the cycle of deposition ends in most areas with coarse conglomerates, called the Bakhtiari Conglomerates, locally many thousands of feet thick, which, as they are usually lime-cemented, form prominent hill-features with steep scarp-faces. Lack of fossil-control prevents any exact time-correlation from area to area, and the age of the massive conglomerates is probably not constant throughout. In the mountain areas to the north-east folding-movements commenced earlier and the resultant conglomerates are probably older than is the case in the foot-hills.

The only palaeontological evidence of the age of the Bakhtiari series is from mammal bones and teeth. Pomeyrol collected at Qara Chauq Dagh various bones and teeth, among which Astre [1, 1936] identified a tooth of *Hipparion gracile*. G. M. Lees [10, 1927] discovered teeth and bones of *Hipparion gracile* cemented by asphalt in a conglomerate at Khadda Sur, north-east of Masjid-i-Sulaiman. Their age is approximately Pontian.

Mio-Pliocene of the Persian Gulf Littoral. The Mio-Pliocene beds of the Persian Gulf show a similar succession of lagunar, marine, and terrigenous deposits; but the most prominent development of gypsum-beds, which follows on the Khamir Limestone and was at first accepted as the equivalent of the Lower Fars Series of the oilfield area, has been found to be older and contemporaneous with the lower part of the Asmari Limestone. Later work has therefore discarded the Fars-Bakhtiari divisions used elsewhere in Iran and distinguished:

(*f*) Upper (Arenaceous) Group	Mio-Pliocene
(*e*) Lower (Argillaceous) Group	
(*d*) Upper or Operculina-Limestone	Miocene
(*c*) Red Beds	
(*b*) Lower or Gypsina-Limestone	
(*a*) Gypsum-series	

The Miocene reaches a thickness of some 4,000 ft. near Champeh, where the lower 2,500 ft. belong to the Gypsum Series (*a*). The Mio-Pliocene beds may be as much as 8,000 ft. thick, half of which thickness belongs to the arenaceous and half to the argillaceous division. The upper division locally includes some thick, massive, limestone-conglomerates similar to the Bakhtiari Conglomerates.

III. Oil Indications

Both the mountain belt and the foothill zone of Iraq and south-western Iran are rich in oil indications of various sorts. The Eocene, Cretaceous, and Jurassic marlstones and limestones carry numerous small veins and pockets of asphaltite ranging in type from semi-soft bitumens through hard brittle glossy 'manjak' to hard infusible and insoluble 'impsonite' with a carbon-hydrogen ratio of as much as 22 to 1. The field relationships of such occurrences, and the fact that such asphaltites can be met with in deep wells, show that they are not the products of inspissation of oil by exposure at the surface, but the detail of the process of their formation has yet to be satisfactorily explained (Lees [12, 1933, p. 4]).

Seepages within the mountain belt are much less frequent than the solid residues within the rocks, but they have an extensive distribution from Bandar Abbas to north of Mosul. For the most part they are small and unimportant, but in some isolated cases the yield amounts to several gallons a day and is sufficient, as in the case of Imam Hassan, to warrant its collection by the local inhabitants.

The most prolific oil- and gas-seepages are contained in the foot-hill zone. Many occur at or close to the outcrops of the Asmari Limestone and represent the last stages in the exhaustion of a one-time oil-accumulation resulting from exposure by erosion of the reservoir-rock, as at Dasht-i-Qil, 20 miles south-east of Gach-i-Qaraghuli; others occur in Lower Fars areas where erosion has weakened the cover-rocks of underground accumulations sufficiently to allow leakage to the surface. The oilfields of Qaiyarah, Kirkuk, Naft Khaneh and Naft-i-Shah, and Masjid-i-Sulaiman all show active escapes of oil and gas at the surface. At Haft Kel and Gach-i-Qaraghuli, where the thickness of cover is greater, only gas-escapes are present over the crestal areas of the underground reservoirs, and at White Oil Springs the light oil is regarded as a condensate from escaping gas. In many places solid or semi-solid bitumen deposits are evidence of an earlier escape of oil, in others, such as near Hit, extensive pitch lakes are formed.

Escaping gas in many places gives rise to a phenomenon named Gach-i-Turush (Iranian for sour gypsum). It is a deposit of soft powdery gypsum, white at the surface, but chocolate-brown beneath, containing many small or large sulphur crystals. Escaping gas may often be detected by an acrid pungent smell indicating an oxidation of sulphur gases. The gypseous earth is usually slightly damp, and tests have shown a free sulphuric acid content of up to 9%. In most areas of strong Gach-i-Turush there is a development of aragonitic limestones which seem to be the product of the action of hydrocarbon gas on original gypsum-beds, a reaction which would account for the richness in sulphur of the gas escaping at the surface.

In areas such as Masjid-i-Sulaiman, where a simple Asmari Limestone anticline is overlain by contorted Lower Fars beds, the escaping gas is concentrated into the crests of these minor folds and both the Gach-i-Turush and the development of aragonitic limestones are confined to these local areas. The Gach-i-Turush and secondary limestones are entirely superficial phenomena and are not encountered in any of the wells below a depth of about 200 ft.

IV. Structural Conditions in the Oilfields

1. Masjid-i-Sulaiman.

The Masjid-i-Sulaiman oilfield lies in a zone of extreme structural complication, as is shown by the accompanying section (Fig. 4, Section 1). The disharmony between the surface formations and the rigid limestone-mass, which includes the Asmari and the underlying limestones and marlstones, is the result of independent movement of great masses of salt within the Lower Fars and of the gliding of the upper groups on this mobile member. The conditions are further complicated by the fact that there were originally great differences in thickness, and particularly in the amount of salt deposited on anticlinal areas and in synclinal regions, the result of gentle warping during the early part of Lower Fars times. Thus, in the axial part of the north-western (or Asiab) half of Masjid-i-Sulaiman, Stages I and II of the Lower Fars are absent and Stage III rests directly on the cap-rock anhydrite immediately overlying

the Asmari Limestone, and detailed stratigraphical work on this problem has indicated that this condition is original and not due to tectonic attenuation. Farther south-east, on the present crest maximum, the Lower Fars is at the surface and seems to have had an originally greater thickness than on the line of section as shown, and structural complications are greater.

Experience with Lower Fars tectonics has shown that date it would be equally permissible, on surface evidence alone, to draw an Asmari syncline and thus to make the surface anticline the result of tectonic packing of the Lower Fars, and, in particular, of its salt members. A notable success in zoning the Lower Fars has been achieved in the Gach-i-Qaraghuli region, and by studying changes of original thickness it is sometimes possible to predict the position of Asmari highs in complicated Lower Fars areas, but in many cases imbrication of the Lower Fars at the surface, combined with confused exposures resulting from the solution of salt, makes this impossible. The value of geophysical assistance in such an area as Andakah does not require emphasis.

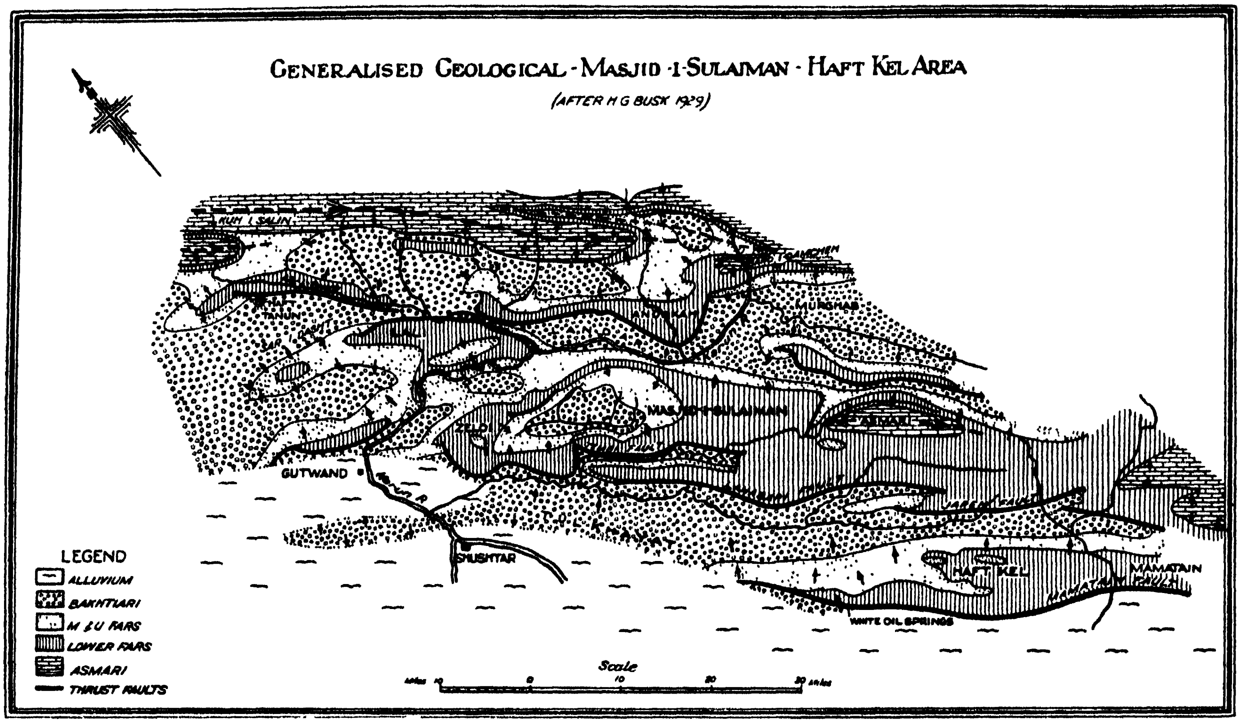

FIG. 3. Outline geological map of the Masjid-i-Sulaiman Haft Kel area.

in areas where the Lower Fars is thin there is an approximate structural concordance between it and the Asmari Limestone, but as the Lower Fars increases in thickness down-flank structural complications set in. The cross-section has been drawn to include three major anticlinal axes on which the thinness of the Lower Fars development has caused the upper structure to be more or less anchored to the Asmari beneath. These axes are the Haft Kel–Tulkhayat axis in the south-west, the Masjid-i-Sulaiman axis, and the Kuh-i-Kamerun axis (the line of section crosses the pitching end of a large anticline which farther south-east exposes Asmari Limestone and older rocks).

The subsequent compression of this zone formed a series of steep, overturned, and perhaps faulted anticlines in the Asmari Limestone, but the mobility of the great thickness of salt in the major synclines prevented the cover-rocks from conforming in detail. Masses of Lower Fars, impelled by the salt, were ejected and burst through at lines of weakness in the cover to form long diapir-like anticlines such as Imam Riza and Tul-i-Bazun. Some of these narrow diapir anticlines (the 'gamma' and 'omega' structures of Busk [3, 1929]) may be underlain by a flexure at depth, as is shown at Imam Riza, or they may be merely a blister which has grown on a monoclinal flank of the Asmari, as is shown in the case of Tul-i-Bazun.

The difficulty of diagnosing the underground conditions is illustrated on this section in the case of Andakah. The section shows a deep Asmari fold, but on experience to

The foregoing paragraphs describe the difficulties met with in attempting to locate anticlinal axes across the strike of the country. Along the strike the handicaps are equally formidable. Masjid-i-Sulaiman is in general terms a simple anticline in the Asmari Limestone separated from Asmari Mountain itself by a simple saddle. The north-western half of the Masjid-i-Sulaiman anticline pitches down under the surface Turkidiz syncline (Fig. 6). This surface syncline is flanked by the Lower Fars of Tul-i-Bazun on the north-east and by the Lower Fars of Sar-i-Naftak and Gach-i-Khalaj on the south-west. Farther to the north-west the Turkidiz syncline rises, and these two Lower Fars limbs coalesce in the Zeloi area in such a way that there seemed a high probability that the surface structure was the effect of an underground dome in the Asmari Limestone, separated by a saddle from the Masjid-i-Sulaiman unit. During the years up to 1930 a number of wells were drilled to explore this possibility, the deepest being Zeloi no. 2 which reached 5,655 ft.

Subsequently the problem was investigated afresh by both geological and geophysical means, and in 1935–6 a well, Pirgah no. 2, was drilled as a result. From a seismic reflection survey the depth of the limestone was assessed at

about 5,000 ft., but at 10,025 ft. the well was still in Lower Fars beds comparatively high stratigraphically, and as there seemed no prospect of reaching the limestone at a depth shallower than 15,000 ft. the well was abandoned. A fresh seismic survey suggested that the axis lies farther to the north-east, and a new well, Zeloi no. 4, has recently been drilled, which reached the Asmari at 10,680 ft. A production-test made after drilling into the limestone to 11,190 ft. yielded only water, but as a core taken indicated a dip of about 50° it is possible that even this well is not located in the best position. The core showed oil-saturation in the Asmari limestone.

2. Haft Kel.

The Haft Kel oilfield is situated on a crest maximum of a long anticlinal line which extends from south-east of Mamatain to Shushtar. Copious seepages at Mamatain drew attention in the early years of development to that area, but drilling results were then disappointing. Mamatain is separated by a saddle from the Haft Kel unit, and it is possible that the seepages at Mamatain may represent an escape of oil to the surface which had spilled across the saddle from Haft Kel. The crestal area of the Haft Kel field is marked by an active gas-escape, but the only oil seepage, a very small and sluggish spring of thick oil, is not situated on the structural crest.

In the central part of the Haft Kel field the Asmari Limestone is covered by a substantial thickness of Lower Fars which is strongly disturbed by numerous faults and steep minor folds, and the Lower Fars zone to the south-west of the Asmari axis is strongly overthrust. At the north-western end of the field the Lower Fars is much thinner and more regular in its behaviour, and the Upper Fars swings across the axis, marking a saddle between the Haft Kel unit and the next crest-maximum to the north-west at White Oil Springs. The White Oil Springs dome is interesting on account of the occurrence of strong gas-escapes and springs of a light straw-coloured oil of 0·779 specific gravity. For many years this oil was regarded as a product of filtration, but recent experience has indicated that it is in reality a condensate from escaping gas. The underground Asmari anticline has a gas-dome of substantial size, and a well in the Asmari Limestone in the crestal region struck a gas pressure of 2,600 lb. per sq. in. at 2,987 ft.

Section 2 illustrates the structural conditions on the Haft Kel axis itself and in the area between it and Asmari Mountain. Within this area the attitude of the Asmari Limestone cannot be determined by surface geology. It is not impossible that the packet of Lower Fars strata is much thicker than is shown, and that the surface structures are entirely the product of salt-movement. Certainly the only deep well drilled in this area, Yamaha no. 2, reached a depth of 8,960 ft., and of this thickness about 53% was rock-salt. Here again the scope for geophysical assistance is obvious.

3. Gach-i-Qaraghuli.

This oilfield, which at the time of writing is in an early stage of definition by exploratory drilling, lies 150 miles south-east of Masjid-i-Sulaiman and 50 miles inland from the Persian Gulf coast. In this case the attitude of the Asmari Limestone is rendered even more obscure than at Masjid-i-Sulaiman and Haft Kel by extreme disharmonic movements of the cover-rocks over the rigid Asmari block. There is, however, a certain similarity with Masjid-i-Sulaiman. The Seh Qalehtun Syncline is found superimposed on an underground arch of Asmari Limestone, in exactly the same way as the Turkidiz Syncline at Masjid-i-Sulaiman.

The structural picture, in so far as it is known at present, is shown on Section 3. To the north-east the Kuh-i-Khumi–Kuh-i-Dil mountain-group rises abruptly from an undulating plain of contorted Lower Fars. The mountain exposures show steep folding and compressed synclines, and it seems possible that much of the Lower Fars complication to the south-west is due to the expression of mobile material from compressed synclines of a type comparable with, but probably less intense than, the exposed examples.

It should be noted that the over-folding of the Asmari Limestone on the north-east flank of Kuh-i-Khumi is due to gravity-collapse and not to normal tectonics. This remarkable phenomena has been described by J. V. Harrison [6, 1934; 7, 1936].

4. Naft Khaneh and Naft-i-Shah.

These oilfields lie on the Iraq–Iranian frontier, 80 miles north-east of Baghdad. Compared with the oilfields in Southern Iran, the structural conditions are simple. Lower Fars rocks are just exposed in the core of a steep asymmetrical anticline, the south-western limb of which is steep and broken by a reversed fault, the effect being to displace the surface axis substantially to the south-west of that in the Lower Miocene limestone. The surface crest is marked by copious oil-seepages and strong gas-escapes.

V. Reservoir Rocks and Conditions

The reservoir-rock of the Iranian oilfields, Masjid-i-Sulaiman, Haft Kel, and Gach-i-Qaraghuli, is the Asmari Limestone of Lower Miocene and Upper Oligocene age. At Naft Khaneh and Naft-i-Shah the reservoir-limestone is approximately of the same age, but its development is different and it has been given the local name of Kalhur Limestone. At Kirkuk the reservoir-rock is of Oligocene and Upper Eocene age and the Lower Miocene has a lime-cemented conglomeratic development, which is of lesser value as an oil-reservoir.

The preponderant association of oil-seepages with the Lower Fars Series within the oilfield belt led at first to the conclusion that the oil was generated within that series. Later the hypothesis was formulated (Richardson [15, 1924]) that the oil was indigenous to the Asmari Limestone, or that it was associated particularly with a lagunar development of that limestone (de Böckh in Discussion to Richardson, 1924). Oil-indications were, of course, known from lower horizons, but such older oils were considered to have no connexion with the Asmari reservoir-system. Later experience, however, has shown that the excellence of the Asmari Limestone as a reservoir-rock is due largely to the efficiency of the overlying Lower Fars as a cover-series, and that the oil which lodges in this reservoir may have migrated upwards from the Eocene or from various horizons within the Mesozoic, and accumulated when trapped beneath the impervious salt-shale-anhydrite series of the Lower Fars. The exact age of the reservoir-rock is therefore not important, and the Oligocene-Upper Eocene limestone of Kirkuk has a function exactly similar to that of the Oligocene-Miocene Asmari Limestone despite its difference in age.

The Asmari Limestone at Asmari Mountain and at Masjid-i-Sulaiman has a thickness of approximately 1,000 ft. The upper half consists of thick-bedded greyish,

foraminiferal limestones; the lower half has many thin intercalations of marl and anhydrite, and at the base there is a strong 25-ft. bed of anhydrite. The limestone is mostly hard, dense, and of low porosity, but there are occasional beds of softer, brownish rock of porosity between 5 and 10%, exceptionally up to 15%, and the highest record is 22%. The rock under the conditions of strong compression and folding is freely fractured, and the high productivity of the Masjid-i-Sulaiman and Haft Kel wells is primarily due to the fissured condition of the limestone. Much of the total oil of the reservoir is, of course, held in the rock-pores, but the permeability of even the most porous bands is insufficient to allow the oil to flow into a well unless an open fissure is encountered, and there are isolated cases of wells which have penetrated the entire thickness of the limestone without obtaining any production. The fissure-system, on the other hand, is so strongly developed that there is free interconnexion between wells many miles distant from one another, a factor which permits of controlled production under ideal conditions.

The Asmari Limestone at Haft Kel and at Gach-i-Qaraghuli is similar in general terms to that at Masjid-i-Sulaiman, although there are some differences in detail. In both these places there are many lenticles of anhydrite in the upper part of the limestone.

The nature of the porosity of the Asmari Limestone has been the subject of much controversy in the past. At one time it was thought that there was a direct connexion between dolomitization and porosity (Richardson [15, 1924]), but subsequent more detailed work showed that this is not the case (Lees [13, 1933]). There is a certain admixture of magnesium carbonate in varying proportions throughout, but careful analyses have failed to show that the porosity is governed by this factor. The limestone as a whole has a ramifying system of mineralized cracks, some filled with calcite, others with anhydrite, more rarely with celestite. These veins are mostly tightly filled, but some have open vugs or enlarge into open cavities. The system of cracks which affords the present channels for fluid movement within the reservoir belong to a later phase, and many of the mineral-veins are traversed by such cracks. These cracks are mostly inclined at steep angles, and many show slickensided faces, although the amount of movement is usually small. Drilling results have proved some small faults, but they are relatively unimportant.

The Asmari Limestone outcropping on the pitching end of the mountain of that name is only 8 miles from the nearest producing wells of the Masjid-i-Sulaiman field, and although there is intimate fluid connexion throughout most of the oilfield, this condition cannot extend across the intervening saddle, since otherwise the withdrawal of oil would result in the free entry of new water from the water-table at Asmari Mountain. It is possible that the saddle area, having been less strongly compressed, is less fractured and, further, since the saddle is below oil-water level, such cracks as have formed may have been sealed to a large extent by mineralization caused by the surface carbonate- and sulphate-bearing waters meeting the brine of the edge-water system of the oilfield.

At Naft Khaneh and Naft-i-Shah the reservoir rock, the Kalhur Limestone, is about 250 ft. in thickness and is in part a foraminiferal limestone, in part somewhat dolomitic with only obscure traces of organic structure, and in part oolitic. It is underlain by about 400 ft. of anhydrite, salt, and thin limestone, below which lie marls and marly limestones similar to those underlying the Asmari Limestone at Masjid-i-Sulaiman. The anhydrite and salt indicate a locally intense lagunar phase, represented at Masjid-i-Sulaiman by the thin beds of anhydrite in the lower part of the Asmari Limestone. The basal part of the Lower Fars of this area carries a number of thin limestones or groups of thin limestones interbedded with anhydrite and shale, and these form part of the reservoir-system, being themselves interconnected and connected with the Kalhur limestones, probably by faults.

VI. Acknowledgements

This short summary of the geology of the oilfield belt is presented on behalf of the geological staff of the Anglo-Iranian Oil Company, Ltd. It represents the results of field work and observations made through many years by a large number of individuals, and it has not been possible to acknowledge separately the part played by each. The writer, however, is particularly indebted to Mr. B. K. N. Wyllie for assistance in the preparation of the manuscript.

THE STRUCTURAL CONDITIONS OF THE KIRKUK OILFIELD, IRAQ

By N. E. BAKER

Chief Geologist, Iraq Petroleum Company, Ltd.

In the article by G. M. Lees, the general stratigraphical and structural conditions of the Iranian-Iraq oilfield belt have been described. In the regional sense this belt forms one single unit, but when the detail of individual oilfields are studied there are, of course, many points of difference.

The following remarks and cross-section attempt to reveal some of the details of the Iraq type of folding. The interpretation here given represents the composite views and opinions held by the numerous geologists who have done a vast amount of geological work in Iraq.

The accompanying cross-section of the Kirkuk structure illustrates the difficulty of locating wells intended to encounter the subsurface crest of the anticlinal fold. Over a large part of the length of the structure only north-east dips are observed together with strike and transverse faults and minor wrinkling of beds on the north-east flank. The monoclinal dip offers very little direct evidence as to the subsurface position of the crest maximum. Likewise, in that portion of the structure where there is well-marked surface evidence of anticlinal reversal, the surface structure is scarcely an approximation of the subsurface crest in the productive horizon. This nonconformity of subsurface to surface folding is not due merely to asymmetry of the fold, but rather to the manner in which the various stratigraphic horizons have reacted to the folding.

The stratigraphy involved embraces at the top of the section a thick series of sands, gravels, and conglomerates (Bakhtiari). Below this is a sand, siltstone, and shale series (Upper Fars) followed by gypsum, anhydrite, siltstones, and limestones (Lower Fars). The basal part of the Lower Fars is a salt series separated from the Main Limestone (the productive horizon) by the Transition Zone limestone and anhydrite, the lowest member of the Lower Fars. The Transition Zone and Main Limestone members are rather massive, dense, resistant rock, while the overlying formations are comparatively soft and plastic and, in comparison with the limestones, are much more incompetent beds. This relative incompetence reveals itself in the manner in which the various horizons have reacted to the force of folding, as depicted in the diagram.

The Kirkuk fold parallels the north-west to south-east trend of the Iranian Mountain Range. Its somewhat sinuous shape indicates that the structure was formed in two stages, between which there was a strengthening and a change in direction of the fold-forming pressure. During the first stage the pressure came from a direction at right angles to the original shore and facies lines of deposition. Later, the pressure came from a more easterly direction. The effect of the first folding caused a thickening of the Salt Zone in front of the Main Limestone arch, making the south-west flank steeper in the Upper Fars and Bakhtiari than in the Main Limestone. This is evidenced in the south-west flank wells, where there is a tectonic thickening of the Salt Zone. Further pressure broke the steep south-west Fars/Bakhtiari flank and allowed the north-east flank to ride forward. The extent of this overriding cannot be determined, as immediately upon entering the Salt Zone the fault becomes a surface of slipping more or less parallel with the bedding. The result of the thrusting also was to pile up a thick mass of Fars and Bakhtiari in front of the Main Limestone crest.

At about this time, corresponding with the strengthening and change in direction of pressure, there began the deposition of the upper unconformable Bakhtiari gravels low on the north-east flank. The effect of this differential loading across the structure, accentuated by the change in the direction of the folding force, was that the Main Limestone was now most free to move upwards, high on the north-east flank. Subsequent pressure caused a further south-westward movement and flattening of the Main Limestone crestal area and a hollowing on the forefront of the limestone arch on the north-east flank.

In the Lower Fars the moving back of the Main Limestone crest caused the almost complete squeezing out of the Salt Zone high on the north-east flank, the materials moving over to the south-west of the crest and forming a crushed and mixed accumulation, such as encountered in the wells drilled and shown in the accompanying sketch.

The principal reason for this independence of movement of beds, and resultant nonconformity of structure in the surface and subsurface horizons, can be attributed to the mobility of the Salt Zone and relative immobility of the Transition Zone and Main Limestone. The salt has acted as a lubricant, facilitating the sliding and wadding of beds along the top of the more rigid limestone mass.

At some points along the structure it appears that the beds above the Main Limestone have merely glided over the stable subsurface arch. However, throughout most of the length of the structure the intensity of the folding has overthrusted and contorted the younger beds, as pictured. The limestone arch, as a whole, has remained stable, though it has suffered faulting locally.

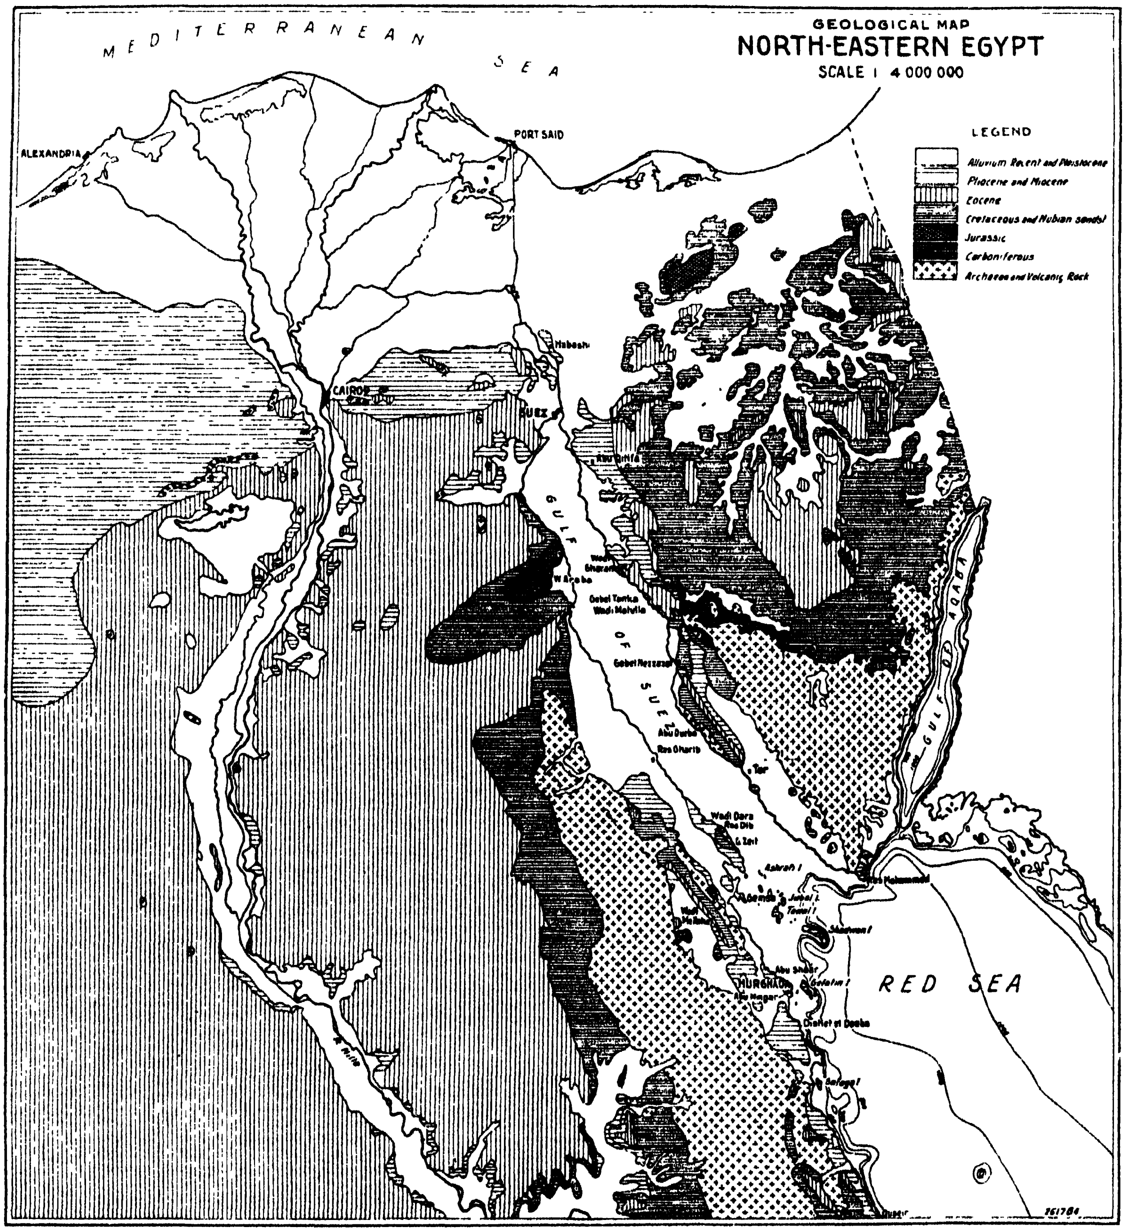
In advance of drilling results, the head of the overthrust fault plane, the amount of thrust and the amount of wadding and compaction of beds are some of the problems open to conjecture. The attendant difficulty of forecasting the crest of the subsurface arch below such a confused mass of stratigraphy becomes apparent.

EGYPT

By Dr. P. VAN DER PLOEG

Bataafsche Petroleum Mij.

A GREAT part of Egypt is covered by sediments of Mesozoic and Tertiary age deposited by Mediterranean Seas over the slightly northward inclining African–Arabian crystalline shield. In Northern Egypt and Sinai these sediments have been folded in SW.–NE. striking ranges which, turning to the north, extend into Palestine and Syria. At right angles to the direction of these ranges rift valleys were formed—that of the Gulf of Suez and that of the Red Sea, with its eastern branch the Gulf of Aqaba. The development of these troughs is due to two main periods of faulting, one in the Upper Oligocene and the other in the Pliocene time. During the first period the relatively shallow Gulf of Suez trough and the border zones of the Red Sea were formed, whereas the much deeper subsidence of the central part of the Red Sea and of the Gulf of Aqaba took place in the second period. During this later time the movements also continued in the Gulf of Suez area, but were comparatively less violent there than farther south.



The Gulf of Suez area specially interests us for its oil occurrences. As may be seen from the igneous ranges of Esh-Mellaha, Zeit, and Abu Durba the subsidence of the crystalline rocks with their cover of Mesozoic and Eocene

strata occurred through step-faulting. The down-thrown blocks were tilted generally in such a way that an igneous front faces the sea and on the opposite side Mesozoic sediments are exposed, dipping away from the Gulf. Where such rigid blocks are covered by more plastic Miocene marl and marl-gypsum series subsequent vertical movements have caused, in addition to faulting, much dragging, squeezing, and superficial folding in these younger series. Such fold-like structures are, for instance, those of Abu-Mingar, Hurghada, and Eastern Gemsa, all three lying over igneous ridges, and Abu-Shaar, Ras el Bahar, and Wadi Dara situated between such ridges in depressions which, as a rule, contain thick masses of salt.

Hereunder the succession of the strata found in the Gulf area are given in brief:

Pleistocene:	Sandstones and oolites.
Unconformity.	
Pliocene:	Limestones, grits, and sandstones.
Unconformity.	
Miocene:	Limestone series.
	Lagoonal series: Marls, gypsum, salt, and limestone beds.
	Globigerina series: Green marls.
	Basal Beds: Reef-limestones, grits, and flint conglomerates.
Unconformity.	
Eocene:	Marl, gypsum and limestones with bands of flint.
Upper Cretaceous:	Limestones.
	Micaceous carbonaceous shales alternating with sand and sandstones.
Cretaceous and older:	'Nubian' sandstone.
Carboniferous: only at Wadi Araba, and central Western Sinai.	Limestones and sandstones with shale bands.
	Igneous.

The surface manifestations of oil are not too impressive in the Gulf area. There are five poor liquid oil seepages. The best one is on the shore near the south-eastern end of the Zeit range, another is in the old sulphur mines at Gemsa; the remaining three seepages rise from under water near the sea-shore, viz. at Gebel Tanka, Abu Durba, and east of the Jubal Islands. Outcropping impregnated sands of Cretaceous or Eocene age were found in the Wadis Gharandel and Matulla, near Gebel Nazazzat, and at Abu Durba.

In view of these indications much drilling has been done on both sides of the Gulf. On the Egyptian side 13 structures were tested and on the Sinai side eight. Most of the wells had gas- or oil-shows; production, however, has so far been obtained only from three fields, viz. Hurghada, Gemsa, and Abu Durba.

Hurghada is the most important of these fields, and the only one which is still producing. The field consists of two structures, both of which exploit or have exploited three oil horizons: Miocene Lagoonal Series, Miocene Basal Beds, and Cretaceous Sandstone Series. The oil from the Miocene is a lighter grade than that from the Cretaceous. Most oil has been obtained from the Cretaceous Series. The total production from both structures up to 31 December 1935 was about 4,000,000 tons.

The Gemsa field has yielded a total of only 180,000 tons of a light oil from a narrow belt on the crest of a steep structure. The oil was obtained from two Miocene dolomitic limestone horizons. Globigerina marls were not encountered in the wells, Lagoonal Series with Basal Beds lying directly on granite.

At Abu-Durba about 12 wells have been drilled, of which three gave production, yielding in all about 7,000 tons. The structure consists of two echeloned igneous fault-blocks, and the producing wells were drilled near the shore on the granite front of the structure into limestones, marls, and sandstones of dubious age.

There is still much difference of opinion regarding the origin of the oil in Egypt. The Cretaceous carbonaceous shales and the Miocene globigerina marls are each regarded as a possible mother formation. In view of the occurrence of the oil in Egypt apparently being confined to the Gulf of Suez area one feels inclined to associate the origin of the oil with a specific Gulf formation such as the Globigerina Marls. Whether outside the Gulf area oil is yet to be found, as, for instance, within the folded area of Northern Egypt and Sinai, future exploration will have to disclose.

AFRICA AND MADAGASCAR

By G. D. HOBSON, Ph.D.
Imperial College of Science and Technology

THE continent of Africa has indications of oil in various parts, but if exception be made of Egypt, its oil production becomes almost negligible. During the past few years intensive research has been in progress in French Morocco. Wells have been sunk on various structures in this geologically complex region, and on the whole the results have been disappointing in that no important oil reserve has been discovered, yet the region is not considered to have been thoroughly tested [5, 1936]. Geophysical work has been carried out in Portuguese East Africa, and bores sunk in different parts of the continent have shown traces of oil, but many were drilled with little knowledge of the local geology and therefore were not adequate tests. Furthermore, some of the areas with oil indications are so difficultly placed geographically and topographically that only very large oil reserves can make their exploitation commercially possible.

North Africa. Seepages are known in the Larache district of Spanish Morocco, and are common in the triangular region, mainly in French Morocco, formed by Larache, Tizeroutine, and Meknes [1, 1932]. In the Rharb oil seeps are connected with Triassic diapirs and are near the Miocene-Flysch contact [2, 1932], and in the area as a whole seeps are reported from Triassic, Liassic, Cretaceous, Nummulitic, and Miocene deposits. Wells at various places, e.g. Bou Drâa (Jurassic), Ain Hamra (Miocene), have found traces of oil, and at times have given a small production. In 1934 a well on the broken, elevated Djebel Tselfat structure gave 250 tons of oil per day, but further work has shown the productive area to be limited to 120 acres, and to be partly water-flooded. The productive horizon is a Liassic limestone which appears to be or to have been oil-bearing over an area of at least 16 miles by 12 miles. Research has largely eliminated the possibilities of much oil in beds younger than the Jurassic, and efforts are being concentrated on finding Liassic limestones or older beds under suitably sealed conditions. The types of structure under investigation include folds with the Domerian crest near the surface; deeper crests beyond the frontal faults, and Liassic structures beneath discordant Cretaceous beds. The last group is of considerable importance, for this concealed condition obtains in about three-quarters of the suitable area in northern Morocco.

Most of the exploration in Algeria has been in the Oran region in the central part of the Tellian Atlas. There, seeps are either in Helvetian marls near dislocations with upthrust Triassic beds, as in the Tliouanet region, or in Sahelian deposits along lines of folding, as in the Chelif plain. A small oilfield has been developed at Tliouanet where 40 out of 100 wells drilled have produced from Helvetian sands. Wells in the Chelif plain have only penetrated the Sahelian and Pliocene, and have found strong water-flows and gas-blows in the upper Sahelian. Oil indications were found in the Sahelian at Ain Zeft, and an appreciable production was obtained, but no commercial field has been discovered in this region. Farther east bituminous Eocene limestones have been prospected by galleries at St. Arnaud, and bitumen occurs in Senonian (Fedj Mzala) and Triassic deposits (Ch. el Kraten). With the exception of the environs of Oran the evidences of oil in the Tellian Atlas are not considered important.

Oil indications are not common in Tunis [4, 1936]. The most pronounced indications are in the zone of isoclinal folding—at Ain Rhelal and Sloughia in Helvetian beds, and at Kef bou Debbous in the Cretaceous. A Triassic massif of gypsum and anhydrite forms the axis of Sloughia where wells drilled into the Miocene at seemingly favourable points found it to be mainly marly and to possess only traces of oil. Trias pierces the Miocene dome of Ain Rhelal on which a well encountered traces of oil in the Tortonian 260 ft. deep, and shows were also found by a well at Cap Bon which penetrated Lower Eocene limestones and Cretaceous marls.

West Coast. Evidences of oil have been found at various points on the west coast of Africa from the French Ivory Coast (Assinié) east to Duala in the Cameroons, and then south to Angola. A belt of sediments with a maximum width of 100 miles borders the coast in French Equatorial Africa [3, 1930]. These are of Cretaceous and Eocene age, with gentle undulations on the general westerly dip, and are covered unconformably by post-Eocene beds. The Lower Cretaceous 'sub-littoral sandstones' with shaly and dolomitic intercalations include beds which are richly impregnated with oil and which give seeps at Poumbou and in other localities. They are believed to be the source of impregnations in other beds, e.g. in the fissured, calcareous Middle and Upper Cretaceous sandstones at Pointe Noire. The Rembo N'Komi seeps are in Eocene (?) sandstones, and at N'Kogho, where an asphalt lake is reported, the inhabitants collect oil in pits. To the south in Angola oil seeps have long been known. Bitumen impregnated sands occur at Dande, and an exploratory well at Calumbo found several horizons with inspissated oil. To the north in the Cameroons oil and gas seeps are present round Duala, where a few wells have encountered traces of oil. Wells in the Gold Coast region have also revealed small amounts of oil and gas [10, 1929].

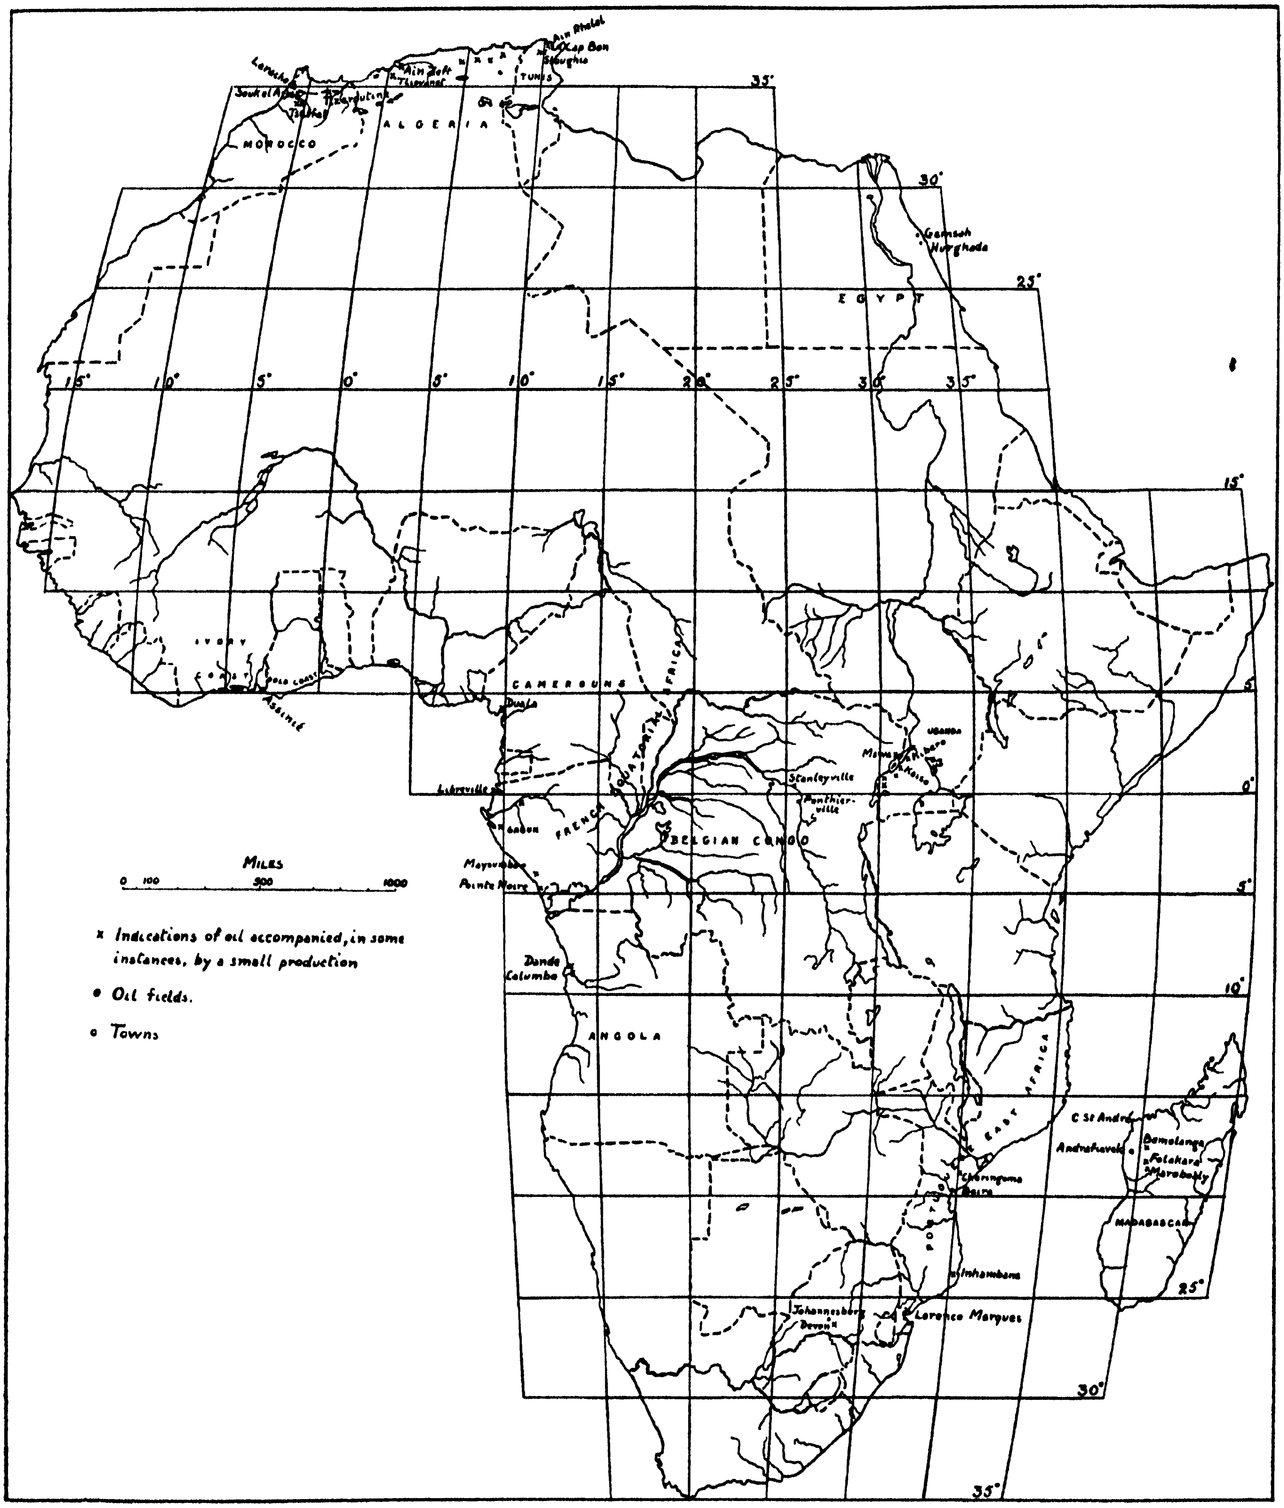
The Rift Valley Region of the Belgian Congo and Uganda. Oil seeps are known at Kibero and Kibiku on the Uganda side of Lake Albert, and at Mswa on the Congo side [9, 1926]; active and extinct mud volcanoes occur between Kisegi and Nybroge, whilst submarine gas eruptions have been reported in Lakes Albert and Kivu. The oil seeps in the Albert depression are not very conspicuous, for the unconsolidated and clayey nature of the Kaiso beds, and other factors, militate against this. Both the Kaiso and the underlying Kisegi beds contain sands, sandstones, and gravels capable of serving as oil reservoirs, but the latter series is considered to have the greatest chances of yielding important accumulations of oil. The gentle structures present are not unfavourable, and the indications are that the formation of oil is not a purely local phenomenon.

The Stanleyville-Ponthierville Basin of the Belgian Congo shows eleven bituminous shale beds in a brackish-water Juro-Triassic series. These beds have yielded 16–22 gal. of oil per ton, and Pirson [7, 1934] suggests that they may

have served as oil-source rocks in parts and fed structures towards the centre of the Congo Basin where they lie buried.

Portuguese East Africa. North-east of Lorenço Marques and in 1931 a well at Inyaminga encountered gas and several showings of oil.

Madagascar. The western side of the island of Madagascar is composed of Triassic to Quaternary beds with a



and in the Inhambane area oil seeps occur. During recent years interest has been shown in the Cheringoma plateau midway between Beira and the Zambesi and about 60 miles inland, where Upper Cretaceous and Eocene partly marine beds are exposed. Geophysical work has been carried out, general westerly dip. For 200 miles from the river Manambolo northwards to Cape St. André oil seeps are known, the most important of which are centred on Bemolanga and Morafenobe, and whilst some occur in Jurassic and Cretaceous beds, the bulk are in Triassic or Permo-Triassic

sands and sandstones [6, 1930]. Many igneous dykes penetrate the sediments, and the degree of oil impregnation appears to be proportional to the size and number of the dykes. Wade [8, 1929] was of the opinion that the oil had been produced in abnormal amounts by igneous distillation of carbonaceous horizons in the Permian (there are high volatile Permian coals at Benitra) and to a less extent in the Trias, though Nicolesco observes that bituminization in some areas has been recognized as pre-igneous injection. The discontinuous nature of the clays in the Trias has not favoured the preservation of oil. Development of the oil-impregnated surface sands by mining has been considered, and numerous wells have been drilled in the Folakara and Maroboaly areas near seeps, but they found only insignificant shows of oil. Better results are expected farther west where the Trias is covered by Jurassic and Cretaceous, and the Triassic clays are probably better developed.

U.S.S.R.

By G. D. HOBSON, Ph.D.
Imperial College of Science and Technology

THE U.S.S.R. is second to the United States of America as an oil-producing country, having given 12·37% of the world's total production up to the end of 1935, and having occupied second place on the world list for annual production since 1873, with the exception of the period 1918–26 inclusive, although in recent years Venezuela has become a serious challenger. Various manifestations of the presence of oil and gas have long been known. Natural gas issues on the Apsheron Peninsula were used in the temples of certain sects, and thither fire-worshippers and Hindus of Burma and India made pilgrimages for over 2,500 years. As recently as 1880 priests are said to have conducted ceremonies in a temple at Surakhany. At times there have been fierce outbursts of oil and gas, startling the people and causing damage to property and even loss of life. Mud volcanoes are common, some erupting at intervals of a few years, and during earthquakes gas has escaped from cracks in the earth and become ignited.

The production of oil from hand-dug pits on the peninsulas of Kertch and Taman was described by the Greeks in ancient history. The first well in Russia was drilled at Balakhany in 1871. Previous to that a considerable output had been obtained from hand-dug pits, and as late as 1923 the bulk of the oil at Binagady was derived from 3,000 pits [6, 1923]. Oil seeps and 'kir' (asphalt) deposits in the Ferghana Basin were used in early times by the Chinese and Turkomans, and there shafts were sunk early in the 19th century. Drilling began in the Ferghana Basin in 1898.

The oil fields of the U.S.S.R. are widely spread and are found in the Caucasian region, the trans-Caspian area, the Ferghana Basin, the Ural-Emba region, at several points west of the Urals, and in northern Sakhalin Island. In 1935 the oil production was distributed as follows [19, 1936]:

	Azerbaijan	*NE. Caucasus (Grozny area)*	*NW. Caucasus (Maikop area)*	*Ural Permian*	*Emba*	*Sakhalin*
Millions of barrels .	136·43	23·3	8·34	2·84	1·7	1·65
Percentage of total	77·2	13·2	4·72	1·61	0·97	0·93

The Caucasian Region

The U.S.S.R.'s main oil production has been, and still is, associated with the Caucasian belt. The Caucasus range runs approximately WNW.–ESE. for about 1,100 km., and is formed of folded Palaeozoic and younger rocks. At its west-north-west end is the Taman Peninsula, and at the east-south-east end is the Apsheron Peninsula. The structures are simpler on the northern margin, and it is there and on the Apsheron Peninsula that the principal oilfield areas lie. Traces of oil and bitumen are found in Mesozoic and Tertiary beds on the southern flank, an almost continuous belt of oil indications runs along the northern slope from the Taman Peninsula to Maikop, oil seeps occur in the Grozny area and southern Daghestan, and mud volcanoes and gas and oil seeps are numerous on the Apsheron Peninsula.

The Apsheron Peninsula.

The following stratigraphical column for the south-eastern Caucasus (Table I) is essentially that of Golubiatnikov and Goubkin [7, 1934].

TABLE I

Quaternary	Recent mud volcano material and alluvium. Recent Caspian deposits; sand, clay, shells. 10 m.	
Upper Pliocene	Ancient Caspian	Upper and middle stages; conglomerates, sands, sandy clays, limestones. 66 m.
		Baku stage; conglomerates, sands, sandstone, sandy clay, limestone. 60 m.
	Unconformity	
	Apsheron stage (marine)	Upper; limestone, sands, clay. 180 m.
		Middle; sands, sandy limestones, calcareous sandstones, marls, clays. 170 m.
		Lower, sands, clays, dark clays with volcanic ash. Gas sands at Bibi-Eibat and Surakhany. 240 m.
	Clay with Limnaea (marine). Clay with marl. 138 m.	
Upper and Middle Pliocene	Akchagyl stage (marine)	Black clays, calcareous clays, sands, volcanic ash, marls, limestone. Petroliferous at Surakhany. 38–60 m.
	Productive series (fresh-water) (terrestrial)	Upper division; clays, sandy clays, sands, lenticular sandstones. 644–826 m.
		Middle division; coarse sands with rock fragments and lumps of clay; sandstone lenses. 154–243 m.
		Lower division; sands, sandy clays, sandstones. 219–394 m.
	Unconformity	
	Pontian stage (brackish and marine)	Upper (Babajan) horizons; dark grey clays, siliceous marls, lenses of detrital limestone. 50 m.
Lower Pliocene		Middle horizon; dark grey clays, siliceous marls. 33 m.
		Lower horizon, dark grey shaly clays. 216 m.
	Sharp break and unconformity in Kabristan.	
Upper and Middle Miocene	Diatom beds (marine)	(Analogous to Meotian and Upper Sarmatian.) Clays with siliceous concretions, white and light grey diatomaceous clays. Oil at Binagady. 136 m.
		(Analogous to Middle (Cryptomactra) and Lower Sarmatian.) Clays with interbedded siliceous marls. 270 m.
		Spaniodontella beds; dark grey, shaly clays with siliceous marls.
	II Mediterranean (marine)	Spirialis beds, 65 m ; Chokrak-Spirialis beds of Kabristan, 500 m. Dark grey, shaly clays; siliceous, dolomitic limestones. Petroliferous sands at Cheil Dag.
Lower Miocene	Maikop beds (marine)	Upper (Cedroxylon) horizon; laminated chocolate-brown clays with yellow ochreous formations. 200 m.
Oligocene		Lower (Amphisyle) horizon; thin alternating layers of chocolate-brown and greenish-grey clays; yellow-brown marl; bituminous in places. 130 m.
	Kown series (marine)	Green clays and sandstone, brownish-black clays, bituminous shales; white and greenish marls, and marly clays with green friable sandstones; local indications of oil throughout series. 200–600 m.
Eocene (marine)	Sumgait series	Clays and sandstones. 100 m.
	Ilkhidag series	Dark clays, coarse sandstones. 300 m.
	Yunus-Dag series	Reddish-brown and grey clays and marls; glauconitic sandstone and breccia limestones. 200 m.
Cretaceous (marine)	Orbitoidal series	White marls, hieroglyphic sandstones, breccia limestones. 550–600 m.

The upper division of the Productive series has three parts which are, in descending order, the Surakhanian

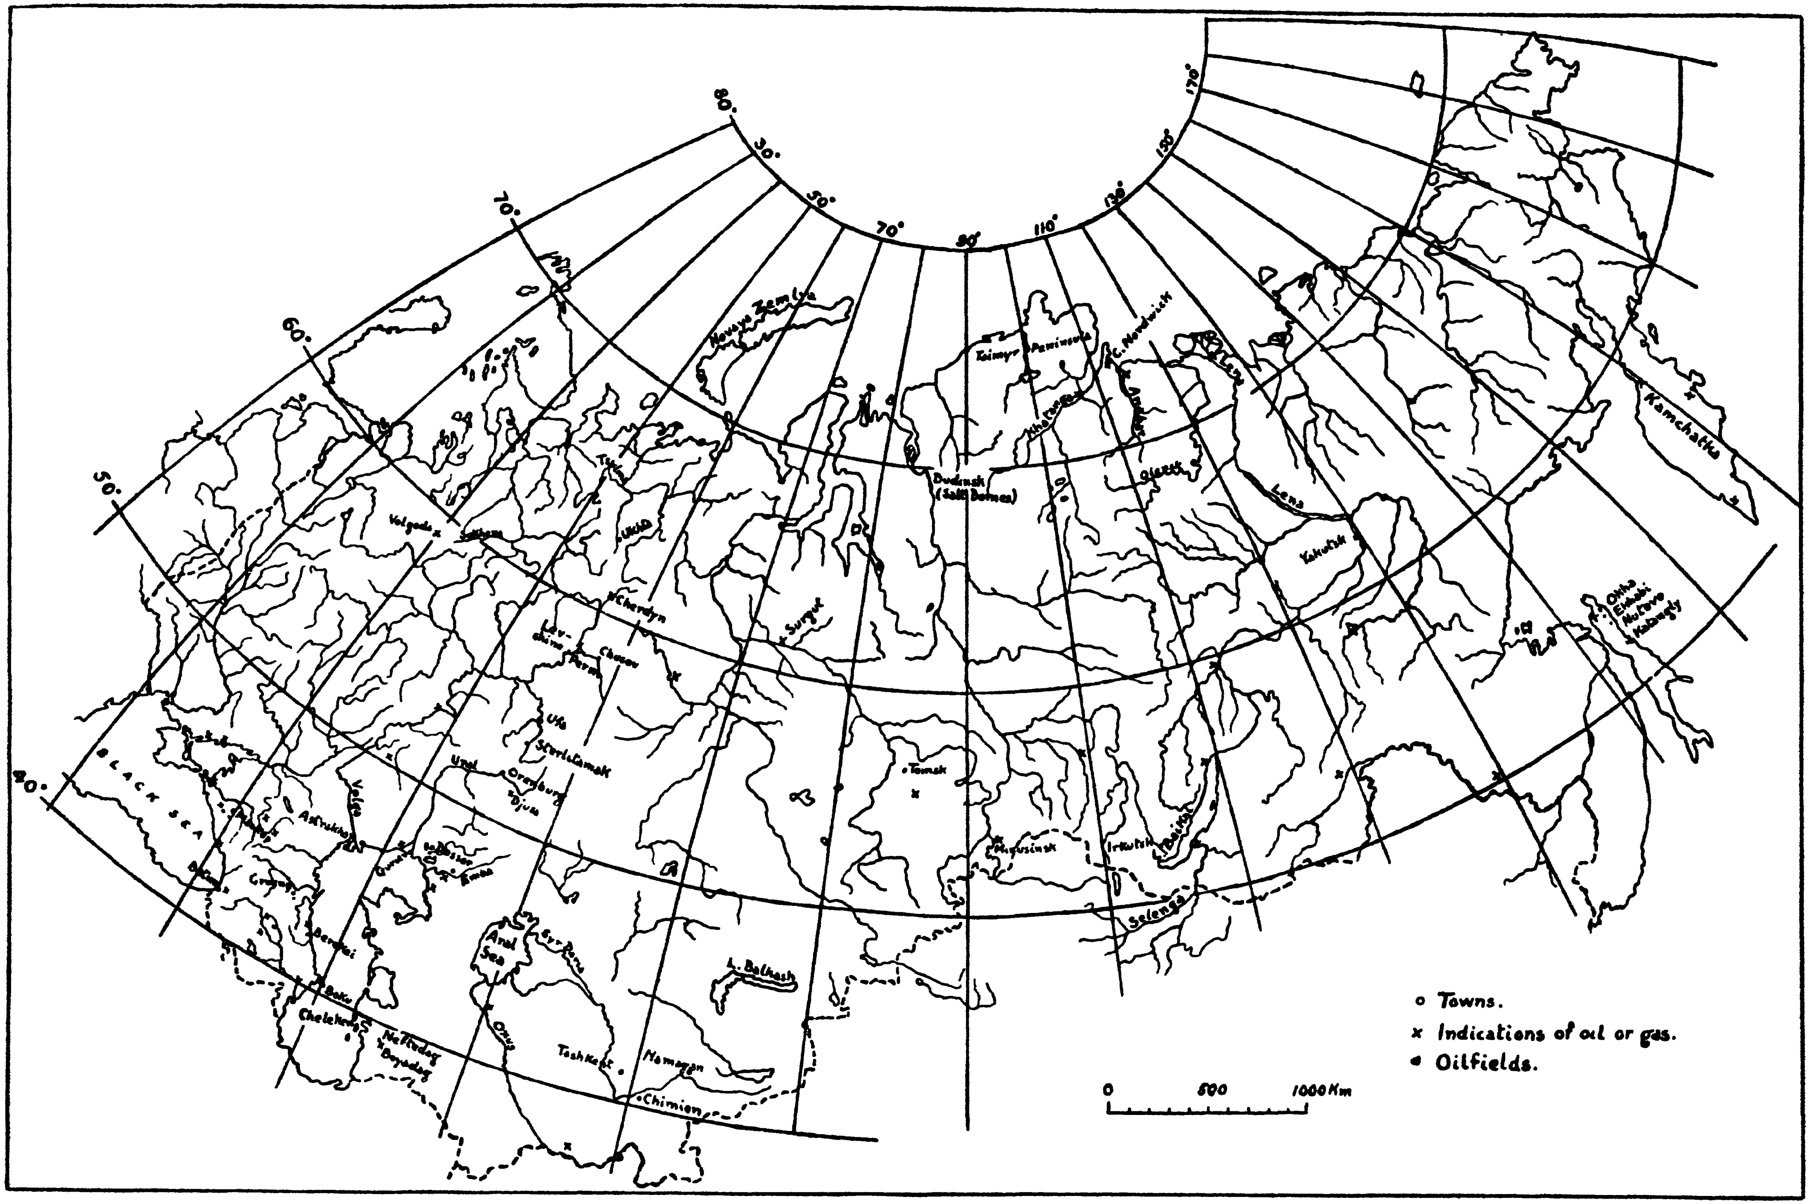

FIG. 1. Distribution of oilfields and indications of oil and gas in the U.S.S.R.

Sabunchian, and Balakhanian. The middle division or 'Break' contains water-bearing horizons, and the lower division is subdivided into super-Kirmaku clays, super-Kirmaku sands, Kirmaku proper, and sub-Kirmaku. The upper division is petroliferous at Bibi-Eibat, Surakhany, Kara-Chukhur, Balakhany-Sabunchy-Romany, Kala, and Lok-Batan; the middle division gives oil at Binagady, Balakhany, Mount Atashka, and Lok-Batan; and the lower division is oil-bearing at Puta, Mount Atashka, Sulu-Tepe, Khurdalany, Baladjary, Binagady, Holy Island, and Bibi-Eibat, but principally at Balakhany-Sabunchy-Romany.

The Productive series increases in thickness from west to east.

TABLE II

(*After Stutzer*)

WEST EAST

Sumgait and Kura valleys, Sallani steppe	*Northern part of Kabristan. Agsi-Kir Tatar*	*Binagady*	*Kirmaku Balakhany*	*Holy Island*
0 m.	360 m.	1,009–40 m.	1,240–70 m.	1,900–2,000 m.

Goubkin suggests that several oil-bearing series were deposited in this area: (1) the bituminous shales and oil shales of the Sumgait series; (2) the Brown Kown which is a typical sapropelic rock; (3) the Maikop series; (4) the Spirialis beds; and (5) all the Diatom series with fish remains as well as diatoms.

West of the base of the peninsula, the axes of the branching, irregular structures tend to run mainly WNW.–ESE., whilst in the east those of Kala and Holy Island (Fig. 3) trend more in a NNW.–SSE. direction, but in the principal productive area Baku is almost encircled, and immediately to the west is another almost complete ring, on the undulations of which lie the fields of Shubany, Lok-Batan, Puta, and Ker-Gez. Many of the structures are characterized by an increase in the dip of the strata on approaching the axes of the uplifts, and evidence, in the form of a more complete succession in the depressions than on the uplifts, shows that they have been rising through long geological periods. These features are regarded by some as an indication of the diapiric nature of the structures and, indeed, in some the discovery of a piercing core of Lower Tertiary clays is reported. Goubkin believes that the conditions favouring the formation of diapirs would also favour the accumulation of organic matter and its transformation into oil and gas, and, at a later stage, their movement towards the elevated core. Water would move with them softening the clay core, and subsequently mud volcanoes and gas

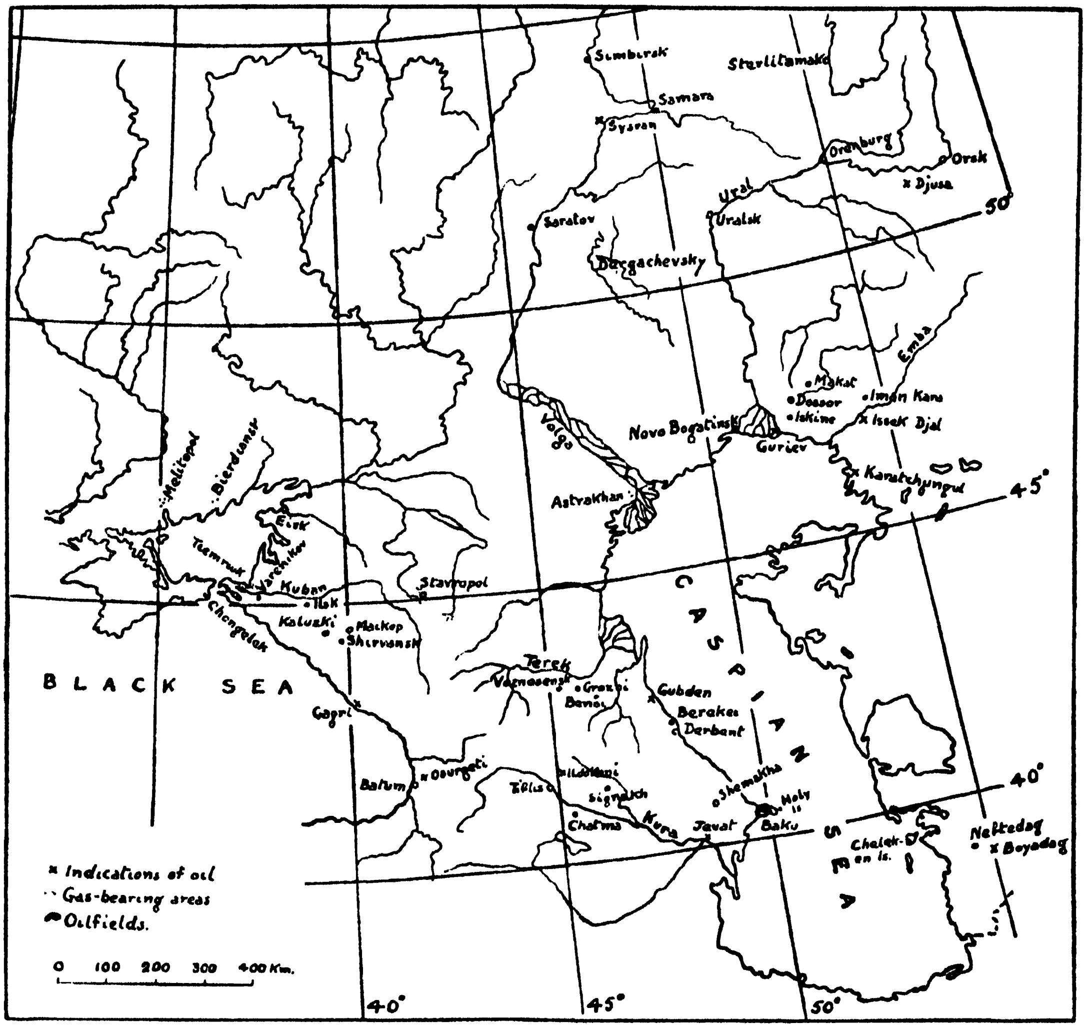

FIG. 2. Map showing the positions of some of the oil and gasfields and indications of petroleum in the Caucasian, Trans-Caspian, and Ural-Emba regions.

seeps would appear. The intrusive core would make fissures in the surrounding strata, thus aiding movement of fluids. The retention of oil and gas in any porous beds they may enter depends on the presence of an impervious cover, e.g. Akchagylian and Lower Apsheronian, and the sealing effect of the piercing core. There is evidence of the rise of some of the cores within recent years, but since it appears that mud volcanoes can eject blocks weighing as much as 100 tons, caution must be exercised in examining these structures for intrusive cores.

Fatmai, Kirmaku, Bog-Boga or Balakhany-Sabunchy-Romany, Binagady, Atashka, Lok-Batan, Puta, and some Kabristan structures are classed as diapirs by Goubkin. Other structures are more normal anticlines or domes, although some may have a rising core which has not reached the surface. To this group belong Surakhany, Bibi-Eibat, Kara-Chukhur, and Kala.

Each field on the Apsheron Peninsula has its own special characteristics as to number of oil horizons, their degree of saturation, and the nature of the crude. Correlation of parts of the Productive series is therefore difficult. Saturation of the oil sands varies in both dip and strike directions, and is most uniform in the lowest division. Even if the Productive series outcrops and is barren at the surface, it is commonly well saturated with oil at depth. The faults on the Apsheron Peninsula structures are generally small, but they affect the distribution of oil and water.

The Balakhany-Sabunchy-Romany uplift, which is broad and faulted, runs mainly west–east for a considerable distance. A part of an intrusive core of Kown is said to be visible in the Bog-Boga mud volcano at its western end. The structure plunges eastwards and the productivity increases in that direction. The upper division of the Productive series has 34 oil sands but is approaching exhaustion, and exploitation of the lower division has begun. Correlation is difficult and wells are often independent, pointing to lenticularity of the sands. The oilfield waters are at temperatures of 19·8–43·4° C., and water shut-off difficulties increase with depth.

Surakhany is a broad, flat arch running north–south, with dips of 10–20° to the east and 4–10° to the west. The crest is much faulted, especially at the southern end. The lowest Middle Apsheron beds outcrop in the centre. There are many gas seepages, and gas is first struck in drilling at depths of about 10 m. All the porous beds in the upper strata have gas, and 23 gas sands are encountered from depths of 36 m. to 480 m. The shallow gas area is about 5 km. by 1·5 km. A white (filtered) oil is found at depths of 200 m. in the top of the Akchagylian, and down to 335 m. five white oil sands occur. Black oil is found at 480 m. and deeper in the Productive series. Emmons [3, 1931] observes that Surakhany is probably the richest field in the world for its size.

South of Surakhany lies the Kara-Chukhur field on a north–south anticline with two branching longitudinal faults. The first well was drilled in 1929, but the principal development dates from 1933. Yet farther south is the flat dome of Zykh, the major axis of which trends NNE.–SSW. and plunges south-south-west. The dips of the flanks are 6–12°. Lower Apsheron beds are exposed on its crest and a mud volcano flow shows fragments of Amphisyle beds. In 1935 the discovery well was brought in at a depth of about 1,750 m. with a production of 7,000 bbl. per day.

The northern branch of the line of uplift, which appears to fork west of Bog-Boga, passes through Kirmaku and Fatmai. Both are considered diapiric, the former showing

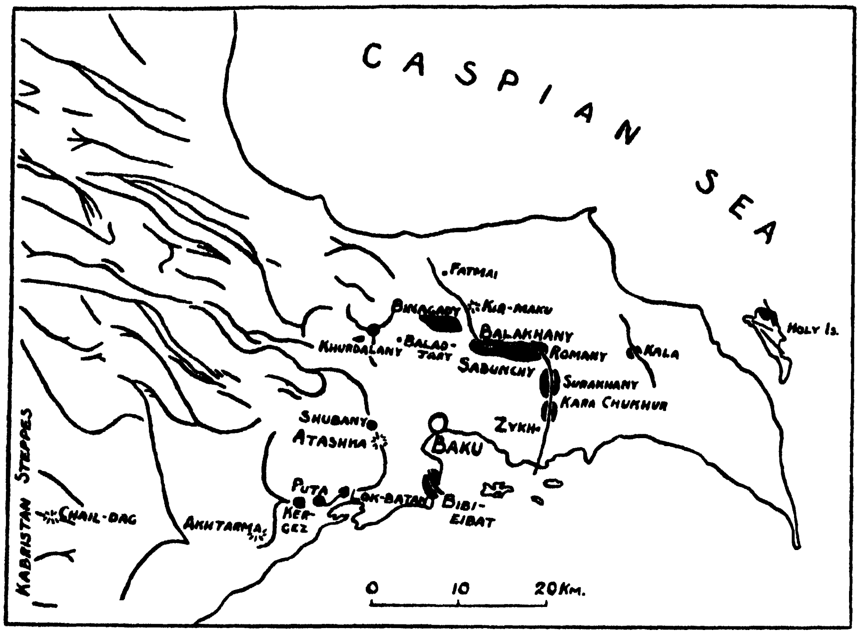

FIG. 3. Map of Apsheron Peninsula, showing the structural trends and the locations of the oilfields. (*After Goubkin.*)

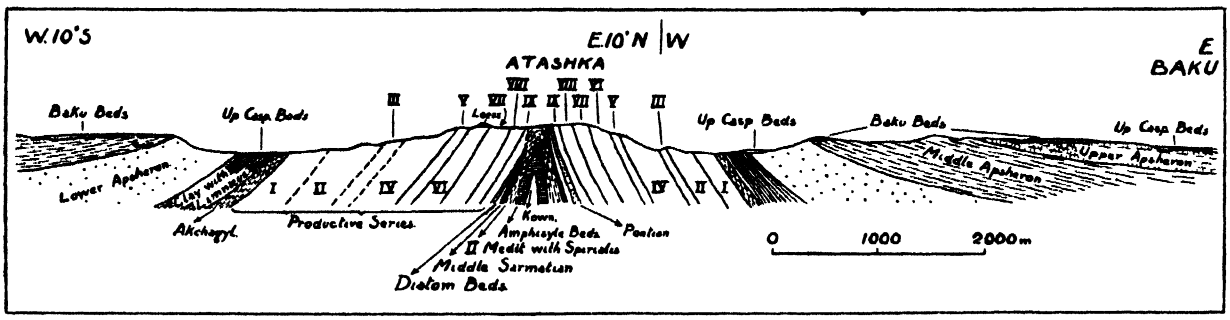

FIG. 4. Cross-section of Atashka. (*After Golubiatnikov.*)

a small core of Kown and the latter green Kown clays and Maikop beds enclosed by the Spirialis series. In the south-east of Fatmai small amounts of oil have been found in the lower parts of the Productive series. The southern branch runs through the broad, faulted Binagady arch in an east–west direction. The piercing core is of white Kown, flanked by Diatom beds on the north and south. There is a good development of Pontian on the southern side, but it is uncertain on the north, where the lower division of the Productive series approaches the core and is cut off by a fault. On the south the lower division is almost fully developed. Production began in 1901. The richest oil sands are mainly in the lower division of the Productive series and on the southern flank, but recently oil has been found on the eastern plunge and on the northern flank.

In the north-eastern part of Baladjary are hand-dug pits and a large asphalt sheet. The beds dip at about 45° to the south-east. Oil production is from the lower division of the Productive series. Khurdalany is a faulted anticline on which a heavy oil has been obtained from four horizons in the Productive series. Hand-dug pits had a considerable output in 1914. At Shubany-Atashka is a sharp north–south fold with the eastern flank dipping at 70–80° and frequently overturned, whilst the faulted western flank dips at an average of 65°. The structure plunges southwards at 15–25°, and there appears to be a core of Maikop beds. Strong gas vents and asphalt deposits are present, and the 30 oil sands in the Productive series are exploited by hand-dug pits and wells.

Lok-Batan is believed to have a core of Maikop clays which pierces the lower horizons of the Productive series. On this structure is a large mud volcano that erupts at intervals of 3 to 5 years. Here and elsewhere it has been found that the mud volcanoes affect only small areas, and the normal stratigraphical sequence is met after passing through 30–50 m. of mud volcano deposits. The discovery well was drilled in 1932 and gave 7,000 bbl. of oil per day. Nine producing horizons lie between depths of 900 m. and 950 m., and it is stated that the sand saturation is the highest ever known in the world. On the faulted Puta anticline early production was from hand-dug pits, the first commercial production from wells being in 1926. Only the upper and middle parts of the oil measures of the Ker-Gez structure had been tested in 1933, when 10 wells were giving a good output.

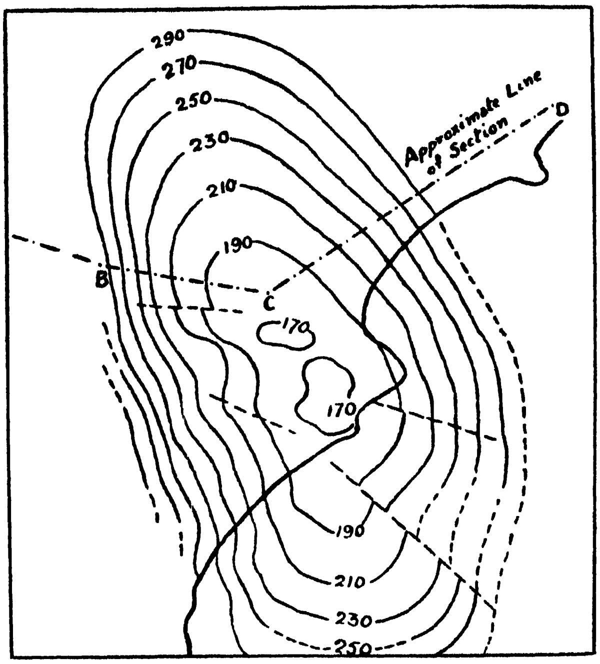

FIG. 5*a*. Stratum contour diagram of the Bibi-Eibat field. (*After Stutzer.*)

Bibi-Eibat is a broad, faulted dome with its major axis running NNW.–SSE. On the crest are two subsidiary elevations. The top of the dome is formed of Akchagyl beds and the upper parts of the Productive series. On the limbs are the Apsheron beds dipping at 7–22°. Ignoring beds of inspissated oil and gas shows in the upper beds, the first important pay is 90 m. deep. From there down to 640 m. are 20 workable sands totalling 120 m. The Productive series is believed to be 800 m. thick, and the lower divisions were untested up to 1935, but were expected to be prolific. Much of the field is on land reclaimed from the Caspian Sea.

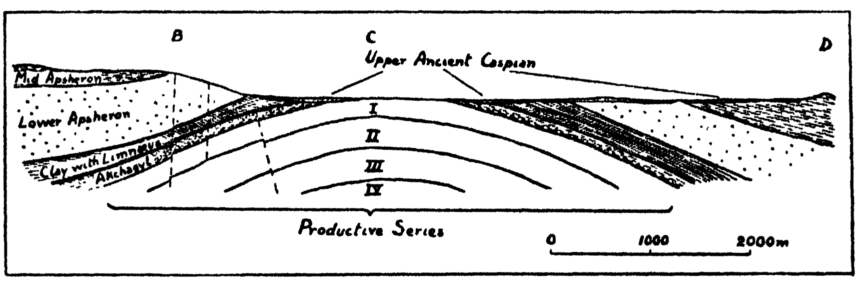

FIG. 5*b*. Cross-section of the Bibi-Eibat field along the line marked on Fig. 5*a*. (*After Golubiatnikov*).

The elliptical dome of Sulu-Tepe has its major axis north–south, with the eastern flank dipping at 80° and the western flank at 50°. Oil is found in the lower division of the Productive series. The Kala structure trends NNW.–SSE. and is similar to Surakhany, though deeper. There are many faults, and a transverse fault divides it into two parts, of which the northern is rich in oil and gas, whilst the southern part is barren in the upper Productive series. Some white oil has been produced. The apex of the Apsheron beds lies over one flank of the oil-bearing horizons, thus accounting for the many failures to locate oil.

The productive anticline on Holy Island strikes NNW.–SSE. Its west-south-west flank is gentle, whilst the east-north-east flank is steep, overturned, or even overthrust with a reversed fault. There are two secondary folds with the same strike and faults. Ancient Caspian deposits rest unconformably on the Pliocene, and the Apsheronian, Akchagylian, and upper part of the Productive series are missing. Oil has filtered into the post-Pliocene sediments, giving deposits of kir in the north-east, and outcropping oil sands are commonly sealed with asphalt. Nineteen oil sands are known. The southern anticline is little prospected.

The Region West of the Apsheron Peninsula.

In Kabristan west and south-west of the Apsheron Peninsula, on the east–west anticlines of Cheil Dag and Akhtarma oil indications are connected with the upper part of the Diatom series, the Spirialis beds, and the upper part of the Maikop formation. Pakhomov [11, 1932] reports that the last is most important because of the presence

of an arenaceous facies. Some wells have given oil on Cheil Dag. The value of the diapiric structures of Kabristan is undetermined as yet.

About 80 km. south-west of Baku a 3,000-bbl. well was completed at Pirsagat early in 1936, and at Nefte-Chala drilling and production were reported in 1934.

To the north-west of Baku, in southern Daghestan, oil seepages are known, gas between Derbent and Kayakent, and oil from mud volcanoes at Khosh Menzil 16 km. south of Derbent. Development of the Daghestan Ogny–Duzlack–Khosh Menzil area has been considered in order to supply gas to Derbent for industrial purposes. The gas is in the Maikop series, and also in the upper Chokrak-Spirialis beds at Khosh Menzil. At Berekei, north of Derbent, exploitation of oil and gas found in Chokrak and Maikop beds on a faulted NW.–SE. anticline took place in the period 1905–10, but the appearance of hot sulphurous waters stopped operations.

Oil indications have been found at Gubden, Izber-bash, and Iskir-bash in Chokrak beds. The 20-km. long Izber-bash anticline is considered more favourable than the more disturbed Iskir-bash structure, since the thick Sarmatian clays on the former may be expected to have preserved any oil present in the areno-argillaceous Spaniodontella and Chokrak beds.

The Grozny Region.

This region lies in the foot-hill zone of the northern flank of the Caucasus Mountains, about 450 km. north-west of Baku.

TABLE III

Stratigraphical Sequence for the Grozny Area (After Prokopov)

Pliocene	Apsheron	Sand, clay, sandstone, conglomerate.
	Akchagyl	Clay, sand, limestone, sandstone, conglomerate. 190–215 m.
	Local discordance.	
Upper Miocene	Meotian	Sandstone, sandy and calcareous clay.
	Upper Sarmatian	Grey clay and sandstone.
	Middle Sarmatian	Grey clay, shales with fish remains, sandstone, marl. Shales with Cryptomactra. Calcareous clay, ferruginous marl.
	Lower Sarmatian	Grey calcareous clay with interbedded yellow marls; grey shaly clay with dolomitized marl.
Middle Miocene. In east up to 1,000 m.; 250 m. or less in west	Spaniodontella beds	Grey clay with sandstone and dolomitic marl. Iron-stained clay with siderite. Oil-bearing sandstones. Hard limestone.
	Chokrak-Spirialis (II Mediterranean)	Grey and brown clay with sandstone and marl. Signs of oil in the sandstones.
Lower Miocene and Upper Oligocene. Up to 600 m.	Maikop	Grey and brown clay; black shaly clay with beds of sandstone and dolomite. Grey-blue clay with interbedded sandstone. Oil.
Middle and Lower Oligocene	Foraminifera beds	Light greenish marls with traces of oil.
Eocene. Up to 160 m.		Greenish and reddish marl; siliceous limestone (the latter has oil and solid bitumen).

The Grozny region has many oil and gas seepages, and production from hand-dug pits existed as early as 1823. The first gusher was completed in 1893 at a depth of 132 m.

The old Grozny field is an asymmetrical anticline, about a kilometre wide, and running WNW.–ESE. for 14 km. Lower Sarmatian beds outcrop on the axis, and dip faults mark out rich provinces as regards oil production. The southern flank dips at 30–50° and the northern flank is steep, overturned, or even broken by a thrust. Many wells on or near the axis of the fold give gas only, and gas reservoirs occur among the oil horizons in the Lower Sarmatian, Spaniodontella, and Spirialis beds. Often the gases are wet and at a temperature of 50° C. The main oil production is from a series of sandstones that are included in the clays and shales of the Chokrak beds. Within the last few years oil has been obtained from the sealed under-limb of the overthrust, probably from Spaniodontella and Chokrak-Spirialis beds [8, 1934]. Only in the western and middle parts of the field is this under-limb at reasonably accessible depths. In the east it lies at depths of 1,500–2,000 m. and its exploitation will call for skilful drilling.

Twelve to eighteen kilometres south-east of the old field is the new Grozny field, a less asymmetrical fold trending NW.–SE. Oil is obtained from 22 horizons within a shale series which is 530 m. thick. The field is under hydrostatic control, and the water, at temperatures of 76–87° C., is believed to move through a very deep syncline. An overthrust occurs in the western part of the field and production below it is thought to be possible.

Production at Voznesensk, north-west of Grozny, began in 1924, but development has not been extensive. South-east of Grozny the broad Benoi anticline lies in difficult country, which has hindered its exploitation. The fold runs WNW.–ESE. for 20 km. Dips do not exceed 16° on the northern flank and 30° on the south. Eastwards the fold flattens and passes into a monocline. Spaniodontella beds outcrop on the axis, and the tectonics of the Chokrak-Spirialis beds are somewhat complicated and differ from the general structure. Oil indications are first met in the Chokrak-Spirialis beds and increase downwards, a rich gusher having been completed in the Maikop beds in 1930. About 4 years ago the Malgobek field was discovered. This fold, which is 12 km. long, appears to be divided into eastern and western parts by a thrust which has left the oil sands sealed. Four rich oil horizons are reported.

The North-west Caucasus Region.

In this region Tertiary beds dip northwards from the Cretaceous hills and the oil occurs on monoclines, probably trapped in sand lenses or along unconformities. Production of oil has been established in a number of places, chief amongst which are Maikop (Neftianaia-Shirvanskaia), Kaluzkaia, and Ilsk.

At Maikop the Oligocene rests on Cretaceous beds, but to the west Eocene beds appear. The general dip of the beds is 8–15° towards N. 35–40° E. The main oil production at Maikop is associated with erosion valleys in the Foraminiferal beds, which are filled with conglomerates, gravels, and coarse sands belonging to the overlying Maikop beds. Oil is also found in sand lenses within the Maikop beds [10, 1923]. Shallow, monoclinal production of oil occurs at Ilsk in Maikop sand lenses and in a dolomitic horizon higher in the Miocene, the former giving a light oil and the latter a heavy oil.

In 1866 Russia's first gusher was completed at a depth of 21 m. at Kudako, 140 km. west of Maikop. Conditions there are similar to those at Maikop and the principal

production has been from Maikop beds at depths of more than 200 m. The Kaluzkaia field is on a monocline dipping north-east, the dips being steeper in the older beds—50° in the Cretaceous and Eocene, 35–25° in Chokrak-Konkski beds, and 15–12° in the Meotian. The chief horizon of heavy oil is in the breccia-like dolomites of the Mediterranean beds [14, 1932]. The Maikop and the bulk of the Foraminifera beds are also oil-bearing, the oil being in thin partings or small lenses of sand in sandy clays. Systematic exploitation of Kaluzkaia began in 1916, but the sporadic and irregular distribution of the oil has led to many wells being failures. It is interesting to note that in the Chokrak-Spirialis beds at Kaluzkaia are clay conglomerates with inclusions of Cretaceous rocks, probably the products of mud volcanoes which were active in Chokrak-Spirialis times. Oil has been produced at Khadigensk during the past few years.

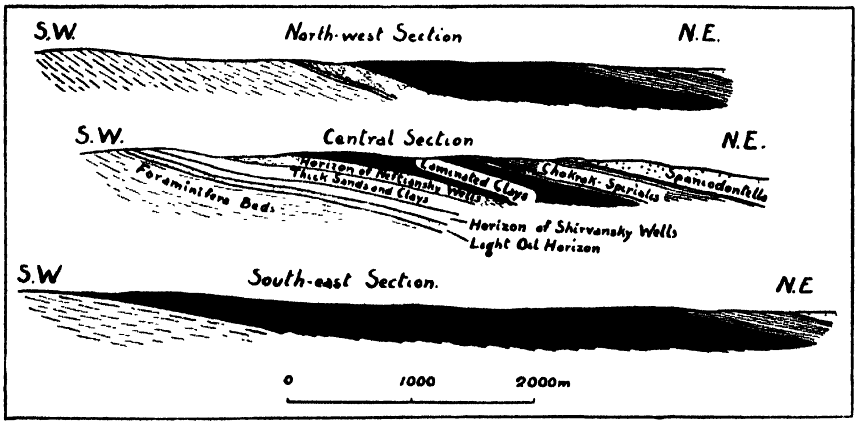

FIG. 6. Serial dip sections across the Neftianaia-Shirvanskaia field, showing changes in the Maikop beds along the strike. (*After Ulianov.*)

TABLE IV

Succession at Neftianaia-Shirvanskaia. (After Ulianov, with some additions)

Middle Miocene	Spaniodontella beds	Predominantly clay. At least 350 m. thick. Characteristic marl at base.
	Chokrak-Spirialis beds	Mainly clay; 200 m. thick. Masses of Chama limestone at base.
Lower Miocene and Upper Oligocene	Tarkhan beds	Clays. Absent beyond Primakovo ravine in the east.
	Maikop beds	Foliated clays with spherosiderite in upper parts. Main outcropping horizon. In the east it gradually replaces all the other Maikop horizons and attains 500 m. in thickness. Oil-well horizon with small lenses and partings of gravel and oil sands; 130–200 m.; wedges out east and west of central oilfield. Thick sands and clays, 80–120 m.; thin east and west.
	Light oil horizon	Grey clay, white marl, green foraminiferal clay; only present in parts.
Middle and Lower Oligocene	Foraminiferal beds	Foraminiferal clays with marls. 200 m. in west, 750 m. in east.

North-east of the Maikop area gas was discovered in the Stavropol district in 1910 while drilling for water [2, 1934]. The principal gas horizons are in the Sarmatian, but gas occurs also in Spaniodontella, Chokrak-Spirialis, and even Maikop beds. Sixty-five kilometres south-east of Stavropol a well encountered gas-bearing clays in Maikop beds. At Eisk on the eastern coast of the Sea of Azov gas horizons have been found in the Sarmatian.

The Taman Peninsula Region.

The Taman Peninsula is marked by many mud volcanoes. Although the production of oil from hand-dug pits was recorded in ancient history, the modern production of oil and gas has been but small. However, in recent years there has been a considerable amount of geological exploration in this area and nine folds have been studied. The lines of folding of the Taman Peninsula have a different trend from that of the Caucasus range, and the E.–W. and NE.–SW. directions correspond with those of the eastern part of the Kertch Peninsula. Often the folds are sharp and, according to Goubkin, diapiric structures are present.

The stratigraphical sequence in Table V is essentially that of Federov for the Varenikov region near the base of the peninsula.

TABLE V

Post-Tertiary	Alluvium, loess, mud volcano deposits.	
Pliocene	Nadrudni beds	Light coloured sands; light grey, non-calcareous clays. 100–165 m.
	Rudni beds	Grey, compact, non-calcareous clays; argillo-arenaceous, ferruginous crag. 110–170 m.
	Pontian	Light grey, calcareous clay; detrital limestones, sandstones, arenaceous clays. Local gas seeps. 165 m.
	Unconformity.	
Upper Miocene	Meotian	Greenish-yellow clay with thin calcareous sand and diatom ooze partings; soft and hard, dolomitized marls, and dark bituminous clays. Oil drops in marls. 70–75 m.
	Unconformity.	
	Middle Sarmatian (Cryptomactra)	Yellowish, unstratified, gypsiferous clays with soft and hard marl beds. 100–110 m.
	Lower Sarmatian	Yellowish calcareous, and purple-grey non-calcareous clays; partings of hard marls. 80–100 m.
Middle Miocene	Spaniodontella	Gypsiferous clay with numerous beds of soft and hard marls; minute drops of oil in marls. 85–100 m.
	Chokrak-Spirialis	Clays alternating with hard and soft marls. 115 m.
	Unconformity in places.	
Lower Miocene and Oligocene	Maikop beds	Purplish-grey and chocolate-coloured non-calcareous clays with spherosiderite. Sandstones at top. Up to 230 m. in thickness.
	Foraminiferal beds	Greenish siliceous clays, sandstones, and marls. Contain oil in some areas.

The Rudni (ore) beds are equivalent to the Productive series of the Apsheron Peninsula, but lack of cover has prevented the retention of any oil that may have been present in them. The poor production of oil on the Taman peninsula is attributed to the almost complete absence of suitable reservoir rocks in the dominantly clay series.

The north Varenikov fold is 3 km. long and 1 km. wide, its core being of Spaniodontella beds bordered by Sarmatian, and showing gas and oil seeps. The northern limb is overturned with some beds cut out. Cryptomactra beds outcrop on the crest of the southern Varenikov anticline. This trends WNW.–ESE. with both limbs dipping at 45–50°. Oil production is said to have begun in this area in 1933. On the Adagum anticline near Varenikov the first producing well was drilled in 1930, and commercial production was established in 1933. The Kessler structure is 2½ km. in length, with a core of upright Maikop beds. The dips increase with the age of the beds and the northern limb may be slightly overturned. It is apparently a diapir with oil in Maikop to Pontian beds. At Tiemriuk are gas seeps, principally connected with mud volcanoes, and wells have found gas in the Sarmatian.

The Kertch Peninsula.

Oil indications on the Kertch Peninsula are mainly in the eastern part and confined to Maikop and Mediterranean beds. On structures exposing the former beds oil seeps, gas shows, and mud volcanoes are common. The uplifts formed by Maikop beds are diapiric, the dips increasing on approaching the axis, where the beds are often vertical and crumpled. The bulk of the old wells were on the axial parts of the structures, but even at more favourable locations on the flanks large accumulations are not to be expected, for porous beds are generally lacking.

Great depth, lack of continuity, low porosity, and absence of oil at the outcrop are factors against commercial production of oil from the sandstones at the base of the Maikop series in the eastern part of the south-western plain. Oil indications, although less frequent, may be more significant in the Mediterranean beds, for at the base of the Chokrak and the Karagan in places there are sands and porous sandstones 3–10 m. and, exceptionally, 20 m. thick. The most common indications of oil are drops in hard marl partings, and sometimes the sandstones are oil-saturated.

On the NE.–SW. trending Chongelek anticline oil has been obtained from Mediterranean beds, and there is evidence of sufficiently thick porous beds in the Chokrak on the Chorelek anticline. The Babchik and Karama structures are viewed favourably for the same reason. On the Kop-Kochegen anticline the porous horizons of the Chokrak outcrop in the south-west and have lost their oil and gas, but it is possible that some oil may be preserved in the north-eastern part. The Spaniodontella and Chokrak beds outcrop on the Karalan, Temesh, Karmysh-Kelechi, and Burash anticlines. Hence they are deemed unfavourable in spite of seeps in the Maikop, for Arkhanguelsky and others do not consider the presence of commercial quantities of oil in the Maikop beds at all likely.

Some 27 structures have been examined within recent years, but the general lack of suitable reservoir rocks scarcely gives much hope for a large production of oil on the Kertch Peninsula.

Region South of the Caucasus Mountains.

On the southern flank of the Caucasus range many of the Mesozoic beds have bitumen. In the Kutais basin traces of oil have been reported from Eocene rocks at Korischi; from the Miocene at Anaklia, Supsa, Omparete, Maghele, Chotchklati, Guliani, Gurianta, Chapeturi, Mikhel-Gabriel, Samkhto, Jacobi, Narudja, and Notanebi [15, 1927]; the Upper Tertiary at Kvirili. At Notanebi asphalt is mined, whilst in the Ozurgety district oil occurs in beds equivalent in age to the Maikop and Chokrak, but at no point are large amounts of oil probable on account of the high dips and extensive faulting.

TABLE VI

Stratigraphical Succession in the Eastern Part of the Kertch Peninsula. (After Arkhanguelsky, Blokhin, and Osipov)

Post-Tertiary	Terrace deposits, alluvium, mud volcano deposits.	
Pliocene	Nadrudni	Sands and clays. 22–50 m.
	Cimmerian	Ore deposits—pisolitic grains cemented by a ferruginous clayey mass—in north-east and central parts. In south-east brown and greenish-grey clays alternating with ore seams. 22 m. Conformable on Pontian in synclines, but on anticlines may rest on any bed down to Pontian.
	Pontian	Green clays, fine sandstones, often grading laterally into limestones. Clays tend to occupy synclines. 20–30 m.
Upper Miocene	Meotian	Rapid changes in lithology laterally. Deep-sea greenish-grey, calcareous clay or light, soft marl; shallow-water Kertchenski shell limestone. Conglomerate marks boundary between upper and lower divisions. 35 m. of Hydrobia limestone at base in Kezenski syncline. 60 m. or more.
	Transition	Greenish clays.
	Upper Sarmatian	Light green or brown diatomaceous clays with rare, fine sand beds (up to 1 m. thick). On Kezenski anticline 26 m. of detrital limestone and loams alternating with marls containing land molluscs. 100–200 m.
	Middle Sarmatian	Argillaceous, marly rocks, bryozoan reefs or limestones. 8–20 m. At base clays merging into Lower Sarmatian.
	Lower Sarmatian	Clearly bedded dark grey or greenish-grey clays, often with marls and pure shell beds. This clay series, with that of Middle Sarmatian, is 370–450 m. thick.
Middle Miocene	Konkski horizon	Clays. 5–10 m.
		Clays with frequent interbedded slaty or pink marls. 100–140 m.
	Karagan	Greenish and brownish-grey clays with sandy streaks; often interbedded siliceous marls. In middle of series sand and sandstone beds 0·3–0·4 or even 2·2 m. thick. 100–130 m.
		Olive-green clays and interbedded marls. 40–50 m.
	Chokrak	In east clays and marls interbedded. 65 m. In west arenaceous-limy beds with rich fauna, in middle of clay. 150 m. The arenaceous-limestone facies rests on the eroded surface of lower clays which are entirely cut out in the north-west, where the arenaceous-limestone facies rests directly on Maikop beds.
Lower Miocene-Oligocene	Tarkhan	0·2 m. of black marl on Azov coast.
	Maikop beds	Closely laminated non-calcareous clay, dark grey concretions, pyrite and gypsum nodules. Gradual transition to Tarkhan.

A broad belt of seepages runs south-east for a considerable distance in the Kura Basin east of Tiflis. At Chatma 57 km. south-east from Tiflis oil has been obtained from the Sarmatian and a lower horizon on a faulted NW.–SE. anticline which is overthrust to the south-west. Oil has also been found in fair quantities at Jevat on the Kura, near Signakh, and at Ildokhany north-east of Tiflis, where there are oil seepages in Sarmatian and Oligocene beds.

The Trans-Caspian Region

Cheleken Island lies approximately on the axis of the Caucasus Mountains produced. There are many surface indications of oil, fossil mud cones are known, and the Persians practised mining at an early date. The first large well was drilled in 1904. Modern production is limited to the south-western part of the island.

The surface is covered by sands and brea deposits which mask the structure. According to Porfiriev [12, 1931] wells reveal the following sequence:

TABLE VII

Pliocene	Lower Apsheron	Compact marls.
	Akchagyl	Ash-grey arenaceous marls.
	Red series	Alternating grey and red marls with oil- and water-bearing sands.

The formations are more continental than on the Apsheron Peninsula, and the Red series, which is equivalent to the Productive series, is half desert, half lagoonal. The productive oil horizons are at the top of the Red series, deeper wells having encountered hot sulphurous waters. In the Upper Pliocene are several oil horizons which are not commercially important. The major axis of the structure exploited runs NW.–SE., with dips of 15–50° on the south-western flank and 18–20° on the north-east. There is much faulting parallel to the axis, and the steep side is involved in a fault trough, from which zone the best production is derived. Many of the faults contain ozokerite formed from ascending oil, and where oil has reached the surface brea deposits are present. The field is extensively water-flooded, some of the wells giving as much as 90% of water which is at an average temperature of 40–42° C., and at times attains 75° C.

Near the centre of the island is a large, faulted dome with the productive Pliocene denuded and Chokrak beds exposed. Many evidences of oil are present, and wells have yielded small amounts of oil.

Along the same general line and on the mainland east of the Caspian Sea is a basin of Tertiary beds cloaked by Quaternary, and possessing many oil and gas seeps and mud volcanoes. As on Cheleken Island the formations are more continental than they are at Baku, and Porfiriev [13, 1932] gives the following section for the Boya-Dag and Syrtlan-Li area:

TABLE VIII

Post-Pliocene	? Baku stage	Sands and clays; ferruginous sand at base.
	Sharp unconformity.	
Pliocene	Apsheron stage	Thick complex of clays; sandy clay series with globular concretions. Thickest on crests of the folds; thins quickly on limbs.
	Unconformity in places.	
	Akchagyl stage	Finely banded calcareous clays; fish remains and layers of volcanic ash.
	Red series	Coarse red sands alternating with calcareous clays. 300 m. of this series exposed on Syrtlan-Li.

The Red series is the age-equivalent of the Productive series of the Apsheron peninsula. Thirty-two kilometres south-south-west of Bala Ischem is the Nefte-Dag field, and 82 km. south-east of Nefte-Dag lies Boya-Dag. Each anticline is marked by a hill rising above the surrounding plain. The axis of Nefte-Dag runs ENE.–WSW. and the fold is faulted. Dips range 7–45°. Five wells were drilled in the period 1882–7, a little oil being found at shallow depths, and exploitation was resumed in 1927 when three dry holes were drilled. Later one was deepened a little and gave a good production of oil, while a second well on deepening came in at 35,000 bbl. per day. Early in 1934 a well was completed which is reported to have yielded 250,000 metric tons of oil in 16 days. Although prolific oil and gas horizons have been found, production in this area is erratic and is probably derived from the Red series.

Boya-Dag has dips of 40–50° on its northern flank and 15–20° on the south. There are many faults of which the throw diminishes from the centre to the periphery of the structure. The two faults bordering the central horst have maximum displacements of 400 m. Along the fissures are gas seepages and oil-impregnated sands, and at the western end of the fold mud volcanoes occur. The seepages diminish with distance from the zone of maximum fracturing. In addition there are dry oil sands, salt- and hot-water springs. For oil production it is thought that a deep horizon must be sought. Syrtlan-Li is a similar structure without oil seeps or dry oil sands, although gas has been found in a few places.

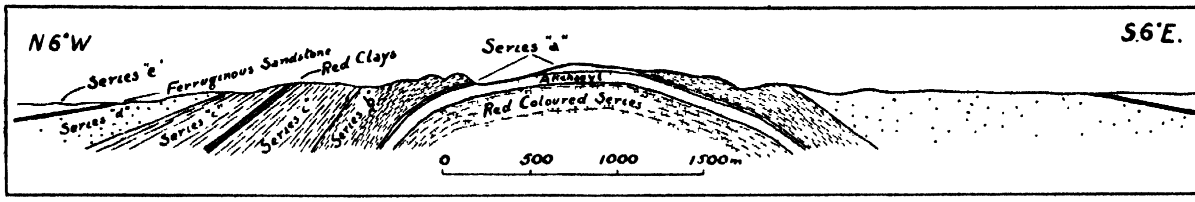

FIG. 7. Cross-section of Boya-Dag. (*After Porfiriev.*)

The Ferghana Basin

Madgwick [10, 1923] records that both the Oxus and Jaxartes valleys have oil shows from the Ferghana beds of the Lower Tertiary. Belts of seepages run along the northern and southern sides of the Jaxartes plain in the Namagan region, where these beds outcrop, and meet in the east.

TABLE IX

Succession at Maili Sai. (*After Golubiatnikov* [10, 1923])

First stage	(*a*) Brownish sandy clay and conglomerates. 1,000 m. (*b*) Brick-red clay, sand, sandstone, and conglomerates. 100 m. (*c*) Variegated sandy clay, sand, sandstone, and conglomerate; alternating blue, green, and red clay. 28 m.
Second stage	(*a*) Marl; red clay with partings of sand and sandstone. 59 m. (*b*) Limestone with Pecten; greyish-green calcareous clays and marls. 26 m. (*c*) Dark bituminous shales; concretions at top; fish remains. 33 m. (*d*) Sand and sandy clay; conglomerate at base. 60 m.
Third stage	Ferghana stage; limestone, marl, clay, sand, conglomerate; three thick limestones. 60 m.
Fourth stage	Sand, clay, and limestone; at base sandy clays, sands, and conglomerates. 150 m.

The oil-bearing rocks are probably Eocene in age and apparently contain oil only in the folds nearest the valley, and not towards the Cretaceous hills.

Within recent years 53 structures are said to have been discovered in this region by geological and geophysical

methods. Chimion gave about 25% of the Ferghana Basin's production in 1926, from Ferghana and Cretaceous beds on a narrow dome, which is overthrust a little to the north. Sel Rokho supplied the remainder of the production in 1926. In this field oil is obtained from Eocene and Cretaceous horizons on the northern limb of an east–west trending anticline. The first well on the Shor-Sou anticline was completed about 10 years ago. Again the productive horizons are in the Ferghana stage. It is also reported that the Ferghana beds cover large areas which have oil indications, south of Lake Balkash.

The Ural-Emba Region

This region, lying mainly between the Ural and Emba rivers, is regarded by some as one of the richest oil reserves in the world, but it is handicapped by its distance from large industrial centres and by poor transport facilities. In 1935 a pipeline to a refinery at Orsk was under construction. The production in 1935 was little different from that of 1916.

Oil seeps and asphalt deposits occur in at least 50 places, and at times the Caspian sands are impregnated by seeping oil. Over 300 salt domes are said to have been found in this general area, but Zavoico is sceptical as to their value, and observes that the fact that they are more faulted than those of the Gulf Coast region will render oil prospecting more difficult. Permian beds underlie the petroliferous area and are followed by Triassic or Jurassic beds unconformably.

TABLE X

Succession in the Issek-djal Area. (After Shumilin)

Post-Tertiary	Alluvium, clay deposits of the sors, Ancient Caspian sands. These beds are horizontal.	
Neogene	Middle and Lower Sarmatian	Sands and limestones. 10 m.
Paleogene	Greenish-grey clays with rare and thin partings of sandstones. 50–80 m.	
Upper Cretaceous	Senonian and Turonian	White chalk with green clays interbedded at base. At top and bottom of Turonian are 10–15 cm. beds of phosphatic rock. Thickness of Senonian unknown; Turonian 7–8 m.
	Cenomanian	Mainly sands with rare clay lenses. 200 m.
Lower Cretaceous	Albian	Rapid alternations of clays, sands, and sandstones. Clays dominant. Apparent thickness about 100 m.
	Aptian	Not exposed.
Upper Jurassic	Absent.	
Middle Jurassic	Dossor series	Violet-grey and yellow clays, grey sands, and coal partings 2–3 cm. thick. 200 m. exposed.

In the Ural-Emba region the Cenomanian, Lower Neocomian, and Middle Jurassic are subject to oil saturation. It is thought that the Permian may be the source of some, if not all, of the oil, for it is oil-bearing to the north of this region. According to Stutzer, there are five main anticlinal zones 150–200 km. long and trending in a northerly direction.

The principal field is Dossor, which lies on a north–south elliptical dome with Upper Cretaceous down-faulted on the west against Jurassic. Production began in 1910 and oil has been obtained from four horizons in the Jurassic, mainly at depths of 75–210 m. Oil is produced from several fairly shallow Jurassic zones on the Makat dome which is less faulted than Dossor, and small wells have found oil and gas at Tass Kuduk and Novo Bogatinsk, whilst valuable wells have recently been drilled at Guriev. Koschagyl is regarded as a typical salt-dome field. It is divided into northern and southern parts by a fault, seepages being especially common in the northern down-faulted part. The first well entered the Jurassic oil horizons at a depth of 290 m., and penetrated three sets of oil sands in 108 m. The productivity was highest in the lower sands. This field is viewed very favourably, since the Jurassic oil series is estimated to be 500 m. thick in this area.

The Issek-djal dome has a central down-faulted north–south block, the graben being filled with Tertiary and Caspian sands. The dome is terminated in the north by a cross fault, and both flanks have north–south faults. A secondary arch is present on the eastern flank. Although there are large seepages along the faults, the absence of outcropping oil sands and the presence of favourable tectonics on the eastern flank have led to its being regarded as a promising structure. At Iskine drilling began in 1932 1 km. south of a sharp salt structure. Some oil was encountered at four points from 22 to 147 m., and the Jurassic, with the main oil sands, was penetrated at a depth of 669 m. In the north at Djusa a good oil was found at shallow depths in 1914, and a little later oil was discovered at Karatchungul. Within the last few years oil has been found at Baichunas, Iman Kara, and Shubar-Kuduk.

West Ural Areas

In the Volga Basin in the vicinity of Samara, Kazan, and Sterlitamak, asphalt-bearing sands and limestones of Permian and Carboniferous age are common. The Sterlitamak area is said to be a rich oil reserve, oil having been discovered at Ishimbaevo in 1932. The productive horizons are limestones, probably of Carboniferous age. Early in 1936 70 wells had been drilled at Ishimbaevo of which 26 were flowing wells. Unfortunately the crude has a high sulphur content (2–5%). Eleven favourable structures similar to Ishimbaevo are now known in this region, which is about 128 km. from four trunk railways leading to European Russia, Siberia, and Turkestan, and is therefore considered of special value. During 1936 a refinery was being built at Ufa, about 80 km. to the north, and, pending the construction of a pipeline, oil is being transported by tank cars.

Some 500 km. farther north, in the vicinity of Perm, a well drilled for potash found oil and gas in commercial quantities. According to Zavoico it penetrated the following section:

TABLE XI

0·0–10·8 m.	Alluvium.
10·8–157·5 m.	Marls and gypsum; a few potash beds; gypsum increases with depth.
157·5–321·0 m.	Massive gypsum grading into anhydrite; towards base anhydrite is interstratified with black bituminous shales.
324 m.	As above; gas pockets and small oil saturation. Dark-grey cherty limestone; heavy oil and strong gas. Tentatively dated as Upper Carboniferous.

Zavoico suggests that the cherty limestone probably marks a major unconformity. In 1930 a well near Cherdyn found oil showings in the same beds at 557–9 m. Subsequently some 60 wells have been drilled to test the Chusovo area, but work has almost been abandoned for lack of satisfactory results, the limestones having been shown to be insufficiently porous. In 1933 production was established at Levshino north of Perm in Carboniferous beds,

and also in the Paper Combine territory 45 km. south of Perm.

Yet farther north oil indications are known for 250 km. along the eastern flank of the Timan range, from the Tsylma (a tributary of the Petchora) south-east beyond Ukhta [15, 1927]. The oil seeps are in the Devonian, which has 800 sq. km. of fairly rich oil shale, and in the Silurian. At Ukhta small wells have been completed in Devonian beds on an anticline. The Devonian consists of marls, bituminous shales, sandstones, limestones, dolomites, and gypsum. Over it lie discordantly Carboniferous limestone and marl, followed by Permian. The severe climate has limited development, for it is only during the period June to September that the ground is free from snow.

North Sakhalin Island

A small amount of oil has been produced on north Sakhalin Island. A belt of seepages runs roughly parallel to the east coast from Okha southwards. Furthermore, on the northern part of the western coast, on the Yrkry, a tributary of the Liangri, other oil seeps occur. Often the seepages are in the form of kir lakes, one of which covers 26,000 sq. m. to a depth of a few centimetres to a metre or more, in the Okha area.

TABLE XII

Stratigraphical Succession in Eastern Sakhalin
(*After Khomenkho* [9, 1931])

Quaternary		
Upper Pliocene	Supra-Nutovo series	Dominantly loose, fine sands, often cross-bedded and iron-stained yellow, yellowish-grey, rusty, bluish; medium coarse gravels, conglomerates; compact sandy, micaceous clays. Dips not over 15–20°. About 1,000 m. thick.
	Nutovo series	(*a*) Cross-bedded sandstones and interbedded conglomerates. (*b*) Compact, fine, bluish-grey, grey, and yellow-grey sandstones. (*c*) Grey and blue oil- and gas-bearing sands with interbedded sandstone and compact clay. Dipping at over 20°, usually 30–40°, occasionally 60°. About 2,700 m. thick.
Middle Pliocene	Ekhabi series	Light yellow, pinkish, dark-brown, grey, and brownish-grey medium-sized conglomerates; white, yellowish-grey, rusty, pale greenish-grey sandstone with mica and a few pebbles; plant remains. 850 m. thick in the Katangly district.
Lower Pliocene	Okobykai series	Sandy clays.

The folds along the east coast run mainly north–south. The Okha anticline stretches 5 km., principally in a north–south direction. Its western flank dips at 6–20°, the eastern flank at 10–85°. The seemingly greater thickness of the oil series on the eastern flank has been suggested by Kosyguin as possibly the result of overthrusting and imbrication. Two uplifts occur along the crest of the structure, and production is from that north of the Okha River. The first well, drilled in 1889, did not find much oil, but in 1921 three wells on the western flank found fairly rich shallow oil. Further wells have been drilled by Japanese and Russian companies in this, Sakhalin's largest field.

The Ekhabi anticline runs 6 km. north–south, with westerly dips of 20–50° and easterly dips of 15–40°. There are two big faults parallel to the axis, and along these oil seeps occur. No rich oil horizon was found by wells 226 m. deep. The Paromai-Kydylani fold is about 16 km. in length. Dips are generally less than 40°, but may attain 70°, and the steeper western limb is overturned in places. There is a series of east–west faults. Oil seepages are confined to the basal parts of the Ekhabi series and the top of the Okobykai. The long Nutovo anticline has dips of 60–70° on its western flank and 80° on the east. In the lower course of the Nutovo River is a small overturned fold with a fault extending north and south. Along this fault are many oil seeps and gas eruptions. A small well on the eastern flank found a little oil at 30 m., and a second well reported much oil at 80 m., whilst on the main anticline a well encountered some oil and much gas at a depth of 879 m. There seem to be seven oil sands, but little development has taken place. Oil seeps occur on a fold at Uini. To the south, in the region of the Imtchin and Uiglekut rivers, are two anticlines on which are oil-sand outcrops in the middle and bottom of the Okobykai series. Both anticlines are almost symmetrical, and the eastern Noglik-Katangli structure has two elevations on its crest.

On the western coast of Sakhalin, in the neighbourhood of the Yrkry seeps, the succession is as shown in Table XIII.

TABLE XIII

(*After Gedroitz*)

Post-Pliocene	Terraces and sands difficult to distinguish from Tertiary beds.
Tertiary	Mainly cross-bedded sands; some clays. Upper 150 m. nearly pure sand. Clays (mainly soft) predominate in the next 100 m., with some brown coals. 120 m. of beds with sands predominant; Yrkry oil seeps in the upper part. 2nd. coal series with hard shaly clays; at least 75 m. thick.

A fossil fauna is lacking in these formations, and the plant remains are badly preserved. Hence it has not been possible to correlate these, the Liangri rocks, with the oil series of the east coast. Their appearance is more youthful, but that may be a consequence of their having suffered less disturbance. Two broad gentle anticlines are known in the area. Their axes run north–south. The core of the western anticline reveals the oil series, and that of the eastern fold the lower clays. The Yrkry seeps are restricted to the western limb of the latter fold.

Climatic conditions in north Sakhalin are severe and not very favourable for oil production. The sea is open for only 4½ months of the year, thus calling for large oil-storage facilities if the fields are developed extensively.

Other Areas with Indications of Petroleum

Oil and gas or other indications of petroleum have been discovered in various other parts of the U.S.S.R. Gas-bearing beds have been observed in 30 localities in the Melitopol-Bierdianesk area north of the Sea of Azov when wells have been sunk for water. Eleven gas horizons were found about 210 m. deep in the Middle Sarmatian near Bierdianesk. Within Astrakhan city, at the mouth of the Volga, two gas horizons were encountered in Caspian beds at depths of less than 200 m. To the north in the Dergachevsky region (on the borders of the districts of Samara and Saratov) two shallow persistent gas horizons occur in the Akchagyl. Oil sands have been reported in the Permian near Volgoda and along the Sukhova River, but they are little prospected and undeveloped.

In Central Asia wells have found oil at Khaudag in limestones of Paleocene age and in the Jurassic, and oil was proved at Khanabad Sai in 1934. Fifty-three other

structures with considerable showings of oil are reported from the same general area. On the south-east coast of Lake Baikal are oil and gas seeps and ozokerite deposits, in addition to submarine seepages. Here, and also on the north-west coast, wells have encountered small flows of oil. A well has been drilled at Cape Nordwick, and indications of petroleum have been noted at the mouth of the Anabar. Oil is reported along the Tavda, at Surguta, and at the mouth of the Khatanga; at the mouth of the Lena, on the Taimir Peninsula, on the east and west coasts of Kamchatka, and on Novaya Zemlia.

Many of these areas, if they do contain important accumulations of oil and gas, are severely handicapped by their geographical position—great distance from industrial centres, and the coldness of their climates. Their development will be a matter of some difficulty. It is, therefore, not surprising to find that the U.S.S.R.'s increased production has been obtained chiefly by the further development of the regions first exploited, in particular the Caucasian region (Apsheron, Grozny, and Maikop), where the discovery of deeper productive horizons and of new structures, and the utilization of the less prolific horizons, has enabled the total production of oil to be more than trebled in the 10-year period ending 1935.

ROUMANIA

By G. D. HOBSON, Ph.D.
Imperial College of Science and Technology

Oil and gas in commercial quantities are obtained from three main areas in Roumania: the Transylvanian basin, the southern sub-Carpathians, and the eastern Carpathian Flysch zone (Bacau district). As yet only gas has been found in the Transylvanian basin, and in recent years the Bacau district has given but about 1% of Roumania's oil production. The southern sub-Carpathian zone may be divided into two parts, of which the Buzau area provides almost 1% of the present annual production, and the rest of the country's output is derived from the Dambovita and Prahova districts. In Transylvania gas seepages have been known on some of the domes for 200 years, and a commission considered the utilization of gas from one of them a century ago, but the first gas well was not completed until 1909 while attempting to locate potassium salt masses by prospecting drilling (Gardescu [2, 1934]). As early as 1650 oil was exploited by shafts at Lucacesti in the Bacau district, whilst the first wells were drilled at Mosoarele in 1860. Exploitation in the Prahova district dates from the excavations of the second half of the sixteenth century. There the first wells were drilled in 1863, but drilling only became important 30 years later (Pizanty [9, 1933]).

Fig. 1. Oil and gas areas of Roumania.

The Transylvanian Basin

The gas is produced from the Sarmatian, and some fifteen productive zones have been developed in 1,200 m. of beds. These gas zones are somewhat irregular in position. It is hoped that gas may be obtained from the Middle and Lower Miocene where suitable reservoir rocks exist.

On the fringes of the Transylvanian basin oil seepages are found near salt springs in the Lower Miocene as well as in the Oligocene, Eocene, and Cretaceous. Within the basin the folds trend generally north-south, being broad and widely spaced in the centre of the basin, and steepening towards its margins, where they may be overturned or even overthrust outwards. Most of the marginal folds have a salt core, and salt cores are thought to be present at depth in the gas-producing areas of the centre. West of a line through Dos, Kolozs, Torda, Nagy-Enyed, and Vizakna, and east of a line through Szasz-Regen, Szovata, and Kohalom, gas in quantity is not expected because of the extent of disturbance of the structures.

Forty-three domes are known, of which thirteen are deemed unfavourable due to absence or extensive erosion of the

Table I

Stratigraphical Sequence in the Transylvanian Basin

Quaternary	Terrace deposits; alluvium; loess near base.
Pliocene	Mainly fresh-water clays, sands, and lignites.
Miocene	Sarmatian. Scattered lakes were left by the Lower Miocene sea. In some the water became fresh. Sandstones and conglomerates were deposited on their margins and marls towards their centres. Upper Mediterranean or Helvetian has alternating beds of grey, poorly cemented sandstones, gypsum, and volcanic ash. The Lower Miocene submergence led to the formation of the basal conglomerates (Lower Mediterranean or Burdigalian).
Oligocene	Calcareous clays, red clays, poorly consolidated sandstones, and some conglomerates. In the north-west the upper conglomerates have beds of brown coals; in the south-west are Upper Oligocene brown coals.
Eocene	Two alternating series of red clays, gypsum, and nummulitic limestones; the upper limestone includes a few fresh-water beds.

Sarmatian; five lack closure in the upper beds, but may have closure at depth; eight have been proved, and the rest are viewed favourably. Methane springs are known on some of the domes, in addition to salt-water and hydrogen sulphide seepages and mud volcanoes. The productive domes are Sarmasel, Moinesti, Sincai, Saros, Bazna, Nades, Daia, and Copsa Mica. At Sarmasel a deep gas horizon has been found in the Mediterranean, and some gas is obtained from the Pliocene at Nades and Copsa Mica. The gas produced is dry and contains 95·46–99·1% of methane.

Bacau District

TABLE II

Stratigraphical Sequence in the Bacau District

QUATERNARY		Terrace deposits.
PLIOCENE	Pontian	Dominantly marls, clays, and a few fine sand intercalations.
	Meotian	Alternations of sands, marls, sandstones, and limestones. Transgressive on to the Flysch in the Comanesti-Moinesti basin. The predominance of sand gives oil reservoirs at Moinesti. About 300 m. thick.
MIOCENE	Sarmatian	Marls, sands, conglomerates, and micaceous sandstones.
	Upper Salifère	*Poduri Beds*: predominance of sands and sandstones, with dacitic tuff intercalations in upper part; rare conglomerates. 100–150 m. thick. *Campeni Beds*: mainly clays, marls, and gypsum; rare sand intercalations (oil-bearing at Campeni). 400–500 m. thick.
	Lower Salifère	*Antal Beds*: upper part red and green marls and sandstones interbedded; lower part thin conglomerates, gravels, and sandstones. About 300 m. thick.
OLIGOCENE		*Salt Horizon*: clays, marls, and sandstones; rich in gypsum and salt; dark coloured and bituminous; conglomerates.
		Kliwa Sandstone: thick bands of sandstone separated by thin marls, but marls become thicker and sandstone beds thinner towards the top of the formation. *Menelite Shale Group*: white sandstones with efflorescent sulphates; characteristic bituminous shales with gypsum and fish remains; brown calcareous marls and thick sandstone intercalations. The marls and shales indicate anaerobic conditions, and are often silicified into lenticular masses.
EOCENE		Micaceous, jointed, calcareous sandstones (Moinesti Sandstones) with ripple marks and hieroglyphics; hard sandstones and conglomerates; grey, red, and green marls. Small amounts of oil. 350–400 m. thick.

The marginal Flysch of the eastern Carpathians has been thrust over the Salifère as a sheet 3–4 km. wide, and folding continued until Pliocene or later times. In the Bacau district, in addition to the marginal faults of the Carpathians and the sub-Carpathians, there are two other important lines of faulting: (1) the Trotus fault running from Onesti to Barlad; (2) the Tazlau fault. It is along these lines of faulting that the petroliferous areas are found (Sergescu [11, 1930–1]).

Solontu and Stanesti lie respectively on the east and west of a structure in which two sheets of Oligocene beds have been thrust over Antal beds and arched, with Upper Salifère partially cloaking the overthrust beds. Five oil sands are found in the Oligocene series. Wells range up to 500 ft. in depth, and their poor production is improved by shooting. At Tetcani a small amount of oil is obtained from sands and conglomerates in the Campeni and Antal beds. Oil seepages have long been known at Tetcani and in the Vallée Sarbilor to the north-west, and in both places oil has been exploited by shafts.

Moinesti shows inverted Eocene and Oligocene, contorted and overthrust eastwards on to the Salifère. Meotian and Pontian have been deposited over the Eocene. Near the thrust the Eocene outcrops, and along with the Oligocene it has been worked by shafts. Water troubles have hindered exploitation of the Meotian, but about 150 m. below its top are a gas sand 25 m. thick and oil sands. The Meotian is productive in the southern part of the field. Below the Pliocene the Eocene yields a little oil, and oil has also been encountered in the Oligocene at depths of more than 900 m. At Lucacesti oil is obtained mainly from the Oligocene. Wells show the Oligocene to have overridden the Salifère eastwards at Tazlau, and oil production is from the Oligocene. The Kliwa sandstone yields oil at Zemes, where the beds are overturned, contorted, and fractured, and the Eocene, which partly covers the Oligocene, shows traces of oil. The wells are long-lived small producers due to the low porosity of the rocks. In the north, production of water with the oil is increasing.

The Campeni field lies east of the Tazlau fault, and in it oil is found in the Campeni and Antal beds. The oil is believed to be secondary and hopes are entertained of Oligocene production beneath the Salifère. According to Sergescu [11, 1930–1] a small amount of good-quality oil was produced from the Sarmatian at Casin. Attempts to exploit oil in the Oligocene, and possibly in the Eocene at Dofteana, by means of inclined galleries and a shaft were abandoned for want of capital, although some oil sands were met. At Mosoarele ozokerite veins occur and the Oligocene has been found productive beneath the Eocene.

A little oil has been found in a number of other places associated with this region of complex tectonics. In these, and in the fields already mentioned, oil has been obtained from numerous pits, about 1 m. square and as deep as 200 m., as well as from wells.

The Southern Sub-Carpathians

The Buzau District.

This lies east of the main Roumanian oilfields. Its principal feature is an anticlinal structure (Arbanasi) running NNE.–SSW., and traceable for almost 30 km. Elevations occur on the crest at Beciu and Berca. The structure is steep, asymmetrical, and probably faulted near its crest, along which mud volcanoes are known. The Meotian is exposed in places and contains the chief oil horizons. Some oil is found in the Sarmatian. At Sarata-Monteoru is a steep and slightly overturned fold with a reversed fault. The Sarmatian outcrops and oil production is obtained from the Meotian and the Sarmatian. There are several wells and, in addition to pits, shafts with drifts and inclines have been made in the oil zones.

TABLE III

Generalized Stratigraphical Succession for Southern Sub-Carpathians

PLIOCENE	*Levantine*: marls, clays, sands, lignites, coarse sandstones, and conglomerates. Fresh-water deposits. 500–700 m. thick.
	Dacian: coarse sandstones, clays, sandy marls, and lignites. Fresh-water deposits. 300–450 m. thick.
	Pontian: marine clay and marls; sandy towards the top. 650–800 m. thick.
	Meotian: coarse sandstones, continental marls, fine, brackish-water sandstones and fresh-water sandstones, marls and sandy marls. 330–580 m. thick.
MIOCENE	*Sarmatian*: marls, clays, sandstones, conglomerates, and limestones. 350–450 m. thick.
	Tortonian: marine to brackish marls, sandy marls, and limestone. About 100 m. thick.
	Upper Helvetian: grey sandy marls, sandstones, dacitic tuff, and salt.
	Lower Helvetian: grey and red marls with gypsum. Total thickness of Helvetian about 600 m.
	Burdigalian: conglomerates, sandstones, and sandy marls. 100–200 m. thick.
OLIGOCENE	Sands, sandstones, conglomerates, shales and black bituminous shales or marls (Cornu beds), gypsum, and salt. (The Helvetian, Burdigalian, and Cornu beds are lagoonal deposits.)
EOCENE	Shallow marine deposits, conglomerates, sandstones, black shales, marls, and limestones.

The Dambovita and Prahova Districts.

In going southwards in this main oilfield area there is a general change in the type of producing structure; from the overthrusts of the north which resemble the structures of the Bacau district, through uplifts with salt cores penetrating to, or almost to, the surface, to more simple anticlines which may or may not show salt masses at depth. There is a tendency for the fields to lie along lines of uplift which fork or lie *en échelon.*

Bustenari is connected with the main line of dislocation in the north. The Oligocene has been thrust southwards over the Salifère, and the southerly dipping Meotian overlaps on to the Oligocene (Slomnicki and Meyer [12, 1925]).

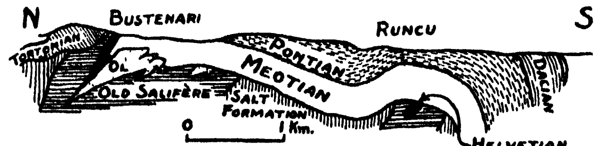

FIG. 2. Bustenari and Runcu. (*After Krejci.*)

Good production is found at comparatively shallow depths in the Oligocene, and oil is also obtained from the Meotian down to depths of 1,000 m. Campina lies immediately south of a line along which the Salifère has been thrust steeply to the surface against the Meotian. A second mass of salt at a shallow depth has folded the Meotian which gives prolific production from the southern flank of the structure. Oil is also found in the Dacian.

To the south is situated the field of Runcu, a simple elliptical dome with its major axis east-west, and yielding oil from the Meotian. West of this dome is Chiciura, where oil occurs in the same horizons.

Around the Moreni salt upthrust are the fields of Pleasa, Stavropoleos (north), Bana (north-east), Piscuri (east), Cricov, Tuicani, and Pascov (south). The Levantine forms the surface beds, and the strata are thinner on the northern than on the southern flank (Gheorghiu [3, 1931]). The salt overhangs considerably on its southern margin. A number of oil zones have been exploited in the Dacian on the south, but they are not generally productive north of the salt (some oil is obtained from the Dacian at Bana). Their importance and productive area increase with depth, and the upper ones only yield oil near the salt. The 'Gros', '6-metre', and '14-metre' sands are water-flooded over

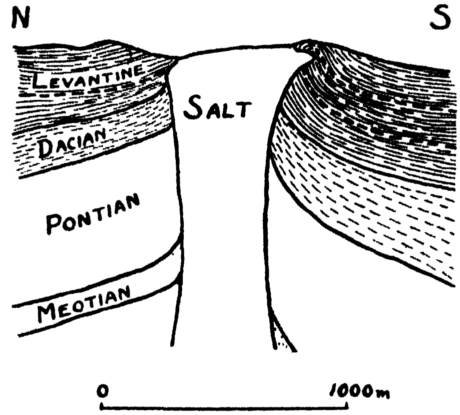

FIG. 3. Moreni: showing overhanging salt. (*After Krejci.*)

much of the area, and the most important Dacian horizons, the Moreni and the Drader sands, run together at the eastern and western ends of the field. The Drader sand is productive at Piscuri. On the northern flank the 1st. Meotian sand is thin but richly impregnated with oil. The 2nd. sand is poor, and although the 3rd. sand has been found to contain oil, usually it is charged with salt water. The 1st. Meotian sand on the southern flank yields oil, but the 2nd. sand is poorly developed. The intermediate gas sand is under very high pressure and presents drilling difficulties. The bulk of the Meotian production is from the 3rd. sand.

The Ochiuri field lies west of Moreni. A small salt upthrust is present. The Levantine is at the surface on its northern edge, whilst the Dacian is the main outcropping

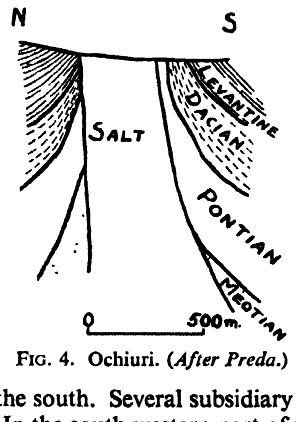

FIG. 4. Ochiuri. (*After Preda.*)

formation on the south. Several subsidiary folds run from the salt mass. In the south-western part of the field (Preda [10, 1929]) is a north-south line which separates a western area, where the Drader is unproductive, from the eastern area where it is productive. The Meotian production is only moderate. East of Moreni is Filipesti, a broad, long anticline with no known salt core. The upper Dacian outcrops and the Meotian alone gives oil.

A salt core comes to the surface at the complicated

western end (Baicoiu) of the Baicoiu-Tintea structure, where the Dacian and Meotian are productive. The eastern part of the Gura Ocnitei field has an outcropping salt mass. In this, the old part, the southern flank is the more important because of the Dacian production. The sands above the Drader are watered. The 1st. Meotian is usually poor, but the 2nd. sand is extensively exploited. The 3rd. sand has only a low gas pressure (Mircea [7, 1931]). The salt mass has a NE.-SW. trend and is at depth in the western extension of the Gura Ocnitei field. Two surface faults are connected with the underground salt mass. On the southern flank the upper oil sands of the Dacian are water-flooded at many points, but the Moreni sand is exploited in some parts. The Drader is the richest and most extensive horizon in the Dacian. Oil is obtained from the 1st. Meotian sand, but not from the 2nd. sand; the intermediate sand contains only gas, and salt water is present in the lower part of the 3rd. Meotian. On the northern flank the rich 1st. Meotian and the 2nd. sand are produced together. Near the salt the 3rd. Meotian sand has salt water in its lower part as on the south. The thickness of this sand diminishes westwards.

Floresti is a further example of an intrusive salt mass. At depth it may be connected with the Tintea-Baicoiu structure. Within a short distance of where the salt ceases to be seen, the Dacian no longer yields oil.

Proceeding southwards along the Teleajen the progressive change in structural type is seen. In the north at Valeni de Munte Eocene and Oligocene rest on Lower Salifère (Basgan [1, 1930]), and there the earliest exploitation took place. On the northern flank of the Gura Vitioarei-Copaceni structure the Oligocene sandstones show inspissated oil at the surface. They have been upthrust into contact with the Meotian, and the latter is cloaked by the Pontian. Oil has accumulated in the Meotian and is obtained at quite shallow depths. Some wells pass through the Oligocene to it. At Scaiosi, 1·5 km. south of Copaceni, the salt is 96 m. below the surface. It has thrust up Meotian, Sarmatian, and Mediterranean beds as a fractured east-west structure. On the northern flank little oil has been found in the Meotian, for that series lacks cover. On the southern flank the Meotian outcrops in places, and the upper beds have been water-flooded, but the basal beds are well preserved and good-quality oil has been obtained 125 m. down in the Meotian. The Boldesti structure lies still farther south, and there no salt is known. It is a broad, elongated dome with its major

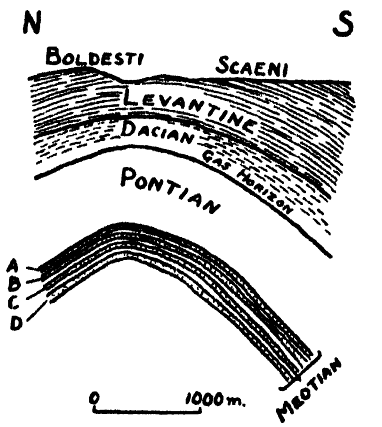

FIG. 5. Boldesti. (*After Patriciu.*) A = Gas zones. B = I Meotian oil complex. C = Intermediate Meotian oil complex. D = II Meotian oil complex.

axis running about N. 70° E. for 13 km. On it are Boldesti and Scaeni, and Harsa in the east. No faults are known, and the northern flank is the steeper. Only the Levantine outcrops. The beds are considerably thicker than in other fields (Iscu [4, 1931]). A little gas is encountered in the Dacian, but no oil. The Meotian is the productive formation, and below four high-pressure (as much as 200 atm.) gas zones are two important oil horizons, the first being 1,450–1,550 m. deep on the crest.

Aricesti is a dome on which the Dacian yields dry gas and a little oil at depths of about 550 m., and oil is obtained from the Meotian at 1,650–2,300 m. The Meotian is in the course of development.

The long, narrow anticline of Ceptura extends NE.-SW. for about 5 km. Pontian outcrops on the crest, and in it a gas bed was found 250 m. above the Meotian. Two important oil zones occur in the Meotian and give a highly paraffinous oil. The productive part of Ceptura seems to continue westwards towards Urlati-Valea Calugareasca, which lies south of the Boldesti-Harsa dome (Mihalache [6, 1931]).

The fields mentioned by no means exhaust the list of those which are productive. Until recently the bulk of Roumania's oil has been obtained from structures in or near the foot-hills of the southern sub-Carpathians. Geophysical work has been carried out on the great plain south of the foot-hills during the past few years, and in 1934 four wildcats were completed in the gravel-covered plains (Penny [8, 1935]). The Bucsani well, 10 km. south of the foot-hills, reached the Meotian at 1,500 m. and found oil. A subsequent well would seem to show that the anticline is broad and several kilometres long. The Dragomiresti well in the Dambovita valley met the Meotian at a depth of 1,800 m. and found high-pressure sands in it, but the production was mainly of water.

The age of the upthrust salt and the oil-source beds are two controversial points in Roumanian oil geology. Voitesti [13, 1926], basing his ideas on the ages of fragments found in the breccias associated with the edges of the salt masses in some places, has gradually lowered the source of the salt down the geological column, until he suggests that it is part of the earth's original crust condensed from a vapour. At various times solution and recrystallization have separated the different salts and deposited them in depressions of the continental areas of the earth's crust. Thus most salt should be attributed to the older formations. But the old fragments have not necessarily been carried up from great depths by the salt. Early Tertiary erosion must have exposed much older rocks, of which fragments would appear in Tertiary conglomerates, and it is possible for these to have been reworked. Pustowka finds that the salt masses are confined to regions where the saliferous Aquitanian, Burdigalian, and Helvetian formations occur, and so assigns an Upper Oligocene and Miocene age to the upthrust salt and the accompanying clay and marl. Bertrand and Joleaud hold the same view, and Mrazec and Krejci put the age as Aquitanian. Posepny, Koch, and Böch have considered the salt of the Transylvanian basin as being intercalated with the marls of the Helvetian.

The Aquitanian shales—black, sulphurous, and highly bituminous marine shales—are believed by Krejci to be the exclusive source of Roumanian oil. They attain thicknesses of as much as 500 m. in southern Roumania between the saliferous horizons of the Oligocene and the Miocene, and all the oil accumulations show contact, connexion, or at

least proximity with these. Macovei has expressed the opinion that the Menelite shales of the marginal Oligocene and the black Barremian (Lower Cretaceous) shales of the interior Carpathian zone are typical oil-source rocks, and, according to Voitesti, all divisions of the stratigraphical series from the Lower Cretaceous to the Upper Pliocene, with the exception of the Senonian, Pontian, and Levantine, contain more or less well-developed source beds. Mrazec points to the Salifère as the main source series, and the Oligocene and Eocene may have been the sources of small amounts of oil. Thus, complete agreement on the question of source beds is lacking, but the general tendency is to favour those Oligocene or Lower Miocene beds which most closely comply with the conventional conceptions of oil mother rocks. A satisfactory solution of the problems of source rocks and oil migration, when reached, must explain why the Dacian seems to give only gas on structures where it is not faulted or intruded by salt, e.g. Boldesti and Aricesti, and the general increased productivity and areal extent of oil sands with greater depth in a single field.

ALBANIA[1]

By STANISLAV ZUBER

University of Cracow

THE main oil occurrences of the country are associated with the Tertiary strata around the Adriatic shores. The Albanian coastal belt is subdivided into two parts: the western part, mainly of Neogene strata, is block-faulted rather than folded. The eastern is closely folded and forms a series of tectonic units mainly composed of Palaeogene Flysch, with calcareous basement rocks in the cores and with narrow belts of Neogene preserved in the zonal depressions.

The direction of folding maintains its Dinaric character (Nowack [3, 1930]), i.e. NNW.–SSE., though this is disturbed in some regions by large transverse flexures. These flexures are associated with subsidence phenomena.

I. Neogene Oil Occurrences (Fig. 1)

The marginal Neogene frequently covers buried Eocene structures which have a Cretaceous limestone basement and flanks composed of Flysch beds which were eroded in pre-Miocene times. In contrast with the frequent buried anticlinal structures, the overlapping Neogene maintains its synclinal attitude. The marginal Neogene sediments are of mixed character, being of salt-, brackish-, and fresh-water types. They correspond to an extensive Middle Miocene transgression, with later post-Miocene oscillations. The unconformities, which follow the pre-Miocene tectonics, are seen towards the eastern margins.

The brown coals are intimately related to the petroliferous strata and they very often take the place of oil sands. Lignitiferous bands of Miocene frequently become petroliferous, though retaining all their other characteristics. The presence of bituminous sands containing organic vegetable matter is very suggestive. The Albanian lignites belong to the asphaltic-pyrobitumens and frequently change into real asphaltites.

Kuchova Oil-pool (Fig. 2). This field is in an angular Neogene embayment following a transverse flexure of the Palaeogene folds. Two main unconformities are present: the upper at the base of the Pliocene and the lower which belongs to the Tortonian. A buried Flysch anticline, eroded to the basement limestones, is directly covered by overlapping Miocene. The edges of the Miocene syncline are upraised, faulted, and even locally overthrust by the Flysch. The oil-bearing strata are subdivided into three complexes: (1) Kuchova—dark grey clays with small sand-lenses; fresh-water fauna; oil impregnations of sands and sandy clays only locally productive. (2) Gorani—grey and variegated clays with numerous sand-lenses, brackish- and fresh-water fauna; numerous sand-lenses well impregnated and productive. (3) Driza—variegated clays with rare and only locally impregnated sand-lenses; brackish fauna prevails. On the top of 'Driza' a layer with Ostrea is present and forms an excellent key-bed therein.

The 'Driza' belongs to the Upper Tortonian. The lower part of the 'Gorani' may also be thus classified. The 'Kuchova' is Upper Miocene.

The oil is asphaltic (sp. gr. 0·930–0·940) with a high percentage of aromatic fractions and a low content of medium boiling-point fractions. Sulphur content is 3–4%. The formation is lenticular in character and production is obtained from individual lenses. The same holds for the brines which are disseminated through the 'Gorani' and 'Driza'. No edge-water has been found. The synclinal depressions of the pool are the best production zones. In the neighbourhood of the buried massifs the oil saturation diminishes considerably.

Initial productions are from 5–10 tons daily but more is obtained from the good sectors of the pool, and this production is apparently constant. Some gushing has occurred. The gas pressures are low and emanate from single sands.

Pahtos-Selenitza Oil-bearing Belt (Fig. 3). Tectonics: a marginal belt transversely faulted, with a central calcareous massif (Selenitza) unconformably covered by Miocene deposits. Local unconformities extend up from the lower Miocene. The Pahtos pool is a monoclinal block uniformly dipping towards the north, composed of Tortonian and Helvetian oil-bearing beds, with an abundant marine fauna, unconformably covering the Schlier (Lower Burdigalian and Aquitanian).

The Selenitza oil shows consist of bituminous oil sands partly weathered, Upper Miocene and Tortonian in age. Fluid oil has been found down-dip towards the north. Between Selenitza and Pahtos a depression exists which is completely covered by the Pliocene. The Selenitza oil shows are similar to those of the Kuchova structure, but the strata are more elevated and therefore more eroded and the oil is residual in character. Secondary asphaltic veins and pockets exist near Selenitza in the Lower Pliocene (old seepages weathered and oxidized). The oils of the belt are asphaltic and sulphurous (sp. gr. 0·940–0·990 and more).

Other oil shows are distributed in the vicinity of the Kuchova pool (Pekisti) and of Selenitza (Greshitza).

II. Palaeogene Oil Shows

Oligocene. These comprise bituminous sands and asphaltic impregnations of fossiliferous sandstones in several localities near Elbassan. The palaeogeographic conditions are, in these cases, similar to those of the Selenitza-Pahtos belt (buried pre-Oligocene structures with eroded Eocene limestone basement).

Middle Eocene. The lowest strata of the Palaeogene Flysch are oil impregnated in several localities. Their tectonics correspond to anticlinal flanks with their calcareous core exposed. Near Valona (Drashovitza) small initial productions of oil (average sp. gr. 0·935) have been obtained. Similar oil impregnations of some extent exist in the neighbourhood of Berat.

The general stratigraphic positions of all the oil shows in Albania are as follows:

Pliocene. Secondary asphaltic veins in the neighbourhood of the oil-bearing basement.

Upper and Middle Miocene. Asphaltic oils near the edges of the Miocene coastal transgression; this is the main oil-bearing formation. Deposits are of the Mediterranean type (Zuber [1, 3–5, 1935–1937]).

Lower Miocene—Oligocene and Upper Eocene (Schlier

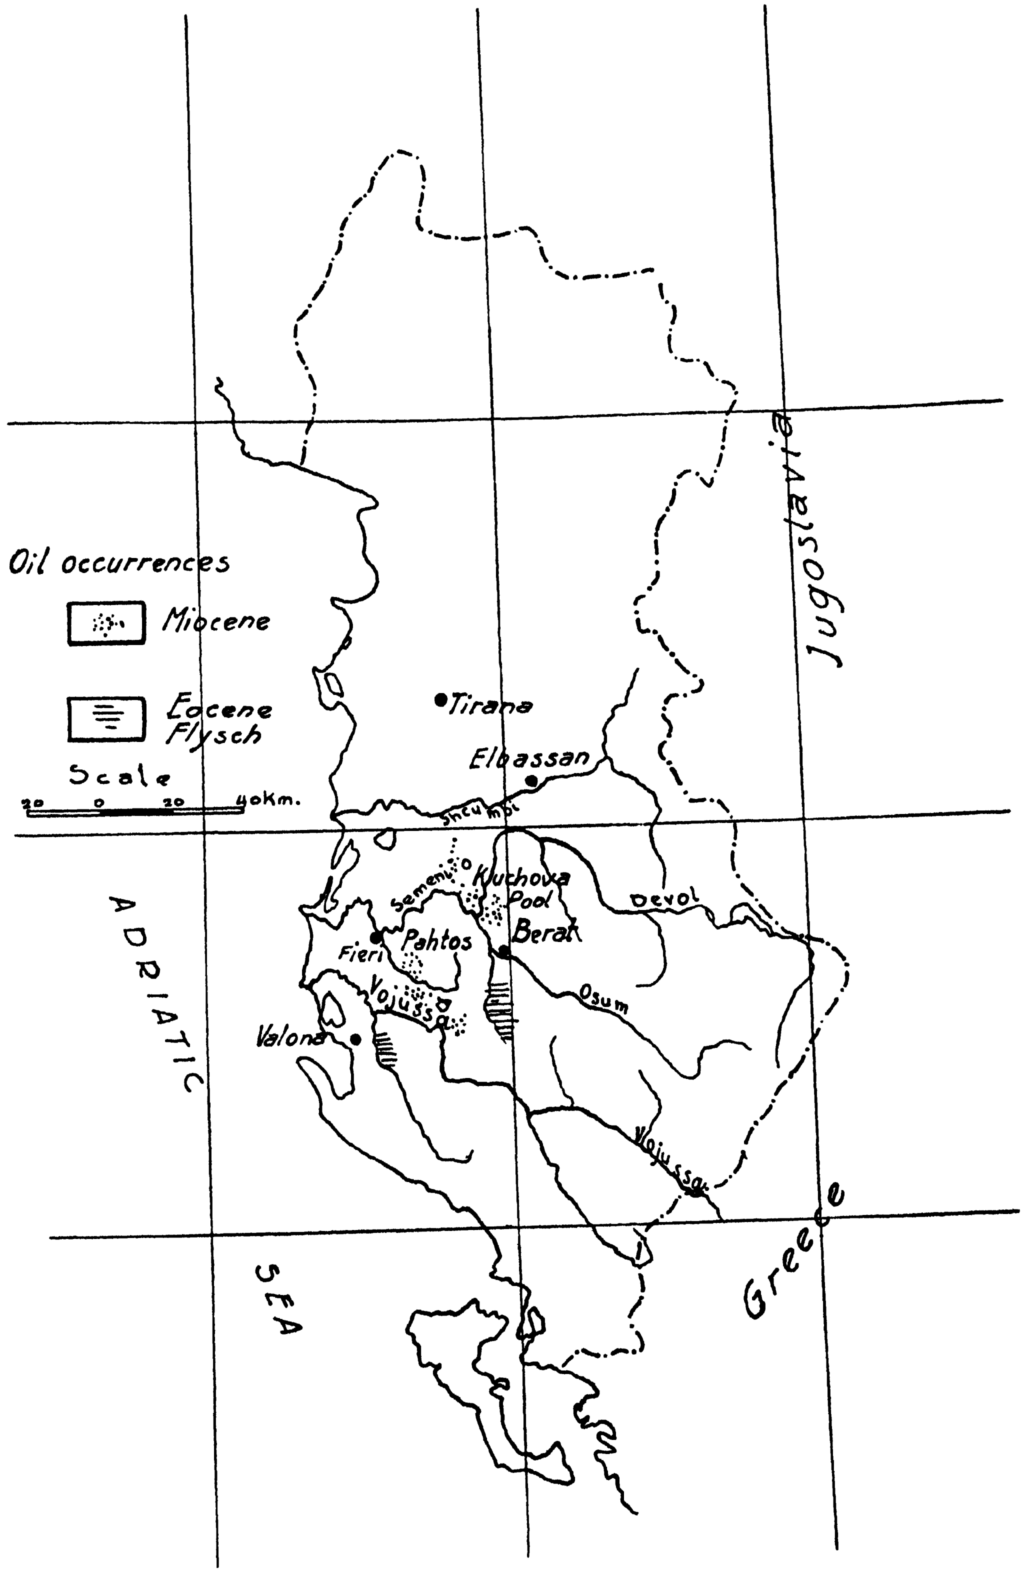

FIG. 1. Sketch-map of the main oil-shows of Albania.

and Flysch). Diffused and isolated shows of no commercial value.

Middle Eocene (Flysch). Frequent traces, sometimes even with commercial possibilities.

Basement Limestones: Lower Eocene—Mesozoic. Isolated asphaltic impregnations in the Eocene limestones. Asphalt and asphaltites are frequent in the Middle Triassic of S. Albania (Nowack [4, 1930]).

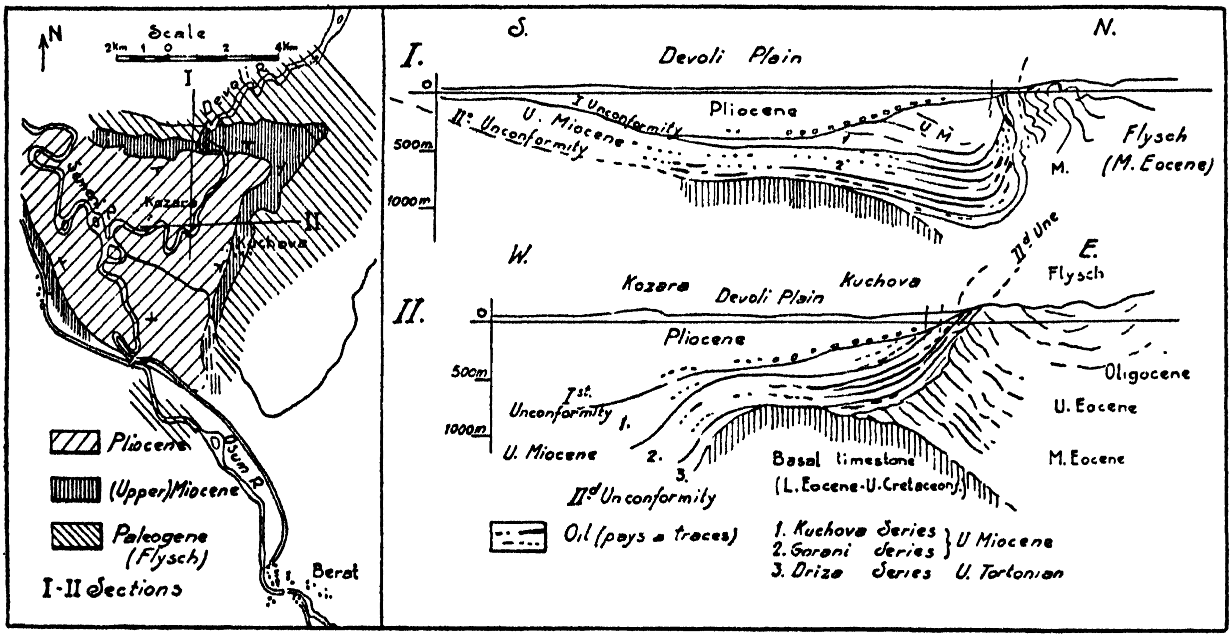

FIG. 2. Sketch-map and sections across the Kuchova oil-pool.

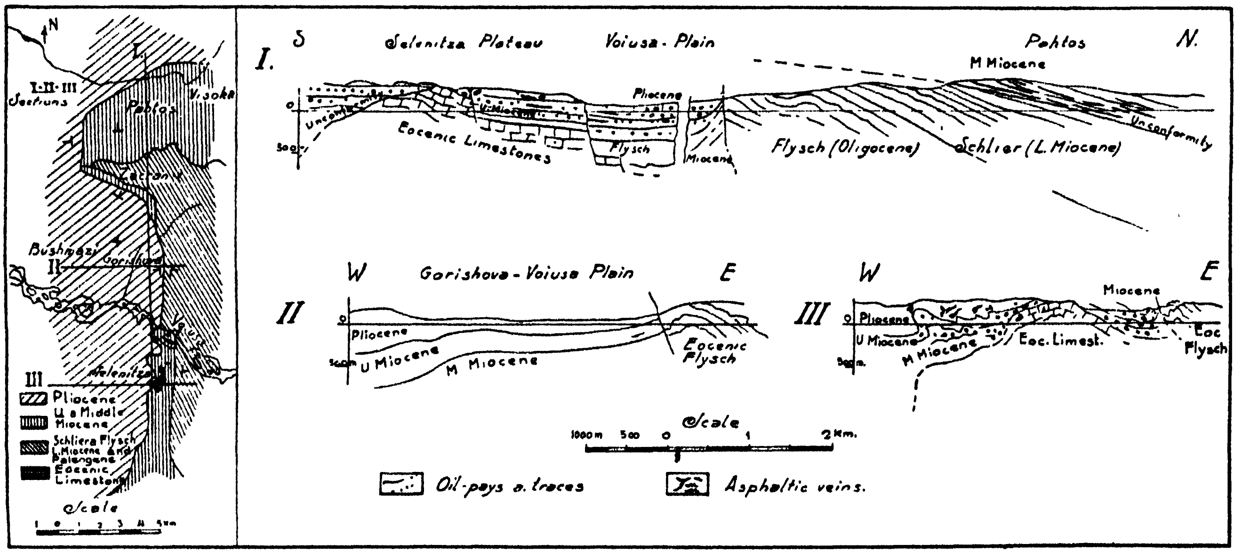

FIG. 3. Sketch-map and sections across the Pathos-Selenitza oil-bearing belt.

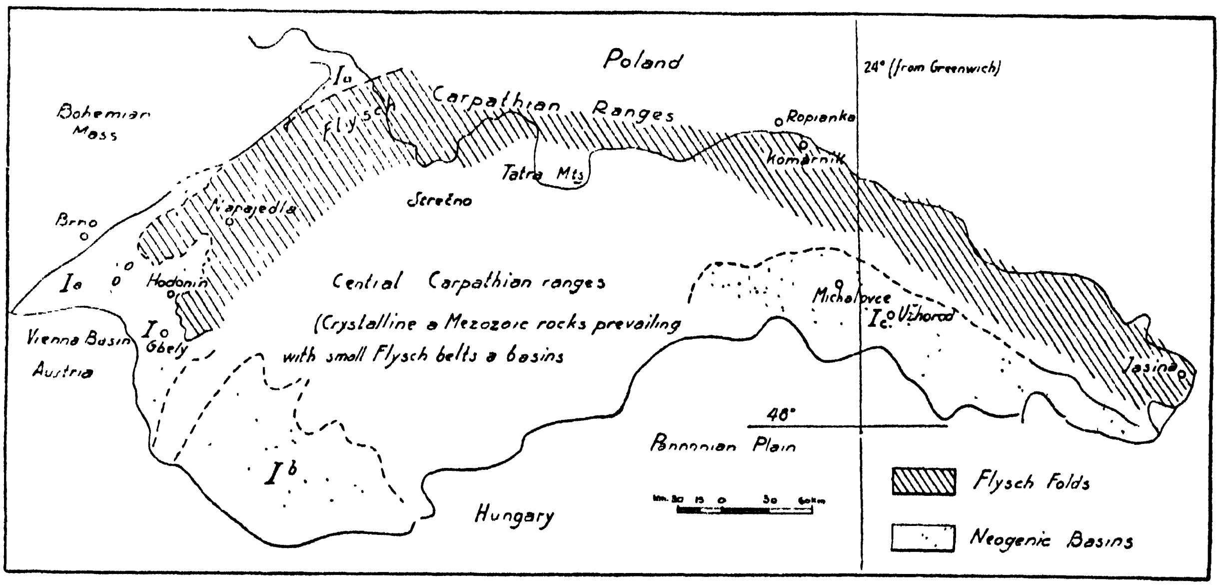
CZECHOSLOVAKIA

By **STANISLAV ZUBER**

University of Cracow

THE oil-shows of this country are located along the Carpathian arch. The two main types correspond exactly to the two different types of sedimentation and, consequently, of tectonics (see Sketch-map). The first belongs to the Carpathian flysch belt, Palaeogene and Cretaceous, composed of a bunch of folds thrust towards the north-west, north, and north-east, and having their main development in Poland with structures designated by Polish geologists as characteristically 'skiba'. The second consists of embayment basins filled up with undulating Neogene deposits, faulted and frequently broken down. These basins mark the edges of great depressions existing between the Alpine Systems, the Carpathians, and the Bohemian Mass, and which penetrate into the Czechoslovakian territory from the Vienna Basin and the Pannonian Plain.



Sketch-map of the main geological units of Eastern Czechoslovakia.

1. **The Carpathian Oil-bearing Units** represent narrow folds, frequently steep, which run parallel to the main axial direction of the chain. Their oil occurrences are connected with the Lower Eocene and Upper Cretaceous Flysch (shales and clays). Oil-shows are frequent and widespread, though production is small, due to the lack of well-developed porous formations. Escape of the oil from the beds is also restricted by the presence of secondary folding in the shales. As in the boundary oilfields of the Polish Carpathians, the search has always been hindered financially and therefore several folds, which are undoubtedly oil-bearing, have not yet been explored. Descriptions by Sommermeier [5, 1930], Zapletal [8, 1935], Matejka and Zelenka [3, 1932], and Hynie [1, 1925] distinguish these two main belts; the western to the south of the Tatra Mountains (western Slovakia and Moravia) and the eastern from the Dukla Pass (Fig. 1) to the Roumanian frontier (eastern Slovakia and the Carpatho-Russia).

The total production of the oil from the western belt has not exceeded more than a few hundred tons of light benzinous oil (average sp. gr. about 0·810).

The somewhat more favourable underground conditions of the eastern belt correspond with the gradual increase in oil saturation of the zone of Central Nappe of the Flysch Carpathians, along the Polish side of the range. At Komàrnik the total production has exceeded 10,000 tons (sp. gr. 0·805). To the east traces only have been found with a few hundred tons of production.

As on the Polish side, i.e. in the area of the Central Nappe of Flysch, all the oil deposits and traces belong to the common Carpathian type with anticlinal distribution of oil and of the edge-waters.

2. **The Moravian Neogene Embayment.** Beyond the partly unconformable Pontic-Meotic overlap, which is undulating and fractured, there is an almost complete Miocene sequence below the Sarmatian. Productive oil impregnations appear through all the Vienna Basin, of which the Moravian embayment represents a sector. Two main pools are recognized: **Gbely** and **Hodonin** (Sommermeier [5, 1930], Vetters [6–7, 1935]). Oil of 0·910–0·945 sp. gr. is found in three sands, somewhat lighter in the two upper levels, and heavier in the lower. The irregularly shaped oil-bearing sectors do not follow the tectonic structures and are distributed haphazardly. Gas blow-outs are frequently associated with the oil lenses. Water also appears irregularly. The average depths of the Sarmatian levels within the fields are 100–500 metres. The oil occurrences of the Moravian Embayment correspond to the Mediterranean type of underground conditions, which must be taken into consideration in prospecting. The successful wells in both the above fields give initial productions up to 20 tons daily.

Below the Sarmatian the Middle and Lower Miocene

are followed by the Palaeogene. The latter forms an uplifted belt which partly divides the Gbely sector from that of Brno (Fig. 1). The Tertiary shows a nearly complete sequence with only very slight unconformities. Promising oil-shows have been found in these basement rocks (Vetters [6–7, 1935], Schnabel [4, 1931]), the lithological character of which should present good conditions for the accumulation of oil, which would be controlled more by lenticularity than by structure. Similar conditions are probably associated with the promontories of the Bohemian Mass, in which region the Tertiary blocks become gradually uplifted.

3. **The Pannonian Neogene Embayment.** So far only slight traces, bounded by the Mesozoic chains of the Central Carpathians or by the Quaternary volcanoes on the edge of the Flysch Carpathians, are known. These depressions present stratigraphic conditions similar to those of the Moravian Embayment.

4. Asphaltic rocks of the Middle Triassic Dolomites of the Central Carpathian chains are known in the vicinity of **Strečno** in Slovakia. These impregnations are associated with a series that frequently shows a diffused bituminosity and probably correspond to large accumulations of heavy oil, destroyed by the thrust movements.

The yearly production of Czechoslovakia averages 15,000 tons, mostly from the Sarmatian pools. The stratigraphical distribution of oil-shows in Czechoslovakia is as follows:

Lower Pontic and Meotic. Oil and gas traces in the Moravian Embayment.

Upper Miocene (Sarmatian). Main productive sands in the Moravian Embayment.

Middle Miocene–Palaeogene. Frequent traces in the Moravian Embayment.

Lower Eocene–Upper Cretaceous. Flysch oil-shows in the Carpathians.

Triassic. An isolated exploitable asphalt occurrence in the Central Carpathians.

POLAND

By S. E. COOMBER, A.R.S.M., B.Sc., D.I.C.

Imperial College of Science and Technology

THE whole of the Polish production comes from fields located along the Carpathian mountain front. The presence of petroleum is indicated by numerous seepages which have been used for centuries by the local inhabitants as a supply of lubricant and as a medicament for domestic animals. The first regular exploitation of these seepages appears to have commenced at the beginning of the nineteenth century, there being a record of the sale of oil from shallow pits at Boryslaw in 1816 to the Magistrate of Prague. The oil was to be used for street lighting. In 1853 the distillation of kerosine from the crude oil was commenced, drilling instead of shaft-sinking began in 1862, and in 1882 the Canadian system of drilling was introduced. With the introduction and gradual improvement of the Canadian system, deep drilling became possible and the production increased rapidly. From the year 1862 there was also a rapid rise in the production of ozokerite, and until the end of the century it remained the principal product at Boryslaw.

Shows of oil have also been reported from time to time in West Poland, especially from a zone which stretches from Tuchola (south-west of Danzig) to Kielce, but apart from a few shallow wells no developments have taken place there. The northern part of this area forms the eastern extension of the North German oil province, and the most interesting occurrence in it is the salt-stock at Inowroclaw (Hohensalza) in the province of Posen. Not only does this indicate the presence of salt structures, but the salt itself is bituminous. Very detailed prospecting work, geological, geophysical, and drilling, would be needed, however, before the possibilities of the area could be rightly judged.

Summary of the Geology of the Polish Carpathians

The Carpathians are part of the great Tertiary mountain system, and their general structure is similar to that in other parts of this system, overfolds and great thrust sheets dominating the picture. Their frontal portion in Poland is composed of Flysch sediments, and the oilfields are concentrated in this zone. Taken as a whole, these sediments are thrust over a Miocene foreland. When considered in more detail, however, it is found that they are themselves subdivided into a complex series of overthrusts and nappes which have developed from overturned and recumbent folds. It is now generally recognized that these structures fall into three major groups or nappes which, following Nowak's [3, 1929] terminology, are called Magura, Central, and East Marginal. Their present surface extent is shown on the accompanying map, and it will be seen that the Central nappe is exposed over by far the greatest area. Nearly all the western and many of the eastern oilfields fall within its limits, but the most productive of the Galician fields are found in the East Marginal nappe.

The general relationship of the above-mentioned structural elements in the Flysch zone is as follows. The Magura nappe is thrust over the Central nappe; this is, in turn, thrust over the East Marginal nappe; and finally the East Marginal nappe is thrust over the Miocene foreland.

Magura Nappe. The Magura nappe does not extend west of the meridian of Sanok. Its northern edge extended originally at least 30 kilometres north of its present position. The general structure may be described as a great overfold nappe which is divided into numerous blocks, thrust outwards over one another like, to use Nowak's simile, the tiles on the roof of a house. There are a few small fields on its outer margin to the east, and these obtain their production from strata in the Magura nappe as well as from the underlying Central nappe. In addition it is to be noted that many of the fields at present located entirely within the western part of the Central nappe were once covered by the Magura nappe.

Central Nappe. The general character of this great unit varies with its length and its breadth. Along its north-east margin there is a zone of folds and frontal overthrusts. Towards the centre this gives place to the central depression, a synclinorial zone from which, in the Sanok area, a number of folds arise and develop into overthrusts as they are traced westwards. Analogous conditions are to be found in the extreme east of the zone. The central part of the synclinorial zone is relatively little compressed, and the greatest accumulation of petroleum in the west Carpathians is to be found in this area.

East Marginal Nappe. This is almost entirely masked by the Central nappe and, in spite of its being by far the most productive region and hence penetrated by many wells, the details of its structure are not wholly clear. This is especially the case in its relationship to the foreland, of which very little is as yet known on account of the thick cover of gravels and alluvium. The question of the subdivision of the East Marginal nappe is a matter of debate. Some workers divide it into a series of sub-nappes, Pokucie, Sloboda, and Boryslaw, whilst others see in these structures a series of connected folds. For the present the subject is best left open until further work, which is being actively pursued in the area, throws new light on the problem.

Stratigraphy

The Carpathian Flysch includes strata of Cretaceous and Lower Tertiary age. It is in general an alternating series of sandstones and shales with irregular intercalations of hornstones and calcareous marls, the total thickness being some 7,000 ft. Nowak [3, 1929] has pointed out that normally these beds become more sandy as they are traced southwards. This is a natural result of the conditions of deposition, the Flysch being a relatively shallow water, shoreline deposit originating in seas of varying depth. The detritus was supplied by the land mass to the south and probably also by chains of islands emerging along zones of uplift in the shallow sea.

Cretaceous. Although the Lower Cretaceous is well developed in the extreme west of the Carpathians, it is relatively unimportant within the zone of the Galician oilfields. It is there represented by the Wernsdorf beds or Spas shales, which are Barremian-Aptian in age and are mainly black shales.

The Upper Cretaceous is of considerably more importance in the oilfield region. Over the greater part of the

area it is represented by the Inoceramus formation, a series of grey clays and sandstones with local intercalations of Fucoid marls. In the extreme east a series of red and green shales and calcareous sandstones—the so-called 'Plattige' beds—forms the higher part of the Upper Cretaceous. Finally, in the marginal area in the east there is the Jamna sandstone. This is a massive, coarse-grained sandstone of Palaeocene age and some 130–300 ft. in thickness.

There is a change in facies of the Upper Cretaceous in the region west of Sanok. This change from east to west is gradual, and the typical western development is the Istebna shale series of black shales and sandstones.

Locally, the Jamna sandstone and the sandy horizons in the Inoceramus beds are oil-bearing.

Eocene. The change in facies from east to west which was noted in the Upper Cretaceous persists into the Eocene. The exact details of the Eocene stratigraphy, however, are not entirely clear. It has been usual to make a threefold subdivision, but, according to Nowak [3, 1929], recent work on nummulitic faunas shows that the two lower divisions are Lower Eocene and the other Upper Eocene. The use of the term 'Hieroglyphic' is also somewhat misleading. Some writers apply it to the whole of the Eocene, others state that it is overlain by the Popiele beds in the eastern area, and yet others confine it to the Upper Eocene and consider the Popiele beds to be a special development in the east.

The lowest strata are coloured shales with interbedded sandstones. These are followed by a more sandy series in which are the Ciezkowice sandstone in the west, and the Wygoda and Pasieczna sandstones in the east. These two series form the Lower and Middle Eocene according to the system in which a threefold subdivision is recognized. The Upper Eocene is characterized principally by the Hieroglyphic beds which are dark, greenish-grey shales with interbedded quartzitic sandstones, on the bedding planes of which the Hieroglyphics are seen. In the East Marginal nappe and also the outer part of the eastern section of the Central nappe the Popiele beds occur at the top of the Eocene. They are mainly sandy and calcareous shales.

The Ciezkowice sandstone is an important reservoir rock in the west Carpathians, whilst some oil is produced from the Popiele beds and the Lower Eocene in the east.

Oligocene. In the Central and East Marginal nappes the Lower Oligocene is characterized by the Menelite shales which are black, thinly bedded, bituminous shales with a bitumen content of 1–8%. Fish remains are abundant, especially scales of *Meletta cranata*. Sandstone intercalations are also common, and one of these, at the base of the Menelite shales, is the Boryslaw sandstone, the principal producing horizon in the Boryslaw field. The exact age of the Menelite shales is doubtful. Although they have generally been considered as Lower Oligocene, there is evidence which would seem to point to them being, at least in part, of Upper Eocene age.

The Menelite shales are normally overlain in the east by the Polanica beds, light-grey, sandy shales. In the central part of the area, however, the Krosno beds are the typical Upper Oligocene development. They are of a more sandy type than the Polanica beds and include an appreciable proportion of sandstone horizons. In the eastern part of the East Marginal nappe the sequence is somewhat different. The Menelite shales are there overlain by the Sloboda conglomerates, and these in turn are overlain by the Dobrotow beds which are sandy marls of Upper Oligocene and possibly even Lower Miocene age.

There is an important change in facies towards the west. The Menelite shales gradually give place to massive sandstone, the Magura sandstone, and this is typical in the Magura nappe for the whole of the Oligocene.

Deposition in the Magura and Central nappes ceased with the Oligocene. It continued into the Miocene in the East Marginal nappe. The important producing horizons in the eastern fields are Oligocene.

Miocene. The Dobrotow beds which cover the Sloboda conglomerate possibly extend into the Lower Miocene. They are followed in the East Marginal nappe by a red series of shales and sandstones which is in turn followed by the Salt series. This latter series consists of light-grey, saliferous, and gypsiferous clays. With the exception of a zone in the south-east, deposition ceased with the Salt series. In this zone, which is the 'Sloboda sub-nappe' of

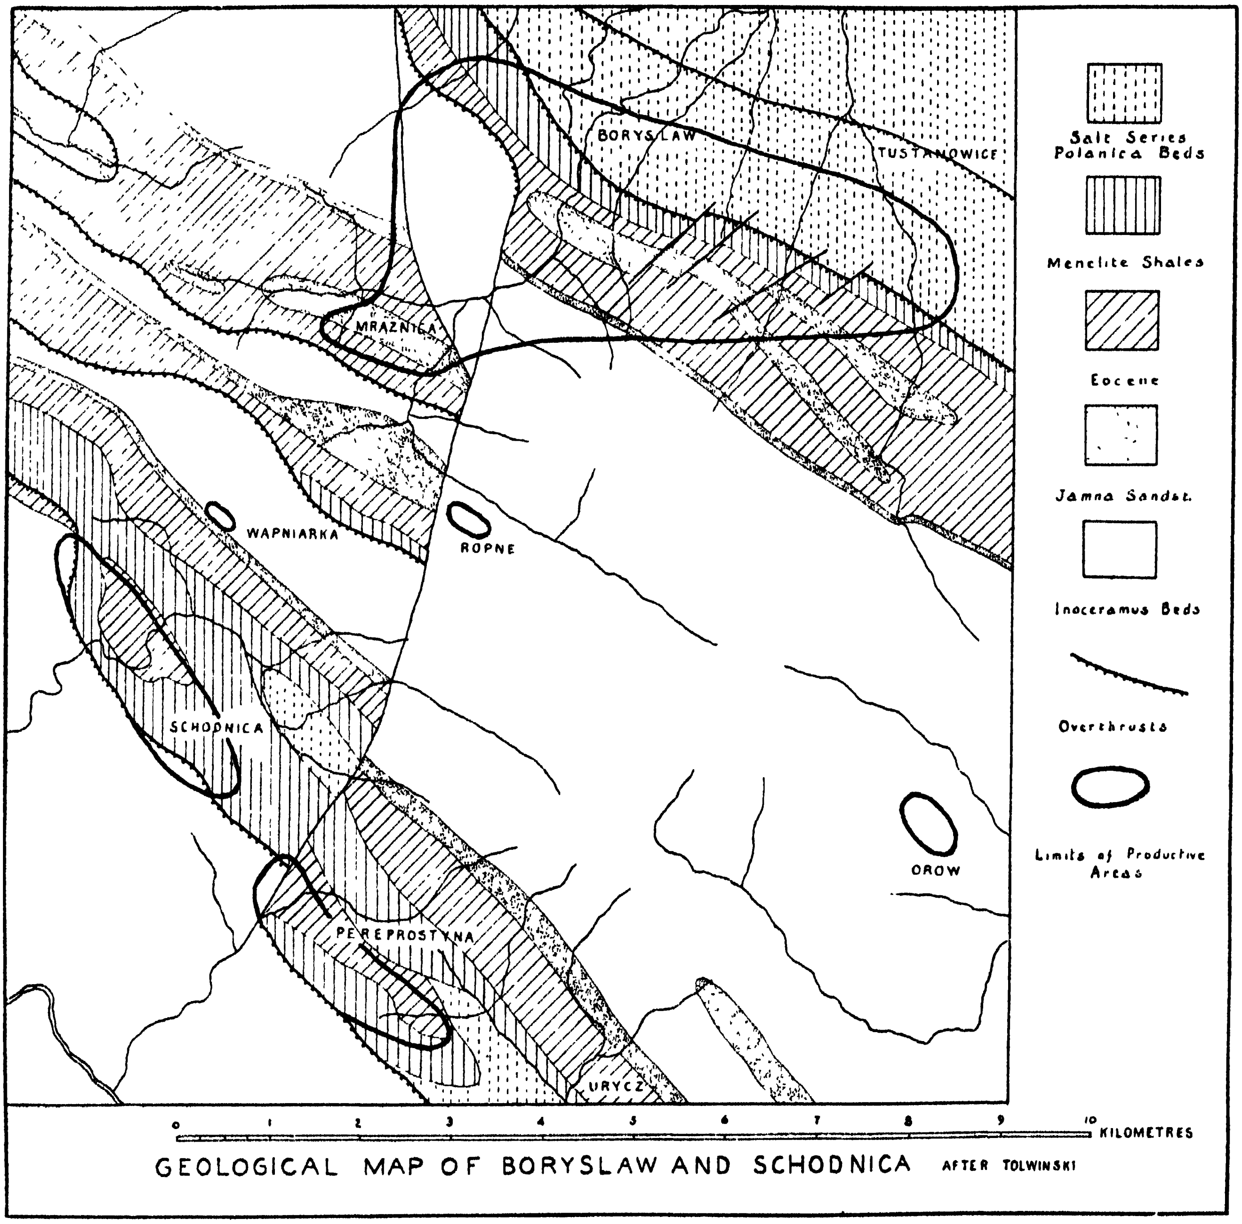
some authors, the Salt series is covered by clays, sands, and marls of Tortonian age. The great overthrusts were developed during the Tortonian.

Miocene strata are characteristic of the foreland. The known sequence begins with a series of saliferous clays with salt and potash deposits, but it is not at all certain whether these are the same as the Salt series in the East Marginal nappe. Above this series are marls, clays, and sands, and then come the Lower and Upper Cerithium beds. The Lower Cerithium beds also contain salt deposits. The exact ages of these series are difficult to determine. They may extend to the Lower Sarmation, but in any case the productive Pliocene of Roumania is definitely absent (Friedl [2, 1930]).

The Polish Oilfields

There has been a more or less continuous decline in the Polish production from the year 1909, when Poland ranked third amongst the producing countries with an annual production of some 2,000,000 tons. In 1935 Poland was fifteenth with an annual production of about 500,000 tons. The Boryslaw field provides about 70% of the total production, Schodnica about 10%, and the remaining 20% is divided amongst forty or more other fields of which five have annual productions of 15,000–25,000 tons. The greater number of the remaining fields are therefore seen to be very small producers. In the following account only some of the more important fields can be described. Full descriptions of all the fields are to be found in papers by Friedl [2, 1930] and Nowak [3, 1929], and descriptive notes on the fields in the 'World Oil Survey Number' of the *Oil Weekly* [4, 1933].



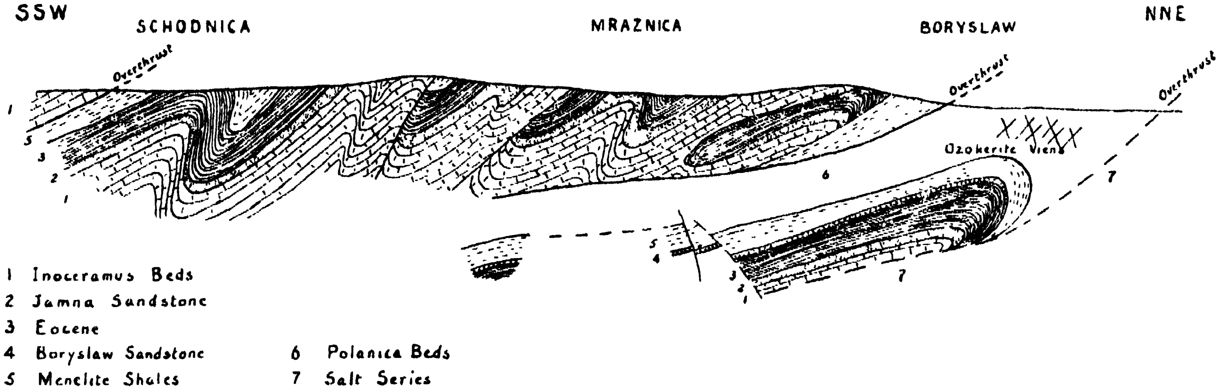
MAP II.

Boryslaw–Tustanowice–Mraznica

The Boryslaw field is located on the margin of the Central nappe, the northern boundary passing through the productive area. In the underlying East Marginal nappe there is a great recumbent fold, the Boryslaw 'deep

fold'. The subsurface of this fold is a matter of controversy. It is not known whether it rests on autochthonous Miocene strata or whether there is another thrust block beneath it. The extent of the movement of these nappes is also unknown, but it is at least several kilometres.

The field extends over an area in which there is subsidary elevation or doming on the main deep fold. It is limited on the north and north-east by the overturn, and on the west by a fault of considerable magnitude, the Ratoczyn fault. Beyond this fault only water is found. Edge-water is found in the south-east and south-west. The dip of the fold in these directions is comparatively gentle and it is broken by minor faults only. The main extension of the field is now in south-west Mraznica.



Cross-section I. From Boryslaw to Schodnica. (*After Friedl.*)

Stratigraphy. The Salt series and Polanica beds have a thickness of 750 m., but in some cases it is reduced. They pass downwards into 200 m. of black, bituminous Menelite shales which contain interbedded sandstones. Below these are the Popiele beds with a regular sandstone zone 50–75 m. from the top. The Lower Eocene is in the form of green shales alternating with quartzitic sandstones. The thickness of the Eocene varies, it being about 400 m. in the major part of the field, and of this some 120 m. are Popiele beds. Below the Eocene there lies the Jamna sandstone, 80 m. thick, and then a reduced thickness of Inoceramus beds.

Producing Horizons. Salt series and Upper Polanica beds: Sand lenses are locally somewhat productive in the crest of the fold.

Lower Polanica beds: The first important producing horizon is found in a sandstone horizon 200 m. above the base of the Polanica beds. Production is limited to the crestal area of the fold.

Upper Menelite shale: Irregular and poor production in a hornstone at the top of the series.

Lower Menelite shale: Good gas production and a little oil in sandstone zones.

Boryslaw sandstone: A series of sandstones, some 20 m. thick, of varying grade and porosity. It occurs at the base of the Menelite shale at depths of 700–800 m. in the crestal part of the fold, and at a depth of 2,000 m. at the south-west boundary of the productive zone. This sandstone series is the richest horizon at Boryslaw and has given one-half of the total production there.

Popiele beds: Good production is obtained from the sandstone horizon 50–75 m. from the top of the series.

Lower Eocene: Productive horizons are found at various parts, but their extent is very limited.

Jamna sandstone: The second best producing horizon at Boryslaw. The upper surface is at depths of 1,400 m. in the crestal zone of the fold.

The greater part of the production is obtained from the deep fold, but small quantities of oil are also obtained from the overlying Central nappe. Most of the Boryslaw oil is fairly heavy, sp. gr. 0·85, with a gasoline content of 10–15% and a wax content of 7–9%. The oil from above the overthrust has a higher gasoline content, 12–28%.

In addition to the oil mention must also be made of the ozokerite deposits for which Boryslaw is famous. The ozokerite occurs in a system of steeply dipping veins in the Salt series and Polanica beds in the crestal region of the deep fold. The strike of the veins is oblique to the trend of the fold, and the greater number strike WSW.–ENE., dipping in a northerly direction. A smaller number of generally wider veins strikes WNW.–ESE. The width of the veins varies from a few millimetres to several metres, and they are filled with a breccia composed of fragments of neighbouring rocks. The ozokerite fills the interstices in this breccia. The hardness of the wax varies with its depth from the surface, and at depth it is so soft that it has flowed into a shaft and risen to the surface.

Schodnica

The Schodnica field is located on a comparatively broad and flat fold in the zone of folds and frontal overthrusts along the north-east margin of the Central nappe. It lies immediately in front of the Skole overthrust. Two domes are developed on this fold. The more northerly of these is the Schodnica dome, and from this the fold plunges, with minor breaks, gently to the south-east until it is cut by the Ratocyn fault. The effect of this fault is to lift the fold again some 300 m., and then, immediately to the east, the second dome (Pereprostyna-Urycz) is developed. The fold plunges gently south-eastwards again from this dome.

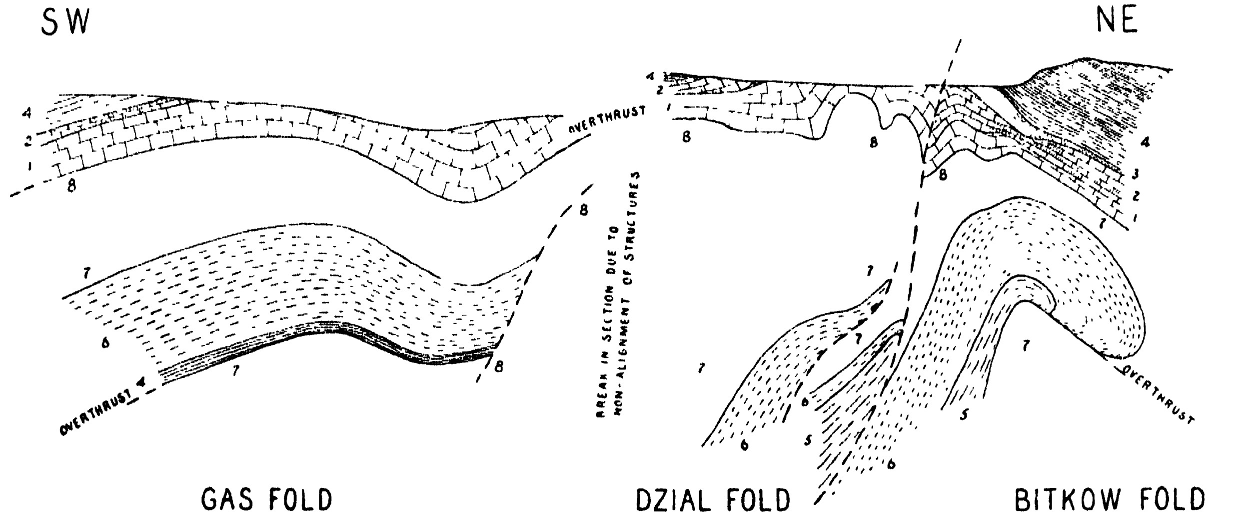
The stratigraphy is, in general, the same as at Boryslaw, with the exception that the Salt series is absent and the Polanica beds are greatly reduced in thickness. The principal producing horizon is the Jamna sandstone which is about 70 m. thick. The productive area is limited by edge-water to the two domes. The Inoceramus beds below the Jamna sandstone are also productive and offer now the best possibilities for expansion. A small amount of oil is obtained from irregular sand lenses in the Lower Eocene, but the Upper Eocene and the Menelite shales outcrop and are not productive.

Bitkow–Pasieczna

The Bitkow field lies more than 100 km. to the south-east

of Boryslaw and is situated 6 km. within the edge of the Central nappe. The producing structures are developed in the underlying East Marginal nappe which can be seen at a number of small windows in the district. The Bitkow fold itself is an arched recumbent fold, the brow of which is overturned. It is part of a schuppen structure of which it forms the northern unit. The Dzial fold follows to the south and is itself divided into a number of thrust blocks, and finally there comes the Gas fold which is a much less disturbed structure.

The Salt series and the Polanica beds are more or less normally developed in the Bitkow fold, but the Eocene is considerably reduced in thickness and the Cretaceous is completely absent. The Bitkow field is the third largest producer in Poland. Production is obtained from both nappes. In the Central nappe, producing horizons are found in the 'Plattigen' beds (Upper Cretaceous) and the Jamna sandstone. The major production is obtained, however, from the Menelite shales in the East Marginal nappe and it is limited to the Bitkow and Dzial folds. The Gas fold yields only gas.



1 Inoceramus Beds 2 Plattige Beds 3 Jamna Sandstone 4 Eocene 5 Shales, age doubtful 6 Menelite Shales 7 Polanica Beds 8 Salt Series

Cross-section II. Through the Bitkow field. (*After Zetechowski.*)

Paszowa–Wankowa–Leszczowate

As an example of the west Carpathian fields Paszowa–Wankowa–Leszczowate may be cited. This field has an annual production of more than 20,000 tons. It is located on a long anticlinal structure which plunges to the west and to the east, and which is overturned to the south-west, instead of the north-east as is usual in this region. The production is mainly from the Krosno beds under the south-west limb. In the south-east part of the field, at Leszczowate, a second producing horizon has been found in the Menelite shales at depths of 700 m., also on the south-west flank.

Dominikowice–Kobylanka–Lipinki Libusza

This field is situated immediately to the east of the town of Gorlice and is one of those fields once covered by the Magura nappe. The structure is anticlinal. It strikes north-east from Lipinki to Libusza with an overturn to the north-west. To the west of Libusza the anticline appears to fork in the Kryg–Kobylanka–Dominikowice area. The southern part is a broad, domed structure, whilst the northern part is a narrow isoclinal fold. Production is from the Ciezkowice sandstone.

Daszawa

Although no oilfields have been discovered in the foreland zone, a gasfield has been developed at Daszawa, 10 km. east of the town of Stryj. The productive horizons are at depths of 700–800 m. and are fine-grained sandstones separated by soft shales of Upper Miocene age. The dip of the beds is gentle, but little is published concerning the structure.

Origin of the Oil

There are two main theories concerning the origin of the Polish oil. The first postulates formation in the sub-Carpathian Salt series, and the second assumes that the mother rock occurs in the Flysch sediments. From a general consideration of the characteristics of the various oils and their occurrence Friedl [2, 1930] favours the first viewpoint and believes that the oil has migrated from the Salt series up into the Flysch which has been thrust for great distances over it. As opposed to this theory, however, Cizancourt [1, 1931] points out that no oil deposits are known in the foreland zone with its great extent of saliferous strata.

Amongst those favouring a Flysch origin for the oil, some limit the mother rock to the bituminous Menelite shales, whilst others consider that suitable mother rocks occur throughout the Flysch. Nowak [3, 1929] has sought to trace a connexion between the petroliferous areas and facies, and states that in these areas deposition was in episynclinal zones.

These different viewpoints have been summarized by Cizancourt [1, 1931], who concludes that the oil was formed in the Flysch during a period of rapid and intermittent sedimentation in not very deep seas. Synclinal zones adjacent to uplifted areas were probably the most favourable regions for its formation and, according to local conditions, all or part of the series may have contributed. Accumulation took place during the Early Tertiary folding, and the subsequent overthrusting and formation of nappes did not appreciably alter the distribution of the fields.

GERMANY

By S. E. COOMBER, A.R.S.M., B.Sc., D.I.C.

Imperial College of Science and Technology

THE German oil occurrences are found in three quite separate areas, viz.:

(1) the Zechstein (Permian) basin in north and central Germany;
(2) the Rhine graben;
(3) the Alpine foreland zone in Bavaria.

The presence of petroleum in Germany has long been known. The seepage at Tegernsee, Bavaria, was famous in the fifteenth century on account of the alleged curative properties of the oil. In north Germany the *teerkuhlen* were a source of lubricating material for the peasants until late in the nineteenth century, when systematic development of the oil resources began. This has reached its height in post-war years, and widespread exploration, subsidized by the government, is now being conducted. The total production during 1935 was of the order of three million barrels, more than double that of 1930, and of this more than 90% came from the Zechstein basin. The Bavarian occurrences are as yet of no economic significance.

The Zechstein Basin of North and Central Germany.

The Zechstein basin began to form at the commencement of Upper Permian time and stretched from England, across north Germany with an embayment into central Germany, and on into Russia. In it were deposited the lower- and mid-Zechstein dolomitic limestones, shales, and marls. Towards the end of the Zechstein conditions changed, the sea became landlocked, and desiccation set in with the consequent formation of large deposits of salt and gypsum. These salt deposits are the characteristic feature of the basin which, as a result of later movements, can be subdivided as follows:

Northern part	North-west basin—almost complete sequence of Trias, Jurassic, Cretaceous, and Tertiary deposited on the Zechstein in central part of basin. Total thickness more than 10,000 ft. The 'Pompeckj Schwelle'—Buried ridge. Jurassic and most of Lower Cretaceous absent. Thick deposits of Upper Cretaceous and Tertiary resting unconformably on the Trias. North-east basin—Jurassic and Cretaceous present above the Trias, but in reduced thickness and incomplete sequence. Facies different from that in north-west basin.
Southern part (of this, only Thuringia is considered here).	Complete sequence of Trias. Deposition stopped very early in Jurassic. Zechstein buried to depths of only 4,000–5,000 ft.

The attitude of the salt changes as it is traced from the margin of the basin towards the interior. In the marginal zone it is interbedded normally with the strata above and below; farther inwards it shows considerable thickening in the crests of anticlines; and finally, as the centre of the basin is approached, the true salt-domes and salt stocks are developed. The reasons for these variations and the mechanics of salt-dome formation are dealt with at some length by Stille [6, 1925], Romanes [4, 1931], Harbort [2, 1913], and Seidl [5, 1913]. The oil is closely associated with these structures, and two types of occurrence may be distinguished:

(1) The marginal zones of the basin—oil occurs in the Zechstein.
(2) The interior of the basin—oil occurs in post-Zechstein strata around the salt-domes.

These two types are structurally very dissimilar and therefore will be considered separately. The general stratigraphy of the Zechstein basin is given in the Table on page 186.

The Marginal Zones of the Zechstein Basin.

The principal areas which are included under this heading are the western margin of the north-west basin, in the neighbourhood of Bentheim on the Dutch border; the southern margin of the north-west basin, north of the Harz mountains; and a large part of Thuringia. Compared with the interior of the basin, the Zechstein in these marginal zones has been affected only to a small degree by the later disturbances. In general the structures are comparatively gentle folds with irregular faulting and, as mentioned earlier, the salt retains its original form as a bedded deposit.

The most important discovery of this type yet made was in the potash mine at Volkenroda, some 10 km. north-east of Mühlhausen in Thuringia. An explosion in 1930 led to borings being made from the mine workings, and these found a prolific source of oil in the mid-Zechstein Hauptdolomit which is there some 180 ft. thick. The oil has accumulated in cracks and fissures in the dolomite on gentle, anticlinal structures. During 1931 over 50,000 metric tons were produced, but after 1932 a very rapid decline began. Other wells have been drilled in Thuringia since this discovery, notably at Mühlhausen, Langensalza, Zimmern, and Kirchenheilingen, but with little or no success.

A small production (75 bbl. per day, Sept. 1935) has been obtained from wells on the Fallstein uplift, an anticline on the north side of the Harz mountains. The Zechstein there is reached at depths of 4,000 to 5,000 ft., and production is reported to be from the 'upper' dolomite. Other wells have been drilled on well-developed anticlines in the Magdeburg-Halberstadt district, but no results of economic importance have as yet been obtained. It should be noted here that the Hauptdolomit, which is the productive horizon in Thuringia, is in this district represented by the Stinkschiefer, which are mostly bituminous and marly limestones.

Well-developed anticlinal structures are found in the Bentheim district, and the asphaltic impregnations which occur there are probably indications of petroliferous horizons. In contrast to the areas already mentioned, however, the Jurassic and Cretaceous are also present. A well drilled on the Ochtrup anticline, 10 km. south of Bentheim, is reported to have obtained heavy oil from shattered mid-Zechstein dolomite at a depth of 1,750–1,800 ft.

The Inner Part of the Zechstein Basin.

The productive areas in this zone are confined to the north-west basin, and the oil has accumulated in structures

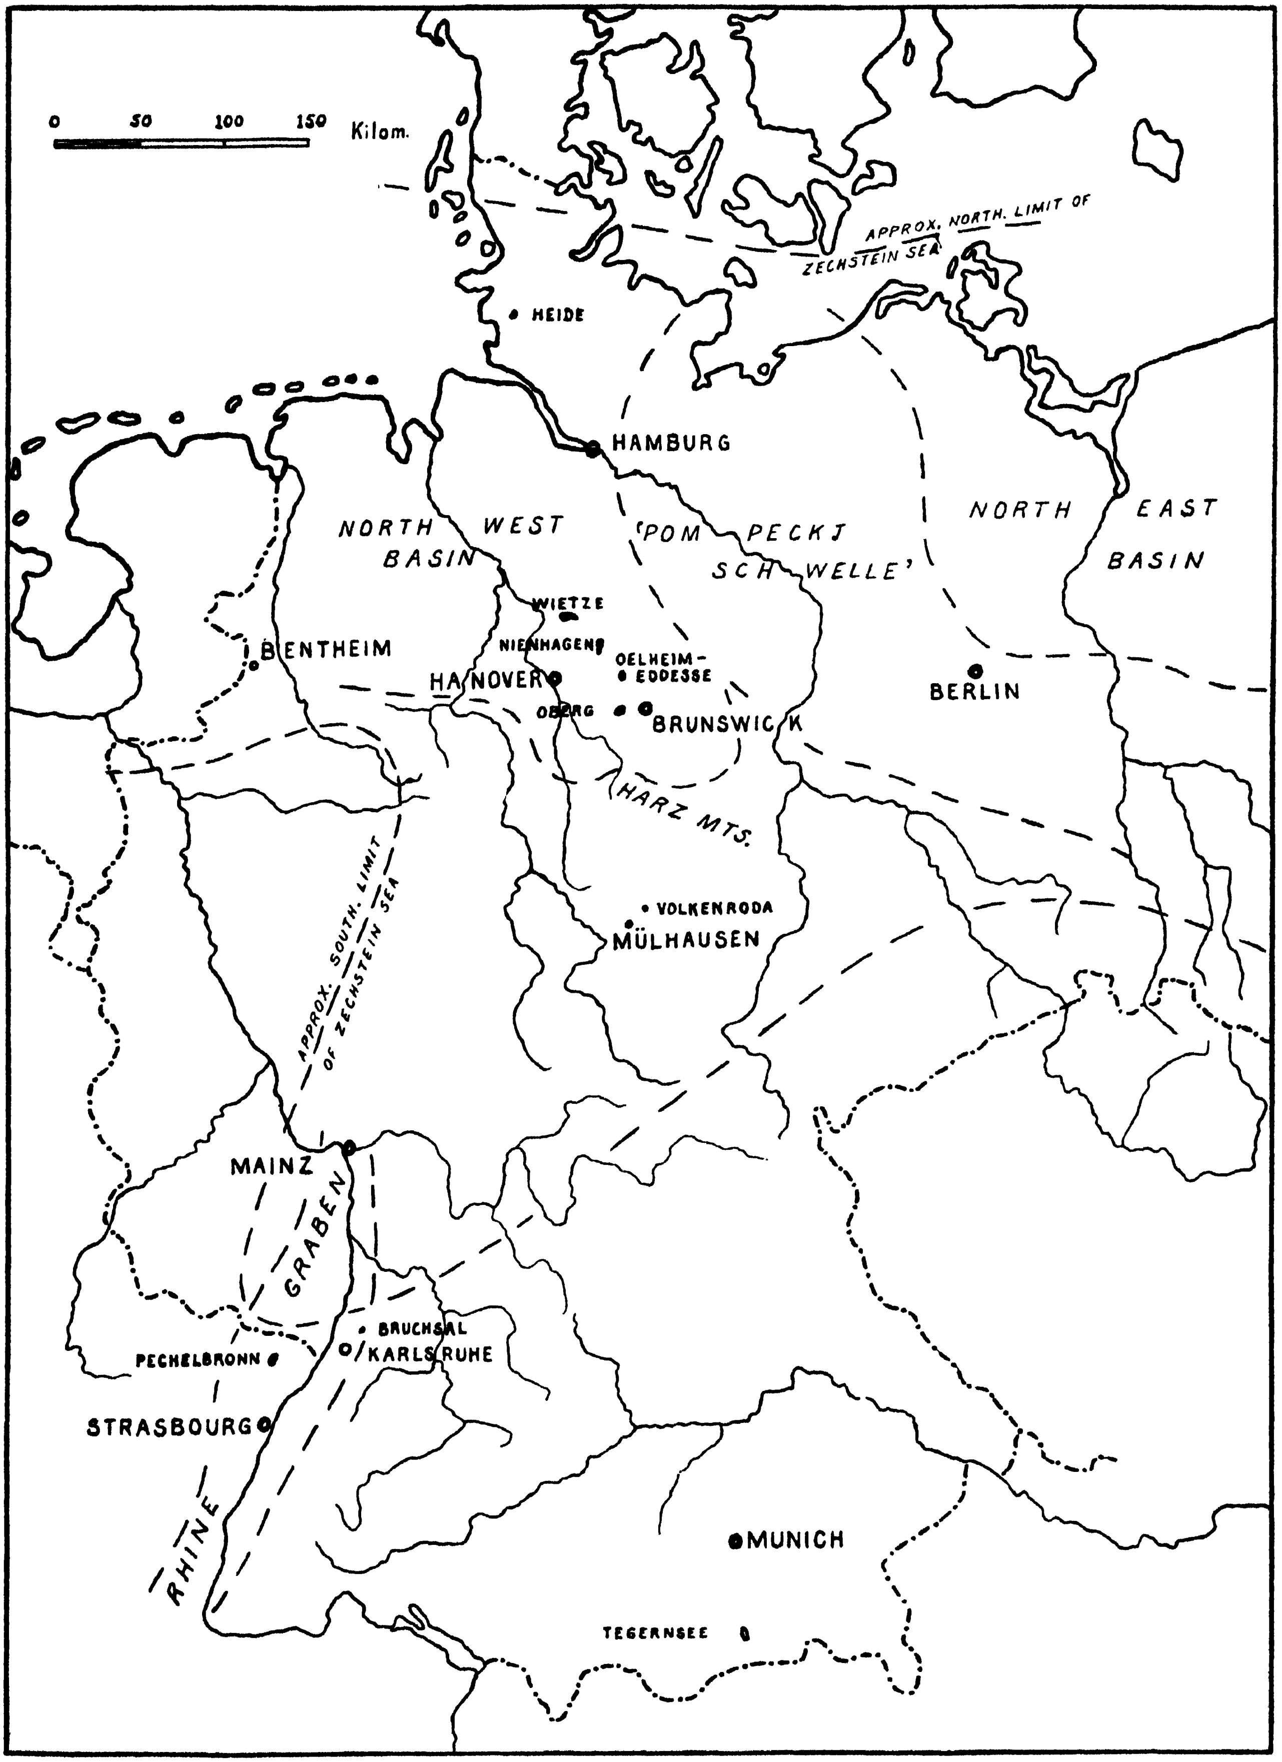

FIG. 1. Map showing the distribution and general geological features of the German oilfields.

developed in post-Zechstein strata by the uplift of the salt. The four principal fields in Germany, Wietze, Nienhagen, Oelheim-Eddesse, and Oberg, are of this type and they lie roughly on a NW.–SE. line some 30 km. to the north-east of the city of Hanover. The producing horizons range in age from Rhaetic to Lower Cretaceous, whilst small quantities of oil have been obtained from Upper Cretaceous and Tertiary horizons. When examined in detail the structures are very complex and are complicated by numerous unconformities due to late Jurassic and Cretaceous earth-movements. It is impossible to review all of these factors in the space here available, and the following account will be confined to a general, and therefore only approximate, description of the structures in the more important cases and brief mention of the others.

Nienhagen is at present the most important field in Germany. The oil is found in structures developed on the west flank of the Hänigsen–Wathlingen salt-stock which is elongated in a NNE.–SSW. direction. Early development was restricted to the seepage zone in the south where heavy oil was produced from shattered formations—mainly Triassic—at the edge of the salt. Later development spread northwards, and first a highly disturbed central zone was found to be productive, mainly from the Rhaetic and Lower Lias. Finally the north field was discovered, and this has proved to be by far the most productive. An anticline strikes WNW.–ESE. across the northern end of the salt. It is strongly folded close to the salt mass but broadens out away from the salt, and deep drilling through the Tertiary and Upper Cretaceous discovered the main oil sand in the Valendis. Oil is also obtained from the Wealden and the Upper Dogger.

General Stratigraphical Table for the Zechstein Basin, showing the Oil Horizons in the Principal Fields

Formation		*Lithology*	*Thickness, ft.*	*Wietze*	*Nienhagen*	*Oelheim-Eddesse*	*Oberg*	*Heide*	*Thuringia*
DILUVIUM		Sands, gravels, loess, peat, clay	300±

* = Main oil horizons. H = Heavy oil. M = Medium oil. L = Light oil.
† Stinkschiefer are here represented by the Hauptdolomit.

The Wietze field is distinguished by the fact that about one-half of the present production is obtained by mining methods. The north-west end of the Steinförde–Hambühren salt mass is anticlinal in structure, with a WNW.–

ESE. strike, the salt forming the core of the anticline, and the Trias, Jurassic, and Cretaceous forming the flanks. These are considerably broken by dip faults, and in addition there is an overthrust on the north flank. The Wietze field is limited to the north and north-west flanks, and oil is obtained from the Rhaetic below the thrust and from the Jurassic and Cretaceous above the thrust. The principal horizons are the Upper Dogger and, especially, the Wealden, whilst an appreciable production is obtained from the Senonian. With the exception of the Rhaetic oil, which is light, all the oil is heavy.

The Oberg structure is separated from the Oelsburg salt-stock by an Upper Cretaceous graben. The structure itself is a broad arch in the centre of which the Upper Dogger outcrops surrounded by crescent-shaped outcrops of Malm, Wealden, and Lower Cretaceous. The subsurface structure is complicated by a number of unconformities as a result of which various zones of the Malm begin to wedge in down dip. The main producing horizon is a sandstone in the Lower Dogger. Small production has also been obtained from the Upper Dogger and the Heersumer beds in the Malm. Some 8 km. to the south-west of Oberg there is a similar structure associated with the Moelme salt-mass. After many test borings had been made a well came in during 1935 and produced 30 tons per day from the Jurassic. Full details of this occurrence are not yet available.

In contrast to the Nienhagen, Wietze, and Oberg fields the Oelheim–Eddesse field is not associated with an obvious anticlinal structure. The strata around the Oedesse salt-stock have been lifted into steeply dipping positions by the salt and broken by radial and peripheral faults. The sequence is complete to the Upper Dogger, but the Wealden lies unconformably on this. The old Oelheim field was developed on the south-east flank where shallow production was obtained from the Wealden and the Tertiary sands. Post-war development led to the discovery of the deeper Eddesse (Berkhöpen) field where light oil is obtained from the Rhaetic at depths of 3,000 ft. Apart from these producing horizons, shows are obtained in all the strata with the exception of the Senonian.

The most northerly occurrence is at Heide in Holstein. A faulted Permian horst is covered by Upper Cretaceous beds and the chalk is in places saturated with heavy oil. Attempts to work this occurrence, both by wells and by mining, have been made at different periods, and recently drilling there has been resumed. It has been reported that a well has given a steady production of 130 bbl. per day from the 'sandy marls of the lower strata of the red sandstone' (Rotliegendes ?).

A recent development is reported from Gifhorn, 25 km. north of Brunswick. Wells have obtained production from the Wealden, which is said to be above the salt-cap, and they are yielding 50–100 bbl. per day. The true significance of this discovery cannot be appreciated until further details are published.

In addition to the above-named areas, small quantities of oil have been obtained from Horst–Wipshausen (15 km. north-west of Brunswick), Hordorf (15 km. north-east of Brunswick), Hope (25 km. north of Hanover), and Lehrte (15 km. east of Hanover), and shows from many other localities. They have, however, so far proved to be of no economic value.

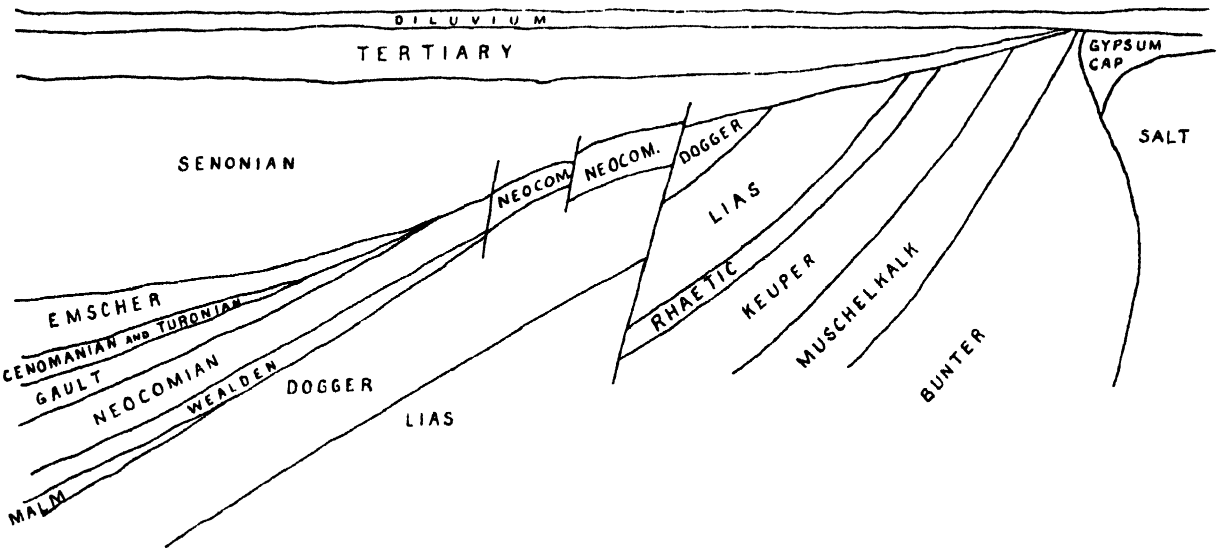

FIG. 2. Cross-section through the Nienhagen field. (*After Strobel.*)

The Origin of the Oil in the Zechstein Basin.

This highly controversial subject can be summarized briefly as follows. There is unanimous agreement that the oil found in Zechstein horizons is primary and originated there. With regard to oil found in post-Zechstein horizons there are two schools of thought. One claims it to be Zechstein oil which has migrated up fault zones at the edges of the salt-stocks; the other considers that suitable source rocks are to be found in the Mesozoic and that to postulate a Zechstein origin for this oil is unnecessary. An excellent summary of the various arguments and points of view is to be found in a publication by Stutzer [7, 1935].

The Rhine Graben.

The Rhine Graben extends from Basle to Mainz and is bounded on the west by the Vosges and the Hardt mountains, and on the east by the Schwarzwald and the Odenwald. The subsidence began in the Tertiary and was especially active during the Oligocene. Altogether there are some 4,500–6,000 ft. of Tertiary sediments, the greater

part being Oligocene in age. The region is broken into numerous fault blocks by faults more or less parallel with the main boundary dislocations. The greater part of the oil production comes from the Pechelbronn field in Alsace, a description of which has been given by Zuber elsewhere in this volume (France: S. Zuber, p. 193). Exploratory drilling at Bruchsal in north Baden during the years 1921–6 led to the discovery of another small field, similar in type to Pechelbronn. A detailed account of this work is given by Moos [3, 1935]. In general the Oligocene is not so well developed at Bruchsal as at Pechelbronn, and the sandy reservoir rocks in the Pechelbronn beds (Lower Oligocene) are missing. Production is obtained from the green marls in the dolomitic zone (Basal Oligocene) and from the upper Meletta beds (Mid-Oligocene). Wells drilled recently in this area have also given a small production from the Jurassic.

Oil and gas shows are found elsewhere within the Rhine graben in German territory, notably in the Palatinate, near the Buchelberg and Durkheim, and on the east side of the Rhine between Heidelberg and Darmstadt. Drilling in these areas is contemplated.

The Alpine Foreland Zone in Bavaria.

Tertiary sediments are found in front of the northern overthrusts of the Alps from Austria, through Bavaria and Switzerland, to France. In Bavaria these sediments are bounded on the north and north-west by the Bohemian massif, whilst in the south they are overridden by the Flysch (Cretaceous) overthrust sheets.

The Tegensee occurrence is in the overthrust zone and the structure is very complicated. The Flysch is overturned and overthrust over itself, and in addition is very much faulted. A number of wells have been drilled but only very small quantities of oil have been obtained. It is a light, paraffin base oil and it is produced from the Flysch and also from the underlying Helvetian. There is little evidence concerning the origin of the oil; it may be a Flysch oil or it may have migrated up from the Molasse (Upper Oligocene) over which the Flysch has been thrust.

In the Tertiary basin to the north of this overthrust zone the structures are more simple (Barton [1, 1934]). Wells are now being drilled near Augsburg to test the possibilities of that area.

ITALY[1]

By STANISLAV ZUBER

University of Cracow

NEARLY all the oil occurrences of Italy belong to the Apennines or to their foreland. Their distribution is quite irregular and no continuous oil-bearing formations can be discerned. Notwithstanding, certain deductions can be made. The main feature of the Peninsula is formed by the Apenninic system, which forms the borders of the Tyrrhenian Sea from the Maritime Alps down to Sicily. At present the opinion prevails that the range owes its structure to great thrusting movements (de Wijkersloth [10, 1934]). The overthrusting, except in the central sector, March–Abruzzo, results in a peculiar character, in which the so-called 'argille scagliose', a kind of 'wildflysch' of the Alpine geologists, is of great importance. The lack of clearly expressed tectonic features and a predominance of small, fractured rather than folded blocks chaotically mixed in a breccia of the 'argille scagliose' also gives an idea of the character of the tectonic movements. Consequently they would not be the common Alpine or Carpathian overthrusts, but earth movements of several phases, one over another, ranging in age from the Cretaceous to the Pliocene.

The oil occurrences directly connected with the 'argille scagliose' Apennines exactly reflect these conditions and certainly are the remnants of greater impregnated units which have been destroyed. In the case of the Apennine sector near Parma and Piacenza a probability exists of the presence of tectonic 'windows' partially visible through the upper tectonic 'slumps'. Notwithstanding the efforts of many geologists, no satisfactory sections across the whole range exist. Some attempts have been made by Anelli, Sacco, Fossa Mancini [5, 1933; 6, 1926; 7, 1923], and lastly by Wijkersloth [10, 1934].

The Central Apennine with its Miocene molasse without the 'scagliose' flysch (Bonarelli [2, 1930]) shows more regular conditions in so far as its structures have a rather autochthonic character. The **Apennine Foreland** consists of block-faulted undulations with a limestone basement which have been partly explored by geophysical means (Belluigi [1, 1932]) and by recent deep tests in the depressions.

The main oil-shows and the oil-pools of Italy so far recognized can be subdivided into several groups. Such subdivisions are territorial, but they coincide with the main types of oil and its occurrences (Fig. 1).

I. The Emilian Belt

The majority of shows follow the disturbed zones, being connected with impregnated rocks of Upper Eocene, Oligocene, and Lower Miocene age. They extend from Pavia and Voghera up to the surroundings of Bologna.

Velleia and Montechino. A faulted and folded block of hard marls and marly sandstones (Eocene and Oligocene) is surrounded by intrusive belts of 'scagliose' breccia. No distinct oil sands have been observed, but productive shows have been obtained with initial productions of some hectolitres daily up to a flow of 40 tons in one of the wells of Montechino. The average depths of wells are 500–800 metres. The oils are highly aromatic (55%) without asphaltic residues (sp. gr. 0·775–0·797) (Salomon-Calvi [8, 1930]). The rapid decrease of production is connected with the abundant edge-water (bromo-iodic brines).

Vallezza. A folded block of hard marls and marly sandstones (Oligocene–Eocene) surrounded by 'scagliose'. The average specific gravity of the oil is 0·810. Production and edge-water conditions are somewhat similar to those in the Montechino pool.

Salsomaggiore. A highly fractured block of sandy marls (Lower Miocene–Oligocene) situated on the edge of the hills with productive oil-shows near the top of the Oligocene (sp. gr. of this oil is 0·801–0·833). The abundant bromo-iodic brines of high salinity are utilized for medicinal purposes.

The Sub-Apennine Emilian Plain.

Podenzano. The oil-shows contain a high percentage of gas. The top of the Upper Miocene is folded and is covered by an unconformable Pliocene overlap (sp. gr. of the oil is 0·869–0·897).

Carpaneto. A small oil-show within the Pliocene beds and near to their base, which is quite an isolated occurrence.

Fontevivo. Oil is found on the top of the Upper Miocene covered by the Pliocene overlap. Gas-shows are found near the base of the Pliocene. Production is several tons daily (sp. gr. 0·847). Bromo-iodic brines of high salinity are very abundant.

The oils and brines so far discovered in the plain are very similar to those of the Emilian Apennine. Stratigraphically they seem connected only with the base of the folded Upper Miocene. Nevertheless, their position still remains somewhat enigmatic. Abundant gas-shows accompanied by strong blows have been noticed in several deep tests drilled in the Emilian Plain.

II. The Central and Southern Apennine

Oil- and Asphalt-shows in the Pescara Basin. Asphaltic oil impregnations occur in a Neogene embayment (Upper and Middle Miocene) along the promontories of the Maiella Massif. Molasse-gypsum sediments are associated with the organic deposits (Lithothamnium and Bryozoic Limestones). Near the asphaltic impregnations in the Middle Miocene fluid oil is found in small quantities (sp. gr. 0·920 and more) (Fig. 2).

Valle Latina. This is a graben-like, folded and faulted depression between calcareous massifs (Cretaceous) filled with Miocene deposits, with molasse on the top (Upper and Middle Miocene) and flysch-like sediments at the base (Lower Miocene). Viscous asphaltic oils (sp. gr. 0·95 and more) are found in the Lower Miocene and insignificant shows of lighter qualities in the Middle Miocene. A pay has been exploited at S. Giovanni Incarico (Fig. 3) yielding several tons daily from average depths of 300–450 metres.

Asphalt-shows. In the whole area of the Abruzzo Highlands large and frequent asphaltic impregnations exist, connected with the breccia limestones of the Lower Cretaceous. They can be considered as weathered oil deposits.

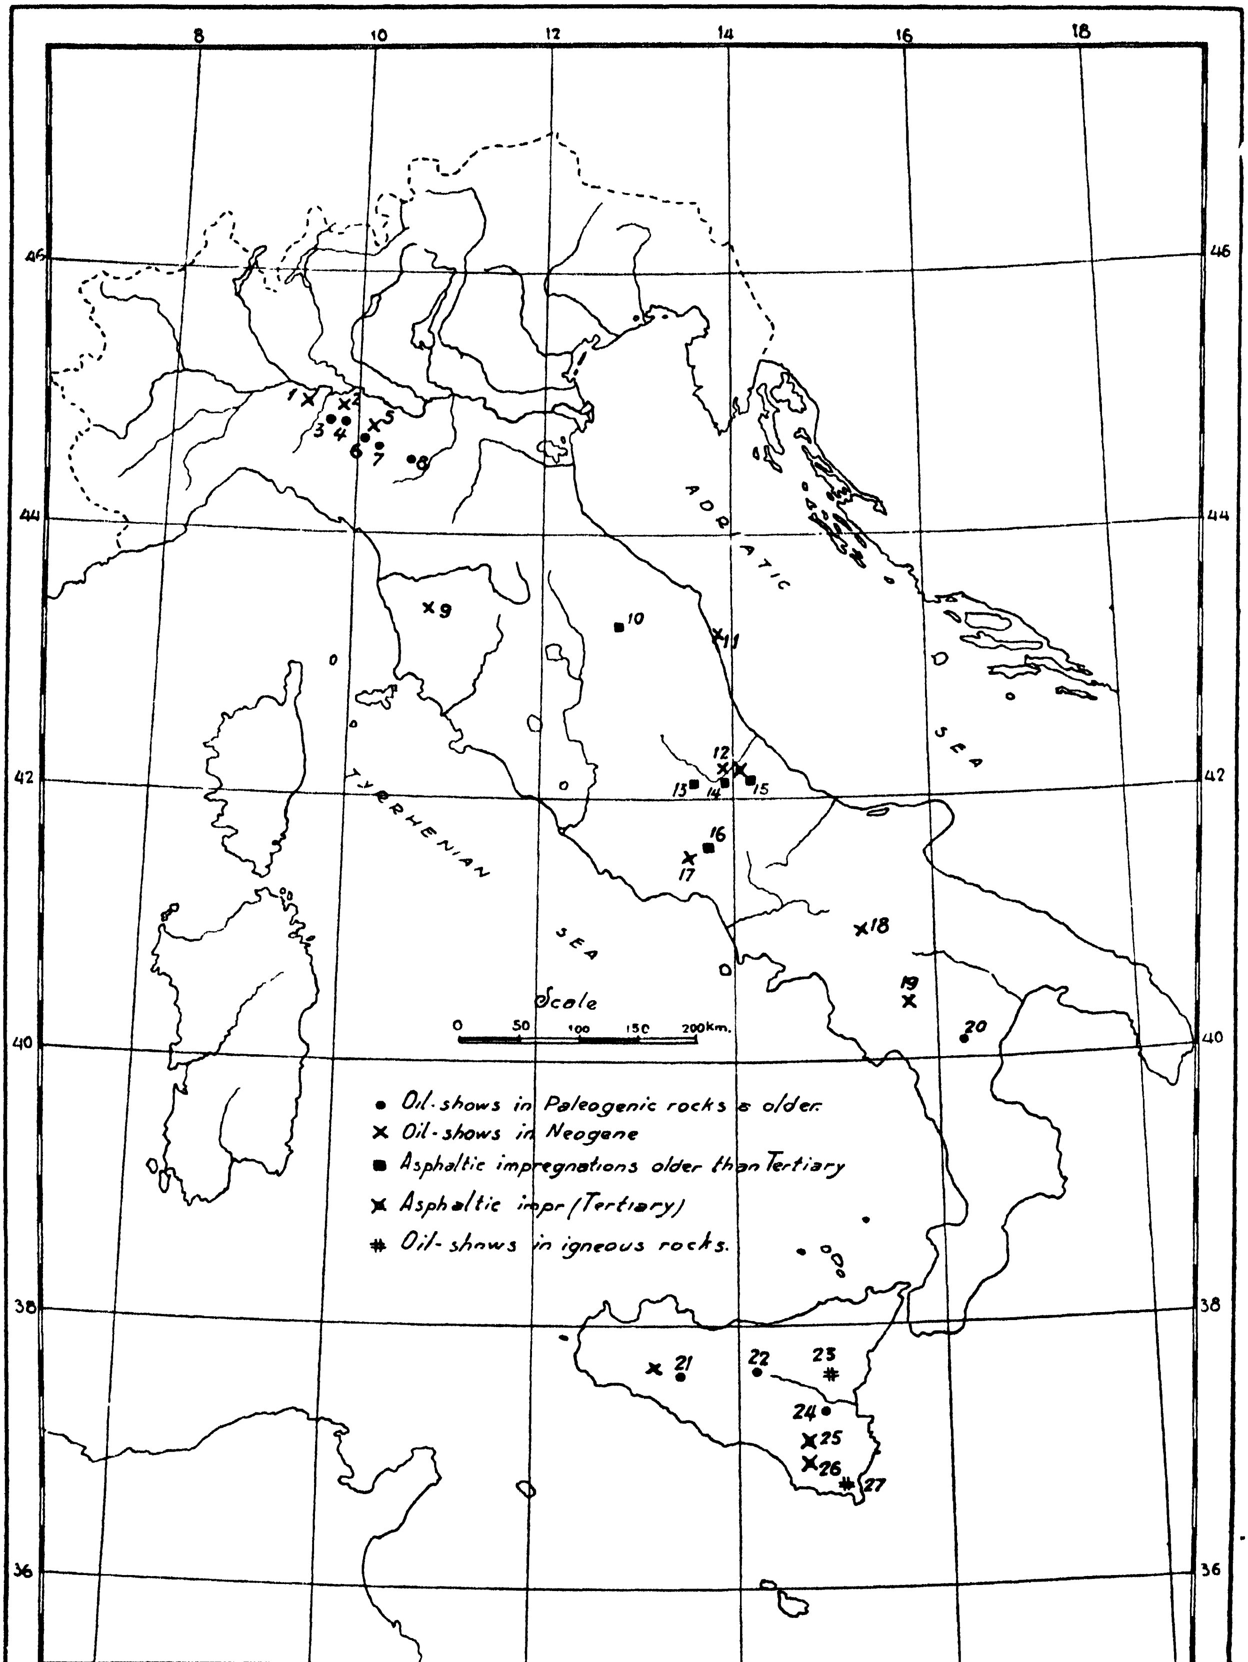

FIG. 1. Sketch-map of the main oil-shows of Italy. 1, Podenzano; 2, Carpaneto; 3, 4, Velleia a. Montechino; 5, Fontevivo; 6, Salsomaggiore; 7, Vallezza; 8, Montegibbio; 9, Volterra; 10, Gubbio (oil shales of the Lower Cretaceous); 11, Fontespina (submarine littoral oil-show); 12, Pescara Basin (oil and asphaltic impregnations); 13, 14, 15, Abruzzo Highlands; 16, Roccasecca; 17, Valle Latina S. Giovanni Incarico a. Ripi; 18, Benevento Apennine (S. Angelo dei Lombardi, Lioni, Montemarano, Casalbore, Laviano Caposele); 19, Tramutola (surroundings of Potenza); 20, Cersosimo; 21, Bivona a. Lercara; 22, Petralia; 23, Paternò; 24, Palagonia (Naftia Lake); 25, 26, Ragusa oil marls (Scicli, Ragusa, Vizzini); 27, Pachino.

of the calcareous type, eroded through the tectonic movements.

The Central and Southern Apennine oil-shows are connected with the Miocene and belong to the Mediterranean type of oil deposits. In some cases the oil-shows appear, as in the Emilian Apennine, in the tectonic 'windows' emerging from below the thrusted Mesozoic limestones. With the exception of very slight traces of oil in the Palaeogene, the structures of which are similar to the Emilian Apennine (beginning from the southern slopes of Abruzzo), the oil-shows follow the small fractured Neogene basins and depressed blocks of the area. Frequent and diffused shows of asphaltic oil are known in the **Benevento Apennine** (Upper and Lower Miocene). In this area occasional asphaltic impregnations of the Lower Eocene and Lower Cretaceous limestones reappear, and these can be considered as a continuation of the Abruzzo asphalt-bearing facies.

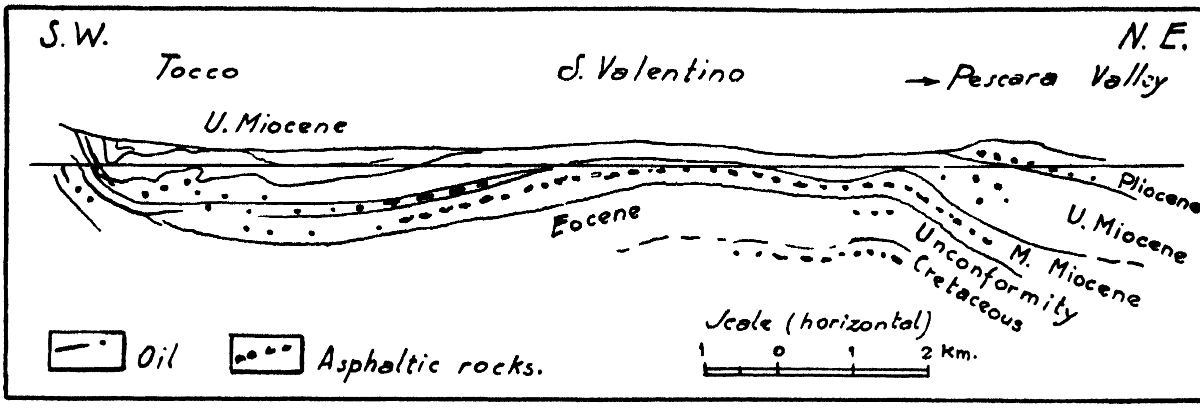

FIG. 2. Schematic section across the oil and asphalt occurrences of the Pescara Valley.

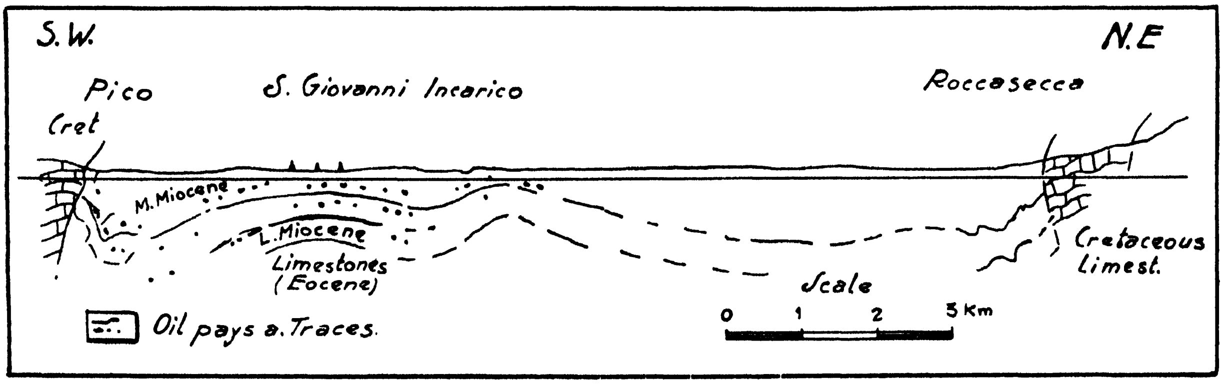

FIG. 3. Schematic section across the Valle Latina.

III. Sicily

(*a*) These comprise several small oil-shows having a certain similarity to the Emilian oil occurrences and are of a residual character in the central part of the island. Slight traces are found in the Upper Miocene (sulphur-bearing series).

(*b*) The following appearances are connected with igneous rocks.

Paternò. Very light kerosine-like oil within the cavities of a basaltic massif of the Etna system (Quaternary or recent). Its origin is probably connected with distillation from the underlying rocks (Neogene?). **Palagonia.** Mud volcano lakes with some oil on the surface and carbonic acid exhalations. Oil traces are found in the basaltic (Pliocene) rocks. **Pachino.** Cretaceous dolerites with cavities filled with asphaltic oil.

(*c*) **Asphaltic Oil-marls: Ragusa.** Large isolated impregnations occur in a Lower Miocene series covering a huge and very flat block anticline in the Sicilian Apennine foreland.

IV. Bituminous Shales

In southern Italy, as far as Sicily, bituminous shows, of Palaeogene or even Upper Miocene (Sicily) age, exist: these shows are rather isolated.

The total yearly production for Italy for the period 1932–3 was about 25,000 tons, obtained mainly from the Emilian pools.

The following scheme represents the stratigraphic subdivision of the oil-shows in Italy.

Pliocene. Slight oil-shows in the Emilian Plain.

Upper Miocene. Emilian Plain, Tuscany (traces), Pescara Basin, Benevento Apennine, Sicily (bituminous shales).

Middle Miocene. Central Italy (Pescara Valley, Valle Latina).

Lower Miocene and Upper Oligocene. Emilian Apennine, Valle Latina, Benevento Apennine, Basilicata, Ragusa (Sicily).

Palaeogene (in general). Oligocene and Upper Eocene flysch oil-shows in the Emilian Apennine, as far as Scilly. Occasional shows: Pescara Valley and Benevento Apennine; asphaltic impregnations in the limestones.

Lower Cretaceous. Extensive asphaltic impregnations in the Abruzzo-Apennine, oil shales near Gubbio, occasional shows in the Benevento-Apennine; oil-shows in igneous rocks in Sicily.

Triassic. Slight asphaltic traces in the limestones of the Alpine Range.

FRANCE

By STANISLAV ZUBER

University of Cracow

THE four main types of oil occurrences are distributed (Fig. 1) as follows: (1) The most recent, Palaeogene, belongs to the narrow pre-Palaeogene depressions, very flat, filled with Palaeogene oil- and asphalt-bearing deposits, and laid down on Mesozoic or even older, previously eroded basement formations. (2) Narrow folds of Mesozoic rocks, which are frequently thrusted, and local oil-bearing Triassic strata. (3) Asphaltic impregnations of Palaeogene and Mesozoic limestones, near the Western Alpine ranges. (4) Bituminous shales.

The majority of the more important shows, known up to the present time, are located between the main Variscan uplifts and the Alpine and Pyrenean ranges, i.e. in the eastern and southern provinces of France. Apart from these, the predominance of old crystalline and Palaeozoic Variscan masses deprives the country of oil. Deep prospecting to test the Palaeozoic has been discussed recently. The search for oil has already been begun in western Germany (Waterschoot v. der Gracht [5, 1935]) in order to test favourable structures in the Carboniferous or lower formations, beyond the thrusted belts and under conditions which could also be expected on the French boundaries.

1 (*a*) **Pechelbronn.** The Pechelbronn Basin represents a sector of an elongated belt known as the Rhine Valley depression (Rhine-Graben). The oil conditions of the pool, well known from the studies of de Chambrier, Gignoux, Hoffmann Haas, Kraiss, Jung, van Werveke, Wagner [7, 1930], &c., correspond exactly to those which the writer has defined as Mediterranean types. The basin forms a faulted flat depression between two Palaeozoic uplifts. The blocks, isolated by a network of oblique fractures (Fig. 2), dip towards the centre of the depression and increase in thickness in this direction. Frequent and gradual changes in the facies of single horizons from marine to brackish and fresh water are also noticed.

The Pechelbronn oil-bearing beds belong to the Oligocene and are composed of marls and shales with sand lenses. Their top is formed by dominantly marine sediments with local edge development of fresh-water limestones. The average thickness of the whole series is about 1,200 metres. Their subdivision gives three groups which, in succession, are: (1) Meletta clays, 400 metres; (2) Pechelbronn series, 400 metres; (3) Dolomitic beds. These main groups are separated from each other by clearly defined key horizons (1 : 2 foraminiferal marls, 2 : 3 red clays with gypsum). The Pechelbronn series is also subdivided into two groups, upper and lower, by the Hydrobia zone. The main sands belong to the Pechelbronn series, although local production has been obtained from the Meletta as well as from the dolomites.

The basement rocks are Jurassic and Triassic and a great unconformity exists at the base of the Rhine Oligocene. Association of saline and gypsiferous strata with the Pechelbronn oil is observed as far as the Mulhouse saline sector which has a similar sequence, and belongs to the same Graben.

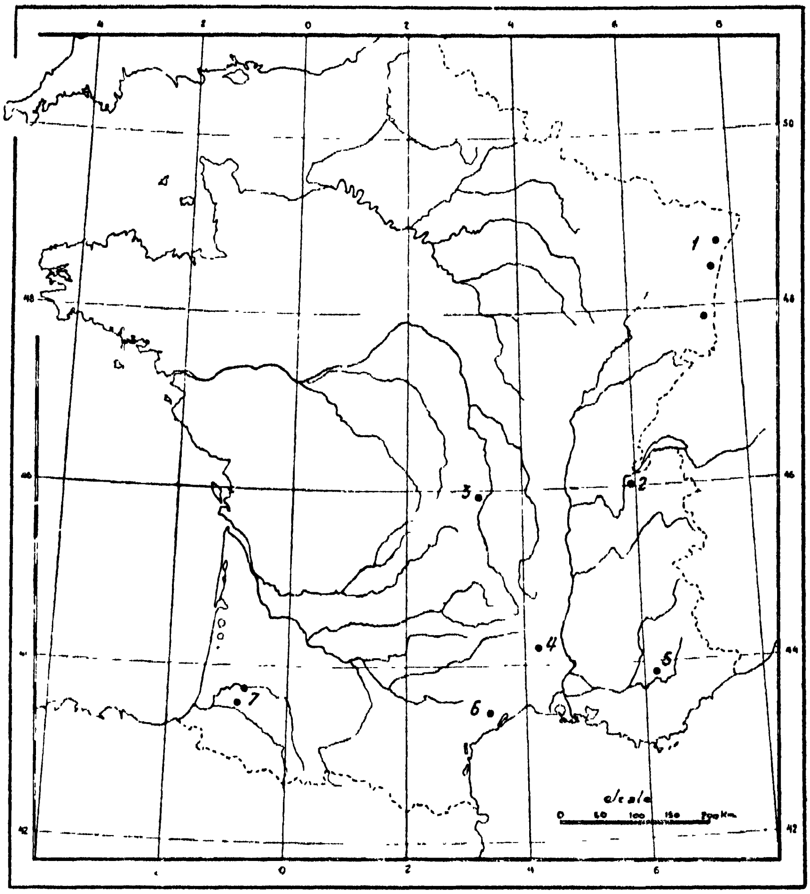

FIG. 1. Sketch-map of the main oil and asphalt occurrences of France. (Redrawn after Gignoux (simplified).) 1, Rhine Basin (Pechelbronn); 2, Savoy Basin; 3, Limagne Basin; 4, Alès Basin (Gard); 5, Manosque; 6, Gabian Pool; 7, Sub-Pyrenean belt.

Occasional oil occurrences, sometimes productive, have been found in the Dogger limestones at the base of the Graben. The oil-bearing Oligocene is considered to be associated with these.

As a consequence of the lack of favourable structures in the block faulted, estuarine strata, the oil distribution is lenticular with complete isolation of individual lenses. Light paraffinic oils predominate (sp. gr. 0·860 and more), although the heavy types are also frequent (up to 0·975). The asphaltic impregnations at Lobsann are considered by Haas and Hoffmann as secondary and due to seepages during the Upper Oligocene period.

The oil production is obtained from wells and galleries (60,000 tons and more per year).

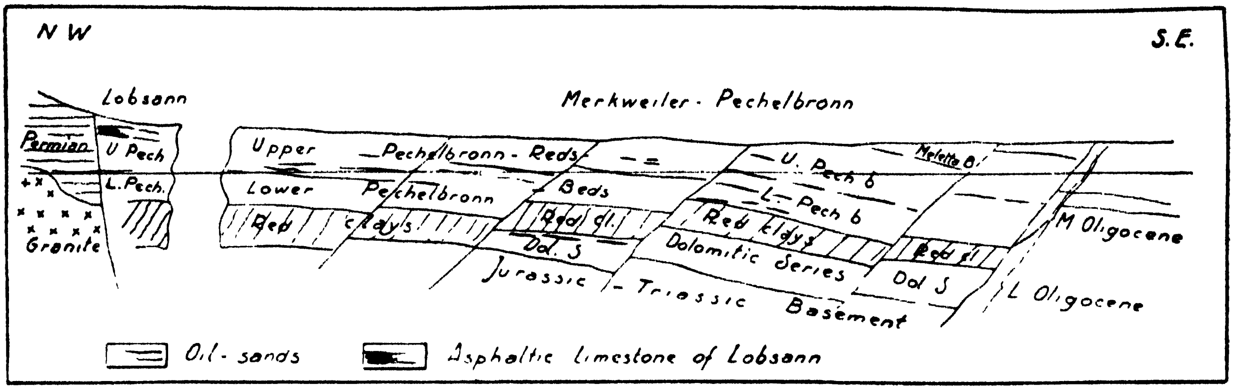

FIG. 2. Section across the Pechelbronn Pool. (Redrawn after Haas and Gignoux (simplified).)

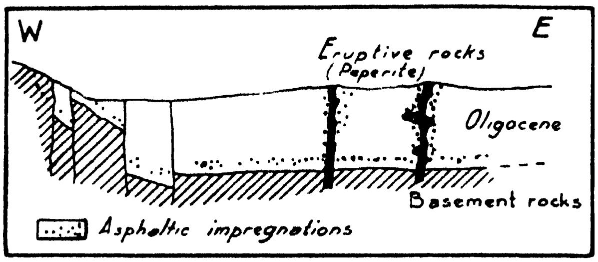

FIG. 3. Ideal section explaining conditions of asphalt deposits of the Limagne Basin. (*After Gignoux.*)

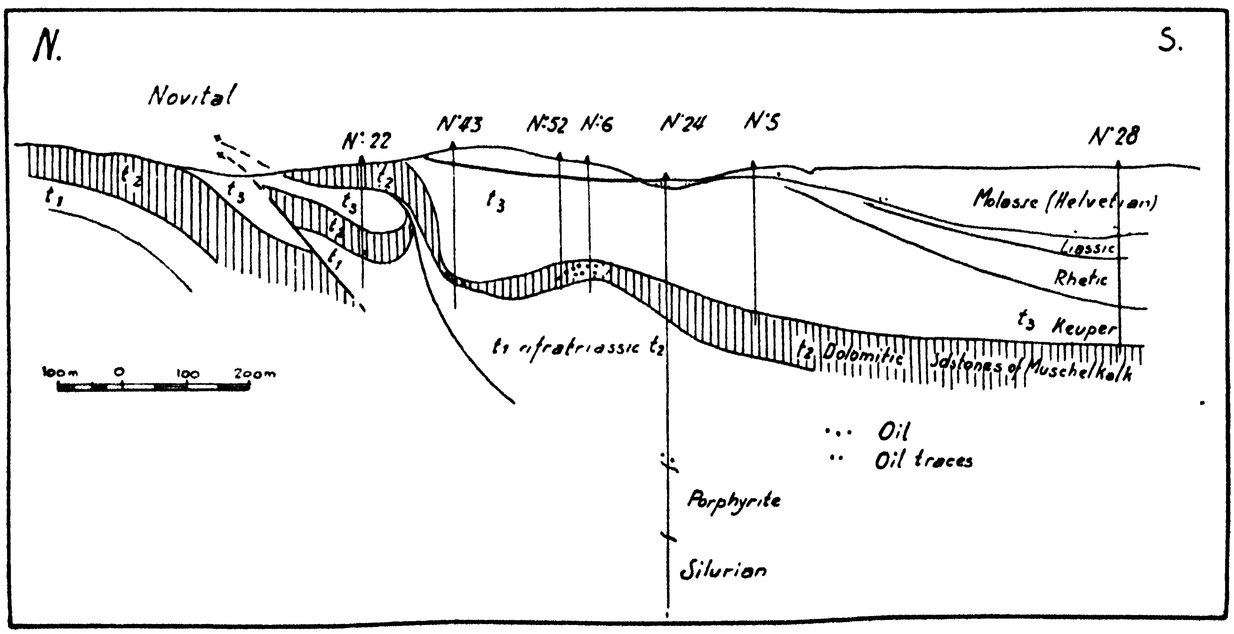

FIG 4. Section across the Gabian Pool. (Redrawn and completed after Barrabé and Schneegans.)

1 (*b*) **The Asphalt-bearing Molasse Basin of Savoy** has impregnations in the Oligocene beds and adjacent unconformably covered Urgonian limestones.

1 (*c*) **The Limagne-Graben Depression** (Fig. 3) is a depression of Mediterranean type filled with Oligocene sediments and frequently pierced by perperite dykes. Asphaltic impregnations are distributed near the basal unconformity and rise vertically near the eruptive dykes.

2. **Triassic Occurrences in the Sub-Pyrenean Zone** are connected with highly disturbed beds of Upper Triassic (Keuper) age, referred to by Viennot [6, 1930]. The well-known **Gabian Pool** is located in a system of narrow, thrusted overfolds in the centre of which an oil sand occurs on the top of an anticlinal fold in the Muschelkalk (Middle Triassic) breccia (Fig. 4). Conditions in the oil-bearing formation, described by Barrabé and Schneegans [1, 1935], prove that there is a residual accumulation of oil localized on the top of the fold with the edge-waters closely occupying its slopes.

Although limited in extent, the Gabian oil-pool has given a good production of light paraffinous oil, 0·846 sp. gr. (up to 1934, 24,000 tons). Notwithstanding the somewhat erratic and highly disturbed character of the Triassic oil-shows of southern France they permit the supposition of a much larger extension of the whole belt from the Atlantic coast up to the Rhone Valley.

3–4. Bituminous and asphalt-bearing limestones and shales are known in several localities in France associated with formations from the Palaeogene down to the Carboniferous. They frequently show association with bituminous coals. From the oil-prospecting point of view and in view of the palaeogeographical conditions they are phenomena of primary importance.

The stratigraphic conditions of the oil occurrences in France are as follows:

Oligocene. Main oil- and asphalt-bearing formations Alsace (Eocene) Limagne Savoy.

Cretaceous–Jurassic. Occasionally asphalt bearing.

Triassic. Sub-Pyrenean oil shows.

Upper Palaeozoic. Occasional development of bituminous shales.

SECTION 5

MIGRATION OF PETROLEUM

THE MEASUREMENT OF THE PERMEABILITY OF RESERVOIR ROCKS AND ITS APPLICATION

By Dr. GERALD L. HASSLER

Assistant Professor of Petroleum and Natural Gas Engineering, School of Mineral Industries and Experiment Station, The Pennsylvania State College, State College, Pennsylvania

The Concept of Permeability

PERMEABILITY is a term which refers to the relationship between the pressure gradient and the resulting rate of flow of fluid through porous materials. As experimental knowledge has increased this concept has undergone subdivision and refinement, so that at present the term permeability will often need a qualifying adjective, such as 'viscous', 'turbulent', 'relative', 'dynamic', or 'stable mixture' permeability. These makeshifts may eventually give way to special terms, but while current experiments are bringing new facts within the range of use it will be important to define permeability carefully.

At present the most common technical meaning of permeability is the constant K which occurs in Darcy's equation [3, 1856] for the viscous flow of a single, homogeneous fluid.

$$\frac{dQ}{dt} = \frac{K}{Z}\frac{dP}{dx}. \tag{1}$$

If in this equation dQ/dt is the rate of passage of fluid per square centimetre of equal pressure surface, Z is the viscosity in centipoises, and dP/dx is the gradient of pressure in atmospheres per centimetre, then K will be expressed in terms of the Darcy unit of permeability as adopted in 1935 by the American Petroleum Institute [1, 1935]. The permeability is thus defined *only for viscous flow and for a single fluid*, on which basis the experimental background is quite adequate [17, 1899; 39, 1934]. However, such a permeability as this ordinarily is not satisfactory for precise calculation in an oilfield. With few exceptions, producing fields contain mixtures of oil and gas, and sometimes salt water as well. In discussing the flow problems of oil production it is important to bear in mind that permeabilities as measured in the laboratory apply only to slow or viscous flow of single fluids, while in practically every field case either immiscible fluids are present or the flow is sufficiently rapid to result in turbulence. Although the flow in the greater part of the *area* of an oilfield is certainly non-turbulent, a considerable part of the pressure drop takes place near the well at such velocities that flow of the gas, at least, is definitely turbulent.

These facts demand that new experiments be made and new concepts be carved out to deal with mixtures and with turbulent flow.

Definitions of symbols used appear at the end of this article.

The Darcy Coefficient of Permeability

Laboratory Procedures.

Recent progress in laboratory technique for measuring the Darcy coefficient has been in the nature of refinement of apparatus rather than fundamental change. The work of Fancher, Lewis, and Barnes [6, 1933] at the Pennsylvania State College, and of Wyckoff, Botset, Muskat, and Reed [39, 1934] at the Gulf Research Laboratory laid down a foundation of good practice which has been improved only in the direction of minor details which speed up the work rather than improve accuracy. Faster procedure has come to be important in secondary recovery work because the charge of explosive which is used in producing wells should be proportioned in accordance with the laboratory measurements of permeability. Since the hole must be shot before the well is finished, the drilling crew is often idle until the measurements made on the core are returned from the laboratory.

It has been found in the laboratory that most of the time is consumed in drilling out from the core the small test specimens and in calculating the results. Certain improvements in procedure may be worth recording here.

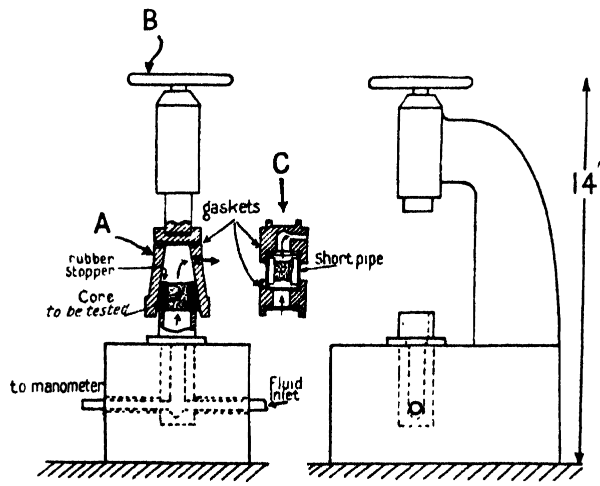

FIG. 1. Quick-change core holder for permeameter.

In mounting the core in the drill press the rock is best embedded in low-melting alloy such as 'woods metal' or other alloy melting below the boiling-point of water. Higher temperatures are undesirable because of possible effects on permeability [14, 1930]. A long double-jacketed vessel which can quickly be heated and cooled with steam or cold water and which can be handled easily on the drill press will speed up the job of obtaining test specimens by drilling with abrasives. For close work with small fragments, as of the 'biscuit' core material, diamond-set tubes of diameter as small as $\frac{1}{8}$ in. are sometimes used. The drill press should be substantial and should permit a wide choice of speeds.

In mounting these specimens for the flow test (generally with air) the method developed by Fancher is now universally used, the sample being placed in a rubber stopper suitably cut out to receive it and then compressed in the rubber by forcing the stopper into a brass cone. The latest type of permeameter holder as built in the shops of the Pennsylvania State College is illustrated in Fig. 1. The design, which is principally due to the shop foreman Mr. E. F. Sheeder, permits rapid insertion and

withdrawal of the conical core holder *A* by spinning the screw handle *B*. The auxiliary holder *C* is used in those rare cases where an irregularly shaped specimen must be set in wax or Wood's metal.

The work of reducing the data for each individual sample (generally obtained in centimetres of mercury pressure, length and diameter, centipoises of viscosity, millilitres of gas received, and seconds of time of test) may be shortened by the use of a nomographic chart [18, 1936].

The fluid used in these measurements is almost invariably dry air, and the pressures should be the lowest for which a measurable rate of flow is obtained. Special permeability studies are occasionally made with the flooding water which is used on the lease concerned; these are sometimes described as 'water permeabilities' and are generally lower than the 'dry permeabilities' because of the swelling of cementing material.

The specimen is prepared for test by extracting the oil with benzol or a low-boiling naphtha in preference to carbon tetrachloride. It has been found (unpublished work by E. S. Hill at the Pennsylvania State College—petroleum production laboratory) that during carbon tetrachloride extractions a definitely acid condition develops which is dangerous to the cementing material of a permeability sample.

Information obtained from Microscopic Examination or Mechanical Analysis of Sandstones.

The only dependable way of determining the permeability of a rock is to measure it directly by comparing the rate of flow of a fluid with the corresponding pressure gradient. This method will also take considerably less time than carefully performed mechanical analyses. However, there are certain cases where the taking of suitable cores is not practicable, where material suitable for grain-size analysis is available without cost, and in which previous direct measurements on diamond cores in the same property provide a primary standard which can be compared with the results of grain-size analysis. In such cases it may be feasible to measure the shot and set the packers for flooding or gas drive in accordance with grain-size measurements. A recent paper by Ryder [30, 1936] gives a suitable procedure and formula for Bradford sands which has had practical application.

It appears that the examination of the rock with a view to locating the direction of alinement of elongated grains may give valuable information about the directional asymmetry of permeability in any given field. It is known that in some fields the flow takes place more easily in one direction than in another [13, 1935] and that greater production can be obtained from secondary recovery operations in which the well spacings are made greater in the direction in which the permeability is greatest [13, 1935; 37, 1936]. This sorting as to shape may be a geological factor of considerable importance in properties whose reservoir contains pebbles in quantity.

When grains are packed against an unyielding wall, as of lead shot against the wall of a beaker, or silica grains against a larger smooth pebble, the porosity of the layer will be increased and the permeability along the boundary will be greatly increased [8, 1935]. It follows, therefore, that in those cases in which the larger asymmetrical grains are oriented by stream or wave action, these boundaries will cause an asymmetrical permeability condition in which the greatest permeability is in a direction at right angles to the direction of the old currents. In a similar way the occurrence of plates of mica, which generally lie parallel with the bedding plane, will mean that abnormally low flow-resistance will be found in the bedding plane. These can be seen readily by causing a fractured surface to bubble air under water. The larger plate of mica, as in Bradford sandstone, will be marked by profuse bubbling along each side of the plate. There is evidence that where this condition is prominent, a microscopic by-passing of oil by the flooding water will take place which may be serious [31].

It is believed that in such accessory items of geological knowledge as this the microscopic analysis of sand grain-size and shape will be important. It should be emphasized, however, that the best way to determine permeability for control of field operations is to core the wells and make direct measurements as described by the A.P.I. tentative standard [1, 1935]. Many excellent papers have been published which attempt to relate porosity and grain-size studies to permeability by elaborate empirical study and theoretical deduction [32, 1932; 7, 1934; 4, 1933], but their importance is in their value as research studies; their value lies largely in their indirect bearing upon wider problems than the determination of the Darcy coefficient of permeability.

The Uses to which a Knowledge of Permeability can be put in Secondary Recovery.

In water flooding or air-gas drive recovery properties the principal purpose of engineering control is so to adjust the spacing of the wells and the position of packers that the driving fluid will be distributed in equal proportion to all parts of the oilfield. A knowledge of permeability conditions is indispensable in deciding these questions. In most cases a failure to learn and understand the permeability distribution will result in a serious loss.

Correct practice in spacing water flood-wells is not yet clearly defined because of our lack of knowledge of the effective fluid resistance and efficiency of the main body of the reservoir. There seems to be no recognized difference in the efficiencies of wide spacings and short spacings of the wells; it is said that a water flood will recover from 35 to 45% of the oil in the sands [5, 1936] without bias as to spacing. Where beds are lenticular it is felt that the spacing should be close enough to avoid the possibility of driving the oil into pockets where the sand is pinched out between shale, but in general, the limiting factor is the length of time involved before a return is gained on the investment [2, 1936]. If the spacing is too wide, the flood may take as long as ten years to reach completion.

The first intensive floods in the Bradford field used close well-spacings—from 200 to 250 ft. between water-wells—but this spacing has been gradually increased [33, 1930] until spacings of from 300 to 450 ft. between water-wells are not uncommon for sands averaging 10 millidarcies. When permeabilities reach 3 or 4 millidarcies it is well to reduce spacings [2, 1936]. The present practice in the Mid-Continent field may be typified by the Alluwe field, Rogers County, Oklahoma, where permeabilities range around 20 millidarcies and the kinematic viscosity of the oil is about 10 centistokes. The spacing chosen is 440 ft. from water-well to water-well [5, 1936] in a five-spot development. An average of from 40 to 50 bbl. of water per day at a pressure of 400 lb. per sq. in. is allowed each input well.

The application of permeability profiles (curves of permeability against depth) to the setting of packers may be

illustrated best by an example. In Allegany County, New York, is a property where two sands are encountered, the upper sand having a permeability averaging 4 millidarcies and an oil content of 3,900 bbl. per acre, while the lower sand has permeability averaging 65 millidarcies and oil content of 8,000 bbl. per acre. When both sands are flooded together at a pressure of 900 lb. per sq. in. the recovery is about 2,900 bbl. per acre. By using two strings of tubing to apply a pressure of 1,500 lb. on the upper sand and 600 lb. on the lower sand, the recovery is raised to 4,500 bbl. per acre [2, 1936].

Such qualitative applications of the permeability as these examples illustrate do not require elaborate calculation since the use of the information is quite obvious. The importance of these applications of permeability measurement will increase as better techniques for acid treatment and chemical plugging of reservoir [16, 1936] rock make it possible to alter the effective permeability in such a way as to produce the desired permeability profile in the well.

The More Recent Experimental Developments of the Concept of Permeability

The above-mentioned control of well spacing and of the setting of packers is only very rough at present because the resistance to flow in an oilfield is not of the single fluid, viscous type. The assumption has been made that the resistance which a sand offers to the flow of mixtures will be about proportional to the Darcy coefficient of permeability. Some companies have developed empirical formulas for the specific intake of new water-wells, probably based on the unit conductivity formulas given by Muskat and Wyckoff [25, 1933] which sum up the results of field experience with permeabilities, pressures, and spacings, and these formulas use that assumption successfully.

Recently research workers have become interested in the effect of turbulent flow and of the presence of mixtures. The following paragraphs attempt to co-ordinate the available results of this work.

Turbulent Flow in Porous Rock.

It is known from studies of the flow of liquids in cylindrical tubes that turbulent motion occurs when the 'Reynolds number' (or ratio of inertia factors to viscosity) exceeds a critical value. One could predict from this experience that the flow of gases in a sandstone whose grains are large and angular would become turbulent more readily than in sandstone whose grains are rounded and well cemented. This is indeed the case. However, the phenomenon of 'critical velocity', at which the flow character changes sharply from streamline to turbulent, does not occur in permeable media. Instead, the transition is so smooth that it is hard to decide where the element of turbulence first enters.

If in equation (1) above Q is replaced by V, a volume of gas measured at an arbitrary pressure P, the resulting equation is

$$\frac{dV}{dt} = \frac{K}{Z}\frac{dP}{dx}. \tag{2}$$

Upon substituting Boyle's law, writing P_2, V_2 for the outlet pressure and volume,

$$\frac{dV}{dt} = \frac{P_2}{P}\frac{dV_2}{dt}. \tag{3}$$

We thus obtain

$$P_2\frac{dV_2}{dt} = \frac{K}{Z}\left(P\frac{dP}{dx}\right) = \frac{K}{2Z}\frac{d}{dx}(P^2). \tag{4}$$

In any actual measurement the inlet pressure P_1 and the outlet pressure P_2 (generally atmospheric) will be held constant so that dV_2/dt, the rate of flow of outlet gas at the measuring pressure P_2 will be constant.

Under these conditions it is clear from equation (4) that $d(P^2)/dx$ must be constant.

Thus the Darcy law of viscous flow for gases should take the integrated form

$$\frac{V_2}{t} = \frac{K}{2ZxP_2}(P_1^2-P_2^2), \tag{5}$$

where V_2 is the outlet volume of gas collected in time t, x is the length of the cylindrical flow specimen, and P_1 is the inlet pressure.

Equation (5) is commonly handled by reducing V_2 to the mean volume V_m. Thus, upon writing $P_1^2-P_2^2 = (P_1-P_2)(P_1+P_2)$ (5) becomes

$$\frac{V_m}{t} = \left(\frac{2P_2}{P_1+P_2}\right)\frac{V_2}{t} = \frac{K}{Zx}(P_1-P_2). \tag{5a}$$

It is found by experiment [9, 1929; 24, 1931; 27, 1935] with the flow of gases in sandstone, and in tubes packed with sand, beads, &c., that,

$$\left(\frac{V_2}{t}\right)^n = \frac{C}{X}\ (P_1^2-P_2^2), \tag{6}$$

where the exponent n may have any value from unity for viscous flow conditions to two for the completely turbulent condition. The constant C involves the viscosity, but not the viscous permeability. It will be found that the exponent n is independent of the external dimensions of the flowing medium [27, 1935] but depends rather on the porosity, angularity, and size of the grains which form the medium. Anything which restricts turbulence reduces n [24, 1931]. Smooth surfaces of the grains or of the cementing material and restricted size of capillary spaces tend to limit the formation of those microscopic eddies which presumably are associated with turbulent flow.

It may be assumed that the smooth change in the value of n from one towards two as the velocity of flow is increased is the composite effect of a great many sharp, critical changes from lamellar to turbulent flow in separate channels of the sand. If the rates of flow and pressure gradients of any chosen microscopic capillary could be plotted there must be a reasonably sharp transition, for this is a general characteristic of fluid flow.

It is because the factors which determine the value of n are not only *microscopic* but also involve a very complicated relationship with the flow properties that one cannot readily correlate n with measurable properties of the sandstone. The flow which is measured in the laboratory is the sum of the contributions of a great many sizes and, perhaps, types of holes, which are connected in series as well as in parallel. The proportion of larger channels in the sandstone would seem to be a very important item in determining the type of flow, for if the larger holes carry the greater part of the gas turbulence in them will control the value of n for the specimen as a whole.

Consider, for example, two specimens of consolidated sandstone having the same porosity, the same viscous flow permeability (by viscous flow permeability is meant the constant K of equation (1), measured at very low-

pressure gradients so as to avoid turbulence) and the same chemical character. Of these two specimens one may have a frequency distribution of capillary sizes such that there are a few abnormally large holes—say a hundred per square centimetre—which the accidental cementation has left open. These will carry practically all of the gas. The other core may have an abnormal number of open middle-sized pores, without any large ones at all. It is obvious that the first core will have a very high velocity of flow in the few large holes, while the second core will have a relatively low velocity in a great many small holes. The first core will therefore give a very turbulent flow with high values of the exponent n at low-pressure gradients, while the second core will persist in its viscous-flow condition up to extremely high values of the pressure gradient.

If it can be shown to be generally true that for a given permeability a high value of n at low-pressure gradients means a heterogeneous or skewed distribution of capillary sizes, then the measurement of n may be important not only from the standpoint of calculations of gas flow but also from the point of view of oil recovery. At present it seems probable that if the gas escapes through a few large holes it will not be as effective in transporting oil as it would be if the energy were distributed more uniformly among the oil-bearing holes of the rock. A sand which is good from the standpoint of secondary recovery is of uniform texture [7, 1934], i.e. it has oil-bearing pores which are also fluid conducting channels. If our analysis is correct, a low value of n may be an indicator of this condition.

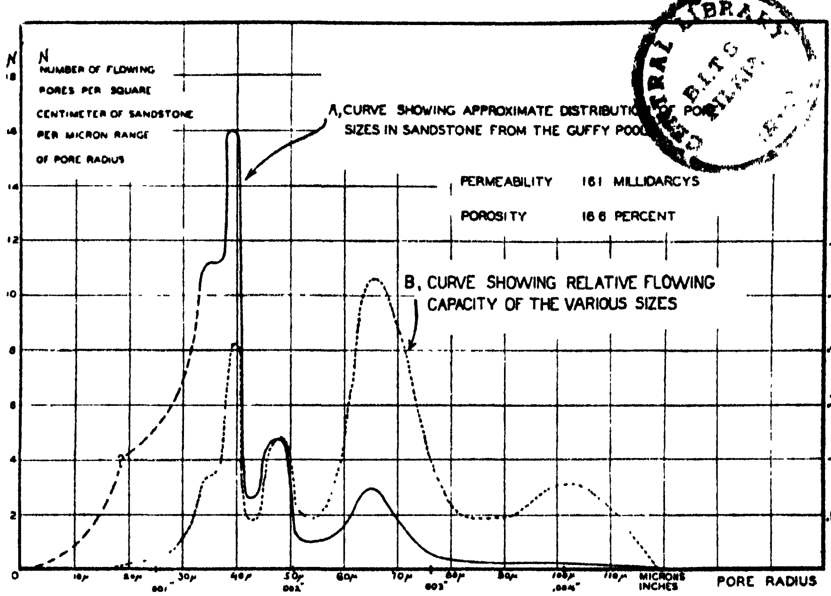

FIG. 2. Curve A is inferred from experimental data on the number of bubbling spots per square centimetre and the corresponding capillary back pressure, when a fractured face was bubbled under water. Curve B is calculated from curve A by assuming that Poiseuille's fourth power law can be used. The area under curve B is proportional to the permeability.

Fig. 2 shows the result of an initial attempt to extend our information about sandstone permeability by measuring the flowing capacity of the *separate hole sizes* of a piece of Bradford sandstone having a permeability of 16 millidarcies. Curve A was measured by comparing the number of bubbling-points per square centimetre at a fractured surface-flowing gas under water with the capillary back pressure developed at the surface for a number of rates of flow. Curve B shows the relative carrying power of the various capillary size ranges on the assumption that the flow through each capillary is proportional to the fourth power of its radius (Poiseuille's law). Large capillaries of course are restricted by other smaller capillaries which are connected in series with them, but curve B would seem to emphasize the relative importance of the larger sizes. The salient feature of curve A is that there are well-defined critical size ranges in which the concentration of capillaries is high. Whether these 'peaks' will persist among other samples of the same sand is not known. Curve B shows that one-half of the carrying capacity of a fractured section is in about one-twentieth of the capillaries, and 90% of the carrying capacity is in capillaries numbering less than 1 per sq. millimetre. This work has not yet been carried forward far enough to prove the relationship suggested above between n and the frequency distribution of capillary sizes.

It may be predicted that such a relationship cannot be exact because the critical velocity at which turbulence is encountered in any tube depends not alone on the size but also on the roughness of the wall and the shape of the tube.

In most cases it will be sufficient to regard both the permeability factor K and the velocity exponent n as constants. Thus Rawlins and Schellhardt [28, 1935] find that data obtained on 582 gas-wells throughout the United States can be represented adequately by the above formula (6) if suitable precautions are taken to make P_2 equal to the actual pressure at the face of the sand and P_1 the true formation pressure. They write their formula

$$\frac{dQ}{dt} = C(P_1^2 - P_2^2)^m, \tag{7}$$

where dQ/dt = rate of flow, cu. ft. per 24 hours,

C = constant,

P_1 = shut in formation pressure, lb. per sq. in. absolute.

P_2, back pressure at the face of the sand in the well bore, lb. per sq. in. absolute.

m is an exponent corresponding to the slope of the straight line relationship between Q and $P_1^2 - P_2^2$ plotted on logarithmic paper.

It should be noted that the m of this expression is the reciprocal of the n of equation (6), and that the constant C includes the permeability, viscosity, and back pressure together with an indeterminable shape factor which depends on the geological peculiarities and the distribution of fluid in the producing sand. Rawlins and Schellhardt further assert that it is necessary to conduct tests at reasonably long intervals on gas-wells to determine new values of m and C. These authors believe that the value of m does not change with the pressure gradient [29, 1935], but feel that a change in m involves a change in the physical condition of the sands. Their curves show quite appreciable changes in the slope m, however, and it is clear that by 'negligible' changes in m these authors mean that

they are not significant for the ordinary purposes of gauging gas-wells.

For a discussion of the relationship between the permeability K and the exponent $n = (1/m)$, however, Muskat and Botset [24, 1931] offer data on glass beads, in which the slope (see Fig. 3) changes from $n = 1$ to $n = 1{\cdot}5$ with no cause other than the change in pressure gradient. Under these conditions they remark that the concept of permeability is not well defined. For if the equation

$$\rho v = \frac{K}{Z}\left(\frac{d}{dx}(P^2)\right)^{\frac{1}{n}} \tag{8}$$

be solved for K by substituting ρv (the mass velocity) and $d(P^2)/dx$, using these and $1/n$ obtained from the point under consideration, the value of K is not a constant at all. It was found from Fig. 3 by this process that when

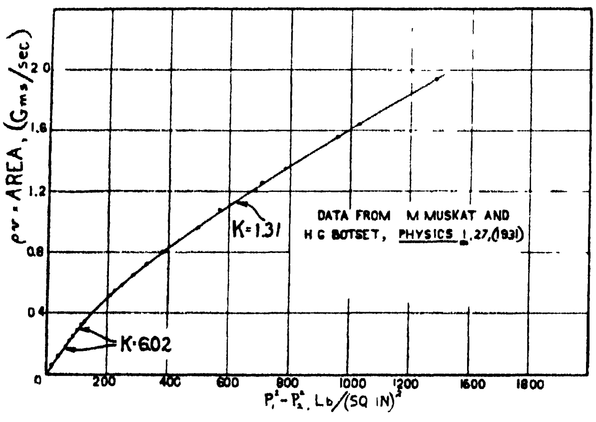

FIG. 3. Data showing increase in turbulence with pressure gradient. When plotted on logarithmic coordinates, the value of the slope n is 1·0 where $K = 6{\cdot}02$ and 1·5 where $K = 1{\cdot}31$.

n rose from 1 to 1·5, K decreased from 6·00 to 1·31. Therefore since the 'permeability' is conceived as an invariant physical property of the medium, it appears that a definition of 'turbulent' permeability is wanted. Since true permeability is not the physical constant which occurs in the C of equation (6), when n is greater than one, the difference being some hundreds per cent., one must be careful not to use a permeability constant determined at very low-pressure gradients in flow calculations where n is appreciably greater than one [1, 1935].

A frequency distribution curve showing the occurrence of the various ranges of this exponent is plotted in Fig. 4. The curve is probably the most extensive set of flow data in existence on the character of reservoir sands from the strictly flow point of view. The surprising thing about it is that so many values of n, as actually measured on hundreds of wells in the field, are definitely less than unity. It is a commonly accepted dogma of laboratory experience that n must lie between one and two—one represents purely viscous flow and two represents completely turbulent flow. Fig. 4 shows that there is a reasonably complete lack of wells whose exponents n are greater than 2; only 5 wells out of 582 have exponents greater than that which means pure turbulence. But 173 wells have exponents less than that which means purely viscous flow. How can one account for an increase in flow with pressure gradient, which is even greater than linear, occurring frequently enough to be called a normal condition of flow?

It is believed that these data may be accounted for by assuming that heavy gaseous hydrocarbons exist as liquids in the reservoir rock adjacent to the well at high pressures, but flash into gases within the formation as they approach the well. Since the disappearance of liquid from the rock reduces the resistance to flow, it is possible that this resistance will be reduced systematically as the well pressure is reduced in such a way that a plot of production rate against the difference in the squares of the pressure will

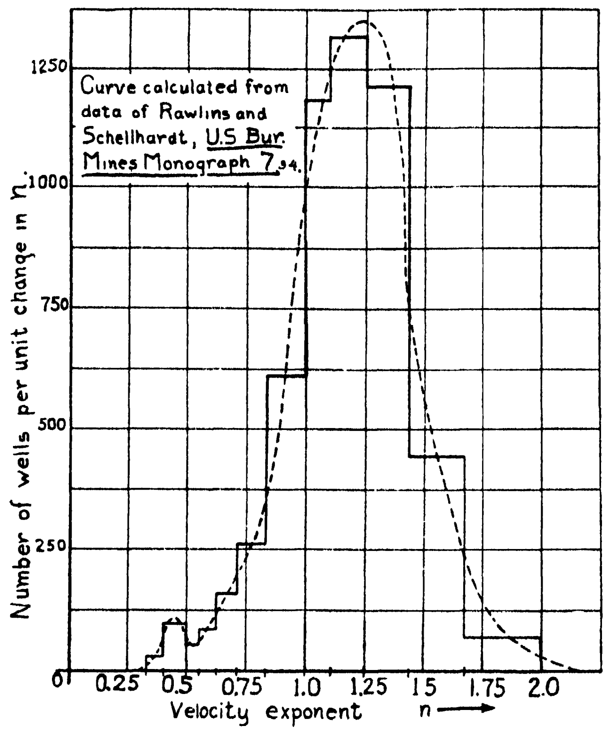

FIG. 4. Curve showing frequency distribution of n in the formula $(V/t)^n = P_1^2 - P_2^2$ as measured in a widely distributed group of 582 gas-wells. For example, the number of wells per unit change in n between 1·0 and 1·11 is plotted as 1,181. Multiplying by the change in n, namely, 0·11, we obtain 130, which number Rawlins and Schellhardt observed.

still be a straight line on logarithmic paper, even though n becomes less than one. Before examining this possibility quantitatively a short discussion of the effect of liquid in sandstone on the permeability will be presented.

The Effect of the Presence of Liquid on the Permeability to Gas.

Recent work concerning the effect on the permeability of the presence of liquids in sandstone and packed sand has established the following points:

1. The liquid in the sandstone is effectively locked to the pore walls so that the combination acts upon gases as if it were dry sand of reduced permeability [10, 1936].

2. The permeability of the wet sandstone depends on the dry permeability and the per cent. saturation in a reproducible way [11, 1936] as shown in Fig. 5 (curve A). Knowing any two of these factors it is now possible to make a reasonably accurate calculation of the other. The empirical equation

$$K(s) = Ke^{-7{\cdot}75\, s^{2{\cdot}25}} \tag{9}$$

approximates this relation for Bradford sandstone. Here $K(s)$ is the permeability to gas at saturation s.

3. When gas is driven through a length of oil-soaked sandstone the oil is removed at a rate which decreases very

rapidly when the saturation decreases. The gas-oil ratio decreases exponentially with increasing saturation. For Bradford sandstone we have approximately

$$\frac{dV}{dq}=\frac{10^{(6\cdot9-8\cdot6s)}}{\sqrt{1/Z}}. \tag{10}$$

where dV/dq is in cubic feet of gas per barrel of oil passing any section of sand.

Here Z = viscosity of oil in centipoises.

flow of gas with pressure gradient is in every case similar to that of dry sand. For low-pressure gradients Darcy's law is followed. Fig. 6 shows data on this point, and the data of curve A, Fig. 5, indicate that it is true over a wide range of saturations. These data were obtained by driving Bradford sandstone cores with air. The cores were small and the saturations could be determined readily by weighing on a chemical balance.

Data for which the saturations are not quite so well stated are reproduced in Fig. 7. A vertical 1½-in pipe 20 in. long was filled with 20–30-mesh river sand and driven with air at high pressure, first as dry sand, then after adding various quantities of oil. The curves of Fig. 7 show plots, on logarithmic co-ordinates, of $P_1^2-P_2^2$ against rate of flow of gas. It will be observed that the oil-wet sand yields straight lines as does the dry sand, and shows the same slope as the dry sand curves. The only difference is in the value of C as defined in equation (7) above, and since the shape of the flow tube does not change one must conclude that the stable 'specific conductivity' or permeability for oil-wet river sand, 20–30 mesh, is about 73% of the dry permeability no matter what the pressure gradient is. The similar slope and straightness of line of the various curves

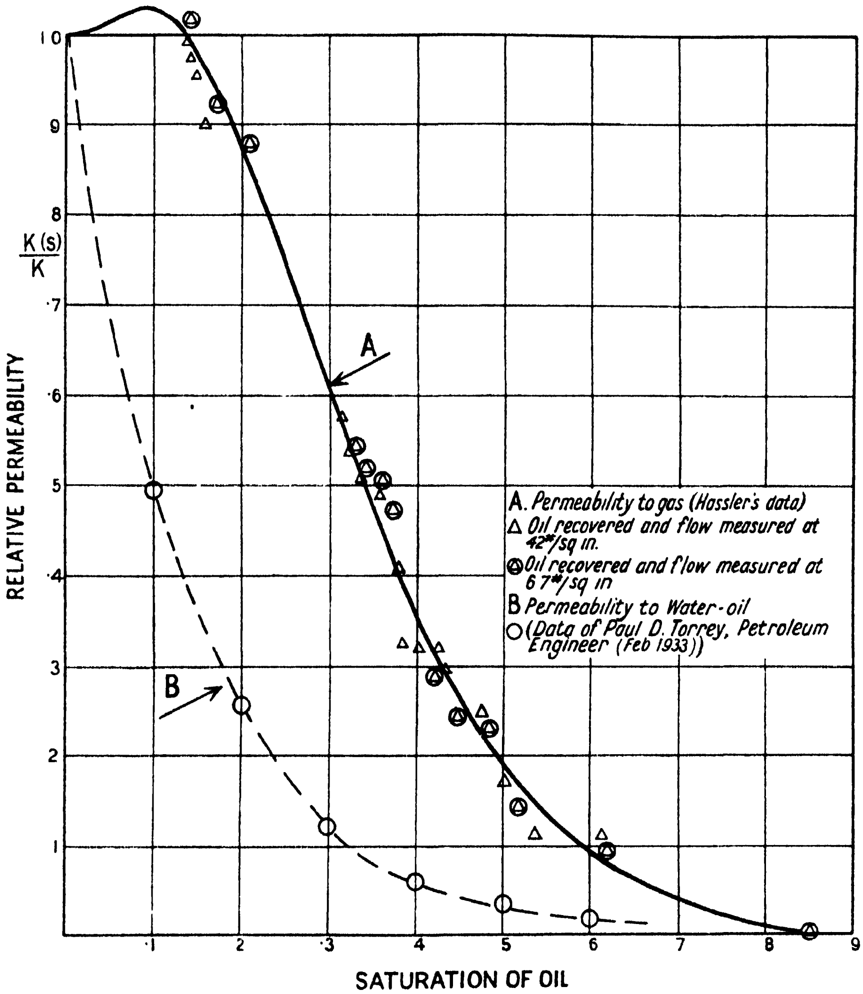

FIG. 5. Curves showing the permeability of sandstone containing (A) oil-air mixtures and (B) oil-water mixtures. The most probable form of curve A is given by equation (9). Curve B seems to be the only published data of this kind. $K(s)$ here refers to the rate of flow of total fluid (both oil and water). No pressure stated.

4. As a result of statements 1, 2, and 3 above, when oil which bears gas in solution is forced through a length of sandstone, the effective permeability near the outlet quickly approaches a stable value. From the number of cubic feet of dissolved gas per barrel of oil an equation such as (10) above can be used to determine the stable saturation. Hence, through equation (9) it is possible to determine the stable permeability to gas.

5. When dry gas is forced through oil-wet sandstone, the rate of oil transfer decreases so rapidly that the sand will appear to approach a stable saturation and a stable permeability to gas.

The statement that the liquid acts as part of the rock may be justified by the fact that the variation of rate of

of Fig. 7 seem to mean that the oil in the sand occupies the same position in the sand during the high rates of flow as it does during the low rates of flow, or, as stated above, it acts upon the gas as if it were a solid part of the porous medium.

The fact that the curves of Fig. 7 approach an asymptotic position near line D may be accounted for by assuming that all oil in excess of the saturation which corresponds to the asymptotic position (about 30%) is quickly driven out of the flow tube by the driving air, the remaining loss of oil being negligible as implied by equation (10).

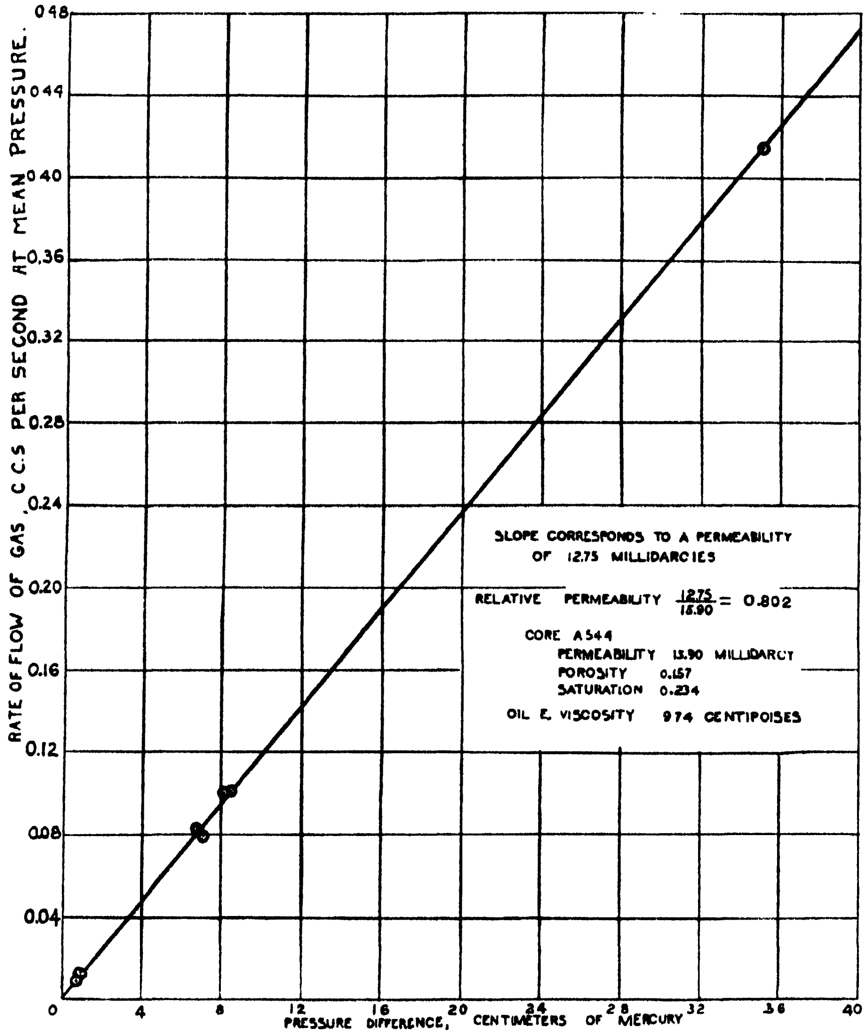

FIG. 6. Data showing how Darcy's law is followed by an oil-bearing sandstone.

An Attempt to Account for Fractional Values of the Velocity Exponent *n*.

Consider the steady flow of a volatile liquid through a sandstone towards a region of lower pressure, as for example, the liquefied hydrocarbons in a gas sand. If it be assumed that the saturation is unity (completely filled void space) at the formation pressure, then as the mixture is moved towards a region of lower pressure the gas will come out of solution in accordance with the pressure-volume relationship for the chosen oil [19, 1936; 20, 1933].

For any back pressure there will be a particular variation of saturation with distance from the well. In this steady state, since the mass velocity is constant, the velocity of gas will increase towards the well as the saturation disappears. The relationship between saturation s and mass velocity of the gas may be written approximately

$$\rho v = C(l-s), \tag{11}$$

where C is a constant involving the ratio of the volume of the gas to the volume of the liquid $(l-s)$ from which it was derived. C also depends on the flow pattern.

This gas is flowing through sandstone in company with the liquid. It is known that in the case of 'dead' liquids the effect upon the pressure gradient is as if the sandstone and liquid were a single porous medium of smaller permeability in accordance with the equation (9). It may not be too far wrong to assume that some such law of variation is valid for the case of a mixture of gas and 'live' or bubbling liquid. The law varies somewhat with type and permeability of the rock. It is not extravagant to suggest that for most reservoir rocks, particularly if the permeability is high, the formula

$$K(s) = K(l-s)^b \tag{12}$$

is adequate for low saturations, say up to 20%, if b is a suitable positive constant around one-half or one-third.

This may best be demonstrated by plotting equation (12) and comparing the plot with the empirical equation (9) for small values of s.

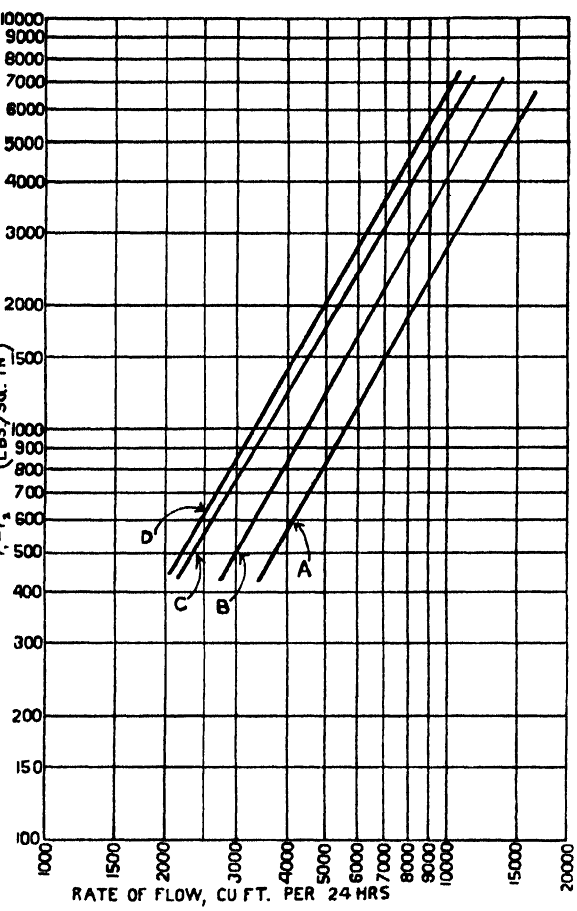

FIG. 7. (Data of Rawlins and Schellhardt. *U.S. Bureau Mines Monograph*, 7, 203 (1935).)

Flow of air through 20–30 separation of river sand wetted with light lubrication oil.

A. Dry sand.
B. After adding 25 cm.³ of light lubricating oil.
C. „ „ 50 „ „ „
D. „ „ 100 „ „ „

The apparatus was so arranged that oil was blown out of the sand during the experiment, so that the saturation is indefinite.

The differential form of the experimentally determined law of flow of gases in porous media, equation (8), may be rewritten,

$$\frac{d}{dx}(P^2) = \frac{Z}{K}(\rho v)^n. \tag{13}$$

Under the conditions of this discussion the mass velocity ρv and the permeability K are expressible as functions of s. Upon substitution from (11) and (12), equation (13) becomes approximately

$$\frac{d}{dx}(P^2) = Zc\,\frac{(l-s)^n}{(l-s)^b} = Zc(l-s)^{n-b}. \tag{14}$$

Upon replacing the expression for mass velocity into (14), (13) becomes

$$\frac{d}{dx}(P^2) = Zc(\rho v)^{n-b}. \tag{15}$$

If the above argument is valid the frequent occurrence of velocity exponents less than one as proved by the data of Rawlins and Schellhardt (Fig. 4) have been accounted for.

Since the lowest possible value of n is unity it may be concluded from Fig. 4 that the largest value of b which occurs commonly in nature is about six-tenths. There are not yet sufficient data to discuss the physical meaning of the constant b from the standpoint of physical structure, but it seems clear that b is associated with that property of a sand which permits it to hold oil in the presence of a gas drive. If b is low the sand can be saturated to a higher degree before any appreciable reduction in permeability occurs; if b is high the presence of a little oil will greatly decrease the permeability.

It may follow that high values of b in an oilfield will imply a low gas factor while low values of b imply less efficiency in the last stages of recovery, since it will be expected that oil which is so distributed that it does not resist the flow of gas will be hard to displace by gas flow.

The data of Fig. 4 were all obtained from gas-wells, but with sufficient experience in correcting for the presence of fluids in the well there is a good chance that similar curves can be obtained in depleted oilfields.

These remarks will not have any practical value unless it is possible to distinguish the turbulence effect, represented by n, from the saturation effect, represented by b, in the velocity exponent $n-b$. However, it will often be possible to estimate what the separate influences are from the production rate and from comparitive experiments made on the dry or partially saturated sand in the laboratory.

It should be emphasized that the above argument is not in any sense complete. There is reason to predict that a more exact statement of the relationship between saturation and gas velocity, and of the relative permeability $K(s)$, will reveal variations in n which will depend on factors important for a better understanding of oil and gas flow.

The Relationship of Permeability Research to Mathematical Analysis of Oil-flow Problems.

The shape factor. In any real problem of flow in nature the calculation of the effect of the shape of the sand is apt to be too difficult to yield readily to the present knowledge of mathematical analysis. As a result of this difficulty only those few cases have been brought under the yoke of common understanding which are so simple in geometry that this shape factor can be handled. Thus the two standard shapes used in calculating the permeability from the flow measurements are the cylindrical sample in which the flow is one-dimensional (generally circular in section but sometimes square) and the radial flow sample, in which the fluid is caused to move along the radii of two concentric cylinders which form the inlet and outlet faces, the top and bottom being ground off as flat planes.

In the first case the differential form of Darcy's law for incompressible fluids, equation (1) above, can be integrated immediately to the form

$$\frac{Q}{t} = \frac{KA(P_1-P_2)}{Z\quad L} \tag{16}$$

A = area in square centimetres of section of cylinder,
L = length of cylinder in centimetres.

Here the shape factor A/L is simple enough to predict by intuition. In the radial flow case dQ/dt must be set inversely proportional to the radius r,

thus, $$\frac{dQ}{dt}\cdot\frac{1}{2\pi r} = \frac{K}{Z}\frac{dP}{dr}, \tag{17}$$

which integrates to the form

$$\frac{Q}{t} = \frac{2\pi K(P_1-P_2)}{Z \log r_1/r_2}. \tag{18}$$

Here the shape factor is

$$\frac{2\pi}{\log r_1/r_2}.$$

In these two cases may be found a geometrical combination which is easy to fabricate in rock (by grinding with an abrasive tube or a flat plane) and which is also easy to handle mathematically.

However, it is easy to see that while these things permit the laboratory measurement of permeability, circular cylinders are a far cry from the geometry of a real secondary recovery oilfield. The more ambitious attempts that have been made to deal with the flow of wells include the following examples:

The above formula (18) for radial flow may be used to calculate the flow of *water* in water-bearing sands [36, 1936] which are uniformly permeable and of uniform thickness by measuring the shut-in pressure at wells which are at distance r_1 and r_2 from a producing well to obtain P_1 and P_2 respectively. A simpler method, which, however, is limited by the accuracy with which a well diameter can be stated, has also been given in the literature [39, 1934]. These methods may not be used directly to deal with oil-wells because the varying saturation of oil, or varying content of gas make it inadvisable to assume uniform permeability to flow of either liquid. There are rare edge-water drive fields in which oil does not release gas in the sand, and in this case the radial flow formula is of course applicable [39, 1934].

In the case of gas-wells which have dry sands the radial-flow formula can be put into the form (39, 1934)

$$\frac{\bar{Q}}{t} = \frac{2\pi K}{Z}\frac{(P_1-P_2)}{\log r_1/r_2} \tag{19}$$

by substituting Boyle's law into (18).

$\bar{Q}$ is the rate of flow reduced to mean pressure $\frac{P_1+P_2}{2}$.

The shape factor $2\pi/\log r_1/r_2$ may be corrected for the exposed bottom of the hole in the case of partially penetrating wells by inserting a correction factor into the formula [39, 1934].

However, it has been shown [28, 1935] that the flow of gas from gas-wells is not generally in accordance with Darcy's law. Instead, one must use the more general form of the law of flow as given in equation (13).

On this basis Botset and Muskat [24, 1931] have derived formulas which may be used to predict the rate of flow in various stages of exhaustion of a gasfield, for any value of n. Recently Muskat [22, 1934] has presented a very complete treatment of compressible fluid flow which includes non-radial flow and transient conditions of flow for homogeneous fluids.

Another very interesting approach to the problem of boundary conditions or shape factor is offered by Moore, Schilthuis, and Hurst [21, 1933] in conjunction with a method for determining the average permeability of a well from field data. In this treatment the boundaries of the medium are the walls of a fully penetrating well and the top and bottom of the sand, while the outer drainage radius is disregarded on the following grounds: If the pressure be changed suddenly on a sand containing a compressible fluid, the instantaneous rate of production of the fluids in the sand near the well will be independent of conditions at a distance from the well. Hence by studying the 'draw down' and 'build up' curves of pressure at the face of the well during a short period, together with the simultaneous oil and gas production and the variation in the casing pressure, it is possible, using certain assumptions, to determine the effective permeability of the sand. It is clear that this cannot be done if adjacent wells are so close that they are affected by the change within the time of the test.

One other possibility of avoiding boundary calculations in permeability measurements that seems to have been neglected by laboratory technicians to date is the very small inlet (or outlet) face in or on a large porous medium of any shape. In this case, if all other significant boundaries be at a distance which is large with respect to the dimension of the inlet, all of the resistance to flow is concentrated around the inlet so that only the geometry of the inlet need be considered. In such a case it is legitimate to speak of the 'flow capacity of the inlet' as a quantity which depends only on the permeability. It should be possible to measure permeabilities, for example, by pressing a 2-in. rubber stopper with a very small central hole against a fractured face of the rock under test. If a fixed suction is then produced at the hole the rate of flow will be dependent only on the permeability of the rock so long as the nearest inlet for air is at a distance greater than the radius of the stopper. Such 'electrode resistance' or 'point resistance' measurements are in common use in electrical practice, and the theory is complete there [15, 1925].

One other group of 'shape factor' problems has received fairly complete treatment at the hands of Muskat and Wyckoff [25, 1933; 38, 1932]. In the case of a sand of uniform thickness bearing a homogeneous gas-free liquid in steady state, viscous flow, the wells may be regarded as point sources and sinks in a logarithmic potential field. The 'shape' of the medium is completely described by the thickness of the sands and the distribution of the wells. In this case these authors have calculated the conductivity and manner of flow of the 'five spot', 'seven spot', 'line drive', and other flow patterns used and proposed for use in water-flood properties. The 'shape factors' so obtained are quite complicated, but the analysis has been checked by the method of electrolytic models [38, 1932] and is without doubt valid under the assumptions.

The Analytical Treatment of Polyphase Flows.

In all of these cases it is necessary to make assumptions which are not permissible for an oilfield which contains mixtures of oil and gas, or oil and water. There are two principal difficulties in such calculations. The first and most important difficulty lies in the fact that the actual fluids are not homogeneous—they are more often immiscible mixtures of oil and gas or oil and water, or all three together.

Thus in the paper by Moore, Schilthuis, and Hurst [21, 1933] a mixture of oil and gas is treated as a single fluid whose compressibility is determined by experiment. There can be no objection to this if there is evidence that the oil and its associated gas move as if they were bound together as a unit. There is reason to believe, however, that this is not true. The fact that the gas-oil ratio of a field changes continually must mean that the gas and oil are not bound together.

The last words of the late Dr. Versluys [35, 1934] on the subject may be quoted to advantage:

'Close to the well, not only a simple depletion occurs, but also part of the oil and gas from outlying regions have to pass. . . . It would appear to be impossible to make any calculations on this subject. . . . The total work . . . cannot be known until production has ceased, because it is impossible to hazard any theory on the way in which the energy from the expanding gas is imparted to the liquid, and how the oil and gas move, so that the consumption of energy through friction is also beyond computation; further calculation is therefore of no value.'

Recent experiments by the author [11, 1936], summarized in equation (10) above, show that the ratio of gas flow to oil flow in the case of dead oil in Bradford sandstone will decrease about tenfold for every 12% increase in saturation. This fact has been determined for all saturations between 20 and 70%. Furthermore, this gas-oil ratio is a function of the pressure gradient [10, 1936]. It seems to vary inversely about as the square of the pressure gradient at 40% saturation.

Hence, even though some resemblance between his conclusions and the facts is observed, Hurst [21, 1933] is not justified, logically, in using in the flow equation

$$\frac{\delta^2\bar{p}}{\delta r^2}+\frac{1}{r}\frac{\delta p}{\delta r}-\frac{c\phi}{\bar{K}}\frac{\delta\bar{p}}{\delta t} \tag{19}$$

$\bar{p}$ density of gas-oil mixture.
r distance from well.
ϕ porosity, fraction.
$\bar{K}$ = permeability cu. ft. per day per sq. ft. per lb. per sq. ft. per ft.

a $\bar{K}$ which lumps together the influence of viscosity of the fluid and the resistance of the rock. Obviously when this oil-gas mixture has expanded from, say, 1% of gas (in which region of saturation the pressure is distributed by movement of the oil) to 30% of gas (in which range the pressure is distributed by the gas) that viscosity which determines the relationship between rate of flow and the pressure gradient will change from the viscosity of oil to the viscosity of gas. Hence $\bar{K}$ as defined is not a constant in fact, and as measured with this theory has no definite meaning.

It is probably true that as a consequence of statement (4) (below equation (10) above) in the *steady state* of flow of oil and gas towards a well, the effective permeability to gas will be reasonably constant in the region near the well, so that a constant such as is implied by the above equation can be defined. However, it is difficult to see how the transient conditions of flow dealt with in the field permeability determination of Moore, Schilthuis, and Hurst [22, 1934] can be treated by this approach.

The discussions of the problems of secondary recovery by water drive [25, 1933; 23, 1934; 38, 1932] are similarly limited by a lack of experimental data on which to base those assumptions which must be made about the permeability of the rock to the respective fluids. Although in the references given these assumptions are clearly stated, they seem to be invalid. Torrey [34, 1933] has published data on the resistance to flow of sandstones which contain oil. These are plotted on Fig. 5 above. These data show, for example, that a mixture of half oil and half water will flow about 3% as fast as pure water. Since a water drive is characterized by a wide transition range at the front of the flood which contains mixtures of oil and water, it is clear that the usual assumptions, according to which the homogeneous fluid permeability is used with a viscosity near the weighted average of the viscosities of the fluids to calculate the flow, are dangerously in error. It is probable that the resistance to flow is much higher in the region of the front of the water-flood and behind it than it is in the unflooded region. These factors will invalidate any calculation which makes direct use of the theory of logarithmic potential.

In particular, Torrey's data on the resistance to flow of water-oil mixtures demand that a greater part of the pressure drop takes place between the inlet water-well and the front of the flood than has been thought possible; the resistance of the oil-gas part of the pattern must be discounted. The flood will therefore take a form more nearly resembling a circle having its centre at the inlet well: the distortion of this circle, which is caused by pressure gradients arising from the neighbouring wells, will be much less than predicted by Muskat [24, 1931], Nowels [26, 1933], or Herold [12, 1928].

It will be impossible to state at present just what is the shape of a water-flood, for we have just enough data to indicate that those assumptions which make the calculation possible are too far wrong. When more data are collected on the resistance to flow of oil through sandstone which contains gas and on the flow of water, oil, and gas mixtures, it may be possible to find methods of calculation which will be serviceable in predicting the relative efficiency of the various water-flood patterns and gas-drive patterns. Until then it will be important to hold firmly in mind that the permeability, as ordinarily understood, is not even an approximate measure of the resistance offered to non-homogeneous fluids by reservoir rock.

Those who wish to make quantitative use of a concept of permeability find themselves in a dilemma the responsibility for which may be laid to the industry as a whole. In the oil-producing business there has never been any adequate support of fundamental research as distinguished from engineering. The problem of keeping a simultaneous record of gas content, oil content, water content, and rate of flow of all these, is so difficult for real sandstone that the ultimate solution of the difficulties set forth above will require dependable support for high-quality research men for a reasonably long period. Nothing like this has been seen until very recently. It is to be hoped that the result of such work, when it is obtained, will be published without delay.

DEFINITIONS OF SYMBOLS

P pressure.
P_m mean pressure $(P_1+P_2)/2$.
P_1 inlet pressure or closed-in reservoir pressure.
P_2 outlet pressure or bottom-hole pressure.
V, V_m, V_1, V_2, volume of gas moved past a section of the rock.
Q volume of fluid moved past a section of the rock.
$\bar{Q}$ volume of fluid moved through the rock reduced to mean pressure $(P_1+P_2)/2$.
t time.
K viscous permeability for single-phase fluid flow [1, 1935].
$\bar{K}$ permeability as defined in reference [21, 1933], cu. ft. per day per sq. ft. per lb. per sq. ft. per ft. referring to a gas-oil mixture.
$K(s)$ ratio of viscous permeability at saturation s to the 'dry' permeability K.
n velocity exponent as defined in equations (6), (8), (13).
m reciprocal of n.
v velocity of flow of gas.
s ratio of liquid volume to total void space (saturation).
A area.
L length.
ρ density of gas.
$\bar{\rho}$ density of oil-gas mixture.
Z viscosity, centipoises.
x length co-ordinate, whose direction is the direction of flow.
r radius of a cylinder, distance from the centre of a well porosity.

THE MIGRATION OF OIL

By Professor V. C. ILLING, M.A., F.G.S., M.Inst.P.T.
Imperial College of Science and Technology

THE commercial supplies of petroleum and natural gas are found normally as impregnations of porous rocks such as sands, dolomites, and limestones. The oil and gas occur in the pores and fissures of these rocks under high pressure, and when the rocks are penetrated during drilling these materials flow towards the well along the channels within these permeable rocks. There can be no doubt that a still larger amount of oil and gas occurs as a more widespread but less concentrated impregnation of the denser rocks, the clays, marls, and limestones surrounding the reservoir rocks. Such rocks are, however, exceedingly impermeable, and there is therefore no commercial method of extraction. It is generally agreed, however, that these denser rocks are, in the main, the media in which the oil originates, and their oil content is therefore not surprising.

So far as the reservoir rocks are concerned few geologists would assert that there is any possibility of oil originating in a sand, though some limestone reservoir rocks may originally have functioned also as source rocks for the petroleum.

While it would be legitimate to consider some oil-pools as having originated *in situ*, the vast majority of fields must have demanded a considerable amount of oil and gas movement and, furthermore, in all cases there must have been a differentiation of oil and gas from water in the sediments. These movements of concentration and segregation are spoken of as the migration of petroleum.

The study of migration begins with the consideration of the factors which govern the first processes of concentration whereby the dispersed oil and gas are gradually shepherded to the reservoir rock. It traces the further movement of the materials within the reservoir, segregating the gas and oil as separate bodies in well-defined zones within the rock mass. It is concerned with all the movements of readjustment in these zones which occur during the passage of geological time as a result of the changes which take place in the rocks around and in the hydrocarbons which have been temporarily imprisoned. Its final aspect is a study of the dispersal of the oil and gas as the processes of denudation permit access to the reservoir, and Nature's forces, previously held in check, give rise to new movements within the reservoir. Then the gas and oil are either moved onwards to new and temporary homes, or they are brought to the earth's surface and dispersed.

There exists in the literature of the subject a great deal of confusion and apparent contradiction due to the use of the term migration in distinctly different senses by different authors. Some visualize the term migration entirely as a process of separation of gas and oil over water within a reservoir rock, whereas others are concerned solely with the processes whereby the oil leaves the source rock and accumulates in the reservoir rock. In order to avoid some of this confusion the author has suggested the use of the terms primary and secondary migration to cover two distinct phases of the process [13, 1933]. It is important to distinguish them because they represent migration under different physical conditions, though it is impossible in many cases to separate the two phases in the final distribution of the oil and gas in the pool.

Primary migration is concerned with the initial process of oil and gas movement whereby the material is moved from the source rock and flows to the reservoir rock. It is essentially a process of rock selection whereby the oil and gas choose a more coarse and porous rock in preference to a fine compact one.

Secondary migration is concerned principally with the fluid movements within the coarser rocks whereby the gas, oil, and water are separated and come to rest in different portions of the reservoir rock. Generally the gas, oil, and water sort themselves out in the reservoir rocks in order of density. The gas occupies the highest part of the reservoir, whilst the water occurs at the base. There is also a certain amount of selection due to coarseness, the water tending to occur in the finer rocks, whereas the oil occurs in the coarser. This effect of pore size sometimes produces anomalous results such as the occurrence of water resting on oil in what appears to be the same sand body. There are, therefore, clearly several influences at work governing the distribution of the gas, oil, and water within the reservoir rock.

Primary Migration

The main problem of primary migration is to explain the enrichment of the sands, dolomites, and limestones with oil and gas at the expense of the more compact source rocks in which the oil is believed to originate.

It might appear at first sight that the problem presented very little difficulty. The oil and gas choose the sands and other reservoir rocks because they are porous. One of the chief difficulties, however, is that the reservoir rocks are surrounded by compact rocks which are themselves impervious, so that it is not easy to see how any movement of oil, gas, or water could have taken place through them. So fundamental is this difficulty that many geologists have, as a consequence, refused to admit extensive migration of this sort and have claimed that the oil must have originated in the compact rocks immediately adjoining the porous reservoir.

It was on this account that Sterry Hunt, as early as 1861, concluded that oil in the Trenton limestone of Canada had a purely local origin. It is, however, argued by others that although the surrounding rocks are compact they are not absolutely impervious and that over long periods of geological time there will be slow movement through the whole rock mass. J. L. Rich [28, 1931] strongly supports this point of view and believes that fluid movement occurs throughout the sedimentary rocks, though of course it is more apparent in the more permeable carrier beds. There is, however, one piece of evidence which makes the assertion of unlimited permeability untenable. It is to be found in the differences in pressure in adjoining sand bodies when they are first penetrated. Were there even only a limited communication between such masses one would expect them to have attained, over long periods of time, an ordered sequence of closely related gas pressures. Whilst it is a general rule that pressures increase with depth, there are so many local anomalies that it is impossible to allow even a limited amount of communication between the sand

bodies showing these anomalies. One must therefore conclude that in the majority of cases the enclosing rocks are in fact impervious.

Causes of Primary Migration.

It is useless to discuss the buoyancy of oil in water and the separation of gas, oil, and water according to their densities within a rock which is itself so compact that any movement whatsoever is extremely doubtful. Clearly, therefore, buoyancy, which is a commonly accredited cause of oil migration, cannot function as a cause of primary migration whatever importance it may have later on within the reservoir rocks themselves.

Of the possible causes of primary oil migration the following may be considered as the most important.

1. Capillarity. The suggestion that oil migration was primarily due to the difference in surface tension of oil and water seems to be ascribable in the first instance to C. W. Washburne [36, 1914], but it has been due largely to the work and writings of A. W. McCoy [18, 1918; 19, 1919] that this theory has gained wide recognition. McCoy uses the term 'replacement theory' for the whole process, and he describes it as a slow process of interchange in which the oil moves to the coarse rocks and the water moves to the fine. The movement is claimed to be due to the fact that the surface tension of water is more than twice that of crude oil, so that the water tends to displace the oil from the finer capillaries. The oil so displaced moves into the rock with the larger pores, thereby enriching the sands with oil at the expense of the finer source rocks.

This theory has gained many adherents, for it gives a simple explanation of one of the dominant characteristics of all oil accumulation—that oil always seeks the coarser rocks. In some oilfield regions, notably Pennsylvania, coarseness appears to be nearly always the major factor, and the oil accumulations in the sand bodies are restricted to the coarser streaks. Numerous experiments have been carried out which appear to support these views, though it may be remarked that the experiments are open to the criticism that they invariably introduce other factors which may possibly be the cause of the movement observed.

It must be remembered that the sands and clays in nature are originally water-wet, so that the oil interspersed through them will exist as globules or masses in the water-wet capillaries. So long as such oil masses lie entirely in the fine or in the coarse zone there can be no driving force acting on them by virtue of surface tension. The oil will assume an external form wherein all the external forces acting on it, buoyancy and surface tension, are in equilibrium. Once this condition is attained surface tension will tend to prevent any change rather than cause further movement. Undoubtedly an oil mass which happens to lie across the interface of a coarse-fine junction will adopt an external form which was related to the capillary conditions in the coarse and the fine portions. It may in doing so retract entirely into the coarse zone, but it can attain equilibrium without doing so. A simple and critical experiment in which all factors save surface tension are eliminated consists in the introduction of oil globules into a converging capillary full of water and placed in a horizontal position [13, 1933]. If this be done, it will be noted that the oil globules assume a rounded but slightly asymmetrical form and then undergo no further movement. There is no tendency for the oil to travel to the wide end of the capillary. Surface tension merely alters the outer form of the globule, and it requires a definite external pressure to produce any further movement. The oil globules resist movement according to the well-known Jamin principle [10, 1928], and no flow can take place in the capillary until the difference in pressure at the ends exceeds the back resistance. In other words, the function of surface tension in the conditions under discussion is to retard rather than to cause movement.

2. Hydraulic Currents. Perhaps the most generally accepted views on the cause of primary migration ascribe the oil movement to the drag effect of water currents within the rocks. There are, however, various hypotheses as to the cause of such currents, and it is essential in discussing fundamentals to inquire how these currents are produced. Three causes of fluid movement are possible: general hydraulic currents due to differences of artesian pressure; the currents due to compaction of sediments; and lastly, the fluid currents due to diastrophism.

Dealing first with the hydraulic currents due to differences of artesian pressure, it is well known that water passes along the more permeable beds for great distances and in doing so it will tend to flush any oil met *en route* in the direction of its flow. This is a common means of oil dispersal whereby oil accumulations are sometimes flushed to the surface and lost. But the principle as applied to primary migration must involve artesian flow in the fine-grained and compact rocks, and it is very doubtful if such movements are possible once these rocks have reached this compacted condition. Some authorities assert that fluid movement takes place through all the sedimentary rocks, the more permeable beds allowing easy flow along their bedding-planes, and the compact rocks allowing only a very slow movement. If this be true, we have in the general water movement a sufficient explanation of migration. But while no one would doubt the effect of hydraulic currents in the permeable beds, there is no good evidence for a general water flow through all rocks. The variations in oil and gas pressure in neighbouring sands support the belief that once a clay has been thoroughly compacted no appreciable fluid movement is possible through it.

One of the first supporters of the theory of oil flushing by hydraulic currents was M. J. Munn [25, 1909]. Although he was not so much concerned with the causes of these currents as with their action in sweeping the oil into suitable reservoirs, yet it is fairly clear that Munn considered that much of this water movement was associated with compaction. The water was squeezed out of the sediments by the increasing load, and in its escape it used the sand beds as convenient avenues of movement. These ideas belong properly to the following section. Munn, however, was mainly concerned with oil and water movement within the porous rocks, and his views have a more important bearing on secondary rather than primary migration.

3. Compaction Currents. When a clay, marl, or argillaceous limestone is first deposited it is primarily a clastic or organic medium containing a large volume of interstitial water. The percentage of this water depends on the type of clay, but it is by no means unusual for such a sediment to contain 60 to 80% of water by volume. Such a material has solid properties in spite of its large water content, it resists deformation and compression within the limits of its own strength, but above these limits water is gradually expressed and the sediment diminishes in volume. Continuous sedimentation therefore, inasmuch as it increases the pressure on the underlying sediments, causes a slow outflow of fluid and a gradual diminution of bulk volume in all the argillaceous or marly sediments. This process of

compression is called compaction, and it involves the outflow from the sediments of a volume of water several times greater than the final volume of the sediment [35, 1932]. Here is a considerable movement of fluid which must take place in all such sediments before they can become rocks, and it is legitimate to consider that this movement may have a profound influence on any other mobile materials such as oil and gas which may occur in the sediments at this early stage in their history. The fact that many of our oil reservoir rocks are completely surrounded by impervious sediments, and yet that we are forced to conclude that the oil must have been able to pass through these rocks at some stage in their history, can have only one logical explanation, that the oil migrated before these rocks were thoroughly compressed and impervious. Here, then, the process of oil migration is linked up with a universal process of fluid movement which takes place in all the argillaceous strata in the early stages of their formation.

It is important to consider a little further how the water flows out from the compacting clays. Obviously it will flow along the paths of least resistance. Much of it will go back directly to the overlying water sheet, particularly in the upper layers of the sediment. Some of it may pass into the permeable rocks which form the foundations of the sea floor and find its way by devious paths back to the sea again. Most of it, however, must pass through the bulk of sediments in a general upward direction, but selecting in its passage the lines of least resistance, i.e. the most permeable rocks. Thus the sand bodies or other permeable rocks become the main channels for the compacting fluids and tend to collect the fluid currents from the surrounding clay masses and concentrate them into a single channel of outflow at the points of minimum back pressure in the sand. This tendency is of the greatest importance, for it makes each sand body into a channel of fluid movement and ensures that all the components of the fluid current make use of the sand bodies in the phase of compaction.

Experimental evidence shows that in such a compacting mass of clays any oil or gas present in the clay medium is squeezed out with the water and tends to follow the general direction of the current. In so doing the flow of gas, oil, and water forms a system or network of channels in the clays and a more simplified type of flow in the sands.

4. Filtration. If attention be focused for the time being on the fluids passing into and out of the sand bodies, it is necessary to consider for a moment the physical processes involved at the interfaces of the sands and clays. Each sand body is a highly permeable receptacle with relatively large pore spaces surrounded by a mass of fine mud in which the capillary interspaces are much smaller in diameter. Both media are water-wet, and the movement of water across the clay-sand boundary is subject to no other factor than the relative permeability of the two media. When gas or oil flows out of the clay mass to the sand interface it passes readily from the fine to the coarse capillaries, for there is no physical barrier to such movement. When, however, the reverse movement is involved, i.e. a flow of oil and gas out of the sand body into the clay medium, the latter being water-wet will not allow the oil and gas to enter the fine capillaries unless or until a sufficient pressure is built up at the interface to overcome the surface-tensional forces at the entrance to these fine capillaries [13, 1933]. The process is analogous to the condition of a fine gauze filter which when wet with water will hold back oil, and when wet with oil will hold back water. It is not primarily a function of the relative surface tension of the two fluids, but is a result of the extra energy necessary to force a liquid into fine capillaries occupied by another liquid with which it is immiscible [34, 1930]. The process involves a large increase in the surface area of the secondary or penetrating fluid, and before it can enter additional pressure must be exerted at the point of entry. It can be shown experimentally that for oil to enter a water-wet capillary or for water to enter an oil-wet capillary a considerable pressure is necessary, and this pressure increases as the capillary diminishes in diameter.

As indicated above, the fluid movement from a sand to a clay is similar in physical terms to the movement from a coarse to a fine capillary. Hence, when the compacting fluids containing oil and gas reach the boundary of the sand bodies the water passes onwards into the clays without difficulty, but the oil and gas are filtered out of the fluid stream at the coarse to fine interface and remain locked in the sand body. By this means a fluid stream with only a small percentage of oil and gas can enrich a sand through which it passes until it becomes an oil and gas sand. There must obviously be a limit to such a process, and the limit is reached when an excess pressure is built up within the sand body sufficient to overcome the surface-tensional forces at the interface. This would certainly arise if a sand became filled with oil or gas, and the excess of the latter would then pass on to be trapped in other sand bodies along the route of the outflowing compaction liquids.

According to this view each sand body acts as a filter for oil or gas because its envelope of clay is water-wet. Furthermore, within the sand bodies themselves each coarser streak selectively retains the oil and gas, the process of filtration always taking place at the point of egress from the coarse to the fine rock. It must be emphasized that this selection of the coarser rock, although dependent on immiscibility and surface tension, is not due to the fact that water has the higher surface tension. If the media were originally oil-wet, the water, not the oil, would be trapped in the coarser rocks, for it is always the secondary fluid which tends to be retained in the coarser medium irrespective of the relative surface tensions of the primary and secondary fluids.

As the process of compaction proceeds the clays lose their fluids and become more compact. Their permeability is thus reduced and the egress of the fluids is hindered. Thus the fluid currents are gradually damped down in their intensity by the gradual increase in density of the clay media. No data are yet available to decide whether the currents cease for lack of available fluids or whether the clays themselves become so dense and impervious that further movement of fluid becomes negligible, but it seems probable that the latter is the more normal course. Further drying of the clays is probably due mainly to mineralogical changes within the clay mass involving the absorption of water by the clay minerals.

The oil and gas trapped in the sand bodies are associated also with water which fills the remaining pores. There may still be some local fluid movement into the sand body after the general flow of the compaction currents has ceased, and this will involve the building up of excess pressures within the sand, but at this stage the covering clays over the sand are so dense that loss of oil due to these excess pressures is impossible.

Until this stage is reached all the neighbouring sand bodies are in direct or indirect communication, and the pressures are controlled by the weight and strength of

the compacting medium. Hence the pressures in the sand bodies will be a function of their depth of burial. Once, however, the clay media become impervious the intercommunication ceases and the pressures in individual sand bodies may be affected by factors peculiar to themselves. A sand highly charged with gas would be peculiarly sensitive to temperature changes and might build up abnormally high pressures merely by increase in the earth temperature, so long as the clay envelope was sufficiently strong and impervious to prevent loss of gas or liquid from the sand.

5. Diastrophism. The fluid currents in the phase of compaction are primarily due to the accumulating weight of sediments. But compression may arise from other causes, in particular the stresses within the earth's crust, such as are associated with folding [6, 1916; 33, 1927–8]. Sometimes these conditions occur very soon after sedimentation, and in such cases it is obvious that the stresses will produce additional squeezing of the sediments and accelerate the flow of the compaction fluids. In most cases, however, we may assume that diastrophism succeeds the early phases of compaction, and its effect will therefore only be noted in the later history of the sediments.

One additional aspect of the effects of lateral pressure needs a passing comment here, though it will be dealt with more fully at a later stage. Lateral pressure compresses the clayey sediments and renders them more impervious as a whole, but if carried to the stage at which disruption occurs, the rocks become fissured and fractured. These new features confer a certain amount of induced permeability on the formation, and if they occur within the clay series its impervious condition may be destroyed and further fluid movement out of the sand bodies may take place. Tensional stresses are particularly prone to produce such effects, and the local conditions of tension that may occur on the zone of curvature on an anticline often result in accentuated movement of the gas and fluids through the zone of induced fractures.

The driving force in these fluid movements may be primarily the gas and oil pressures, but diastrophism has opened the door to such movements by the creation of induced permeability, and in some cases the lateral pressures themselves may have caused some of the fluid outflow.

Secondary Migration

It has been emphasized already that there are two aspects of migration. First, the original enrichment of the reservoir rock with oil and gas, and secondly the segregation of this material into certain restricted zones within this rock. Sometimes these two stages of movement are merged into one, but more commonly, and particularly in extensive reservoir rocks, the internal adjustments are very considerable.

Two major features are common to all cases of secondary migration. First, the gas and oil seek the highest possible position within the porous rock, the gas being above the oil or in solution. Secondly, the coarser sections of the reservoir rock tend to retain the oil, whereas the water lies in the finer sections. It is difficult to say which of these two principles is the dominant one, for their relative importance varies with the conditions.

Flotation.

The fact that the gas, oil, and water are generally separated into three layers in the order of their densities seems to find an obvious explanation in the principle of flotation. This has been accepted almost without question as the fundamental principle of oil accumulation and was the basis of the anticlinal theory as promulgated by Sterry Hunt [12, 1861]. Before, however, the theory is accepted it is necessary to examine more closely the conditions of the fluids and gas in the reservoir rock. The latter is not an open receptacle, but is a solid medium full of minute capillaries. Within these minute pores the fluids are obviously confined much more effectively than they would be in an open receptacle and their power of free circulation is severely limited by their being in the capillaries. In the case of mixed fluids of different densities the gravitational forces will tend to separate the lighter fluids into the upper zones, but unless these forces are sufficient to overcome the forces of surface tension inhibiting movement in the capillaries, it is difficult to see how flotation can occur. A drop of oil in a water-saturated sand would exist as an irregularly shaped mass bounded by numerous water-oil interfaces in the capillaries. To allow any movement of this mass of oil the oil-water interfaces would have to be distorted and then set in motion. To achieve this a sufficient pressure would have to be exerted to overcome the forces of surface tension at these interfaces, and these forces would obviously be greater the finer the capillaries. It is therefore not at all certain from first principles that gas, oil, and water will separate out by flotation in the pores of a rock, and it is clear that the separation will depend on certain limiting conditions, the relative importance of surface tension and buoyancy. When these principles are examined experimentally it is found that in normal sands the effect of gravitation is too small to cause oil to separate over water and form an upper layer [8, 1921]. An effective separation will occur only when the coarseness of the reservoir rock approaches that of grit, but normal oil sands are too fine for such separation.

It might be argued that oil separation would be induced by flotation provided the oil masses were originally large enough [2, 1930; 36, 1914]. The upward thrust of buoyancy would increase as the cube of the diameter of the oil masses, whereas the resistance to movement would be proportional to the square of the diameter. This argument is, however, invalid, for before these masses can become large there must be sufficient movement to allow them to grow by combination.

In addition to the evidence of experimental investigations there are several instances in oil-pools where the original oil-water surfaces have such a marked inclination that it is difficult to explain on any principle of gravitational separation how such inclined surfaces could be maintained.

On the other hand, there are some oil-pools where a clear case can be made out for static separation of oil and gas over water. These three materials are found in the first instance in separate layers with horizontal planes of demarcation. When these conditions are upset by uneven drilling and production, the readjustments set up obey the normal flotation principles. In other pools it is found that the oil and water layers are interbedded, and the distribution of the oil and water is altogether irregular.

It is therefore considered that, whereas in the coarser reservoir rocks such as grits, dolomites, and fractured limestones the principle of buoyancy is a complete explanation of the internal segregation of gas, oil, and water, this explanation is inapplicable to the large proportion of normal oil sands where the capillary interspaces are too fine to allow buoyancy to overcome the resistance offered by surface tension.

Buoyancy due to Gas.

Claims have been made that whereas oil and water will not separate under normal conditions, the presence of gas enables such separation to take place. There is considerable experimental evidence which seems to support this view, mostly based on the introduction of gas into an oil-water mixture in a sand [31, 1920]. Such experiments show a marked separation of oil and gas above the water, but it must be realized that the conditions involving the introduction of gas cannot be achieved without altering the conditions of pressure in the sand and thus causing fluid movement, and, as will be seen later, it is generally admitted that in moving conditions complete separation of oil and water is possible without the help of gas. While, therefore, it is clear that in a flowing stream of water, oil, and gas, the gas aids the separation of the oil, it is not by any means certain that oil and gas lying interspersed in the pores of a water sand will segregate upwards under their own buoyancy unless the pores are large enough to allow buoyancy to overcome surface tension. It seems probable that although buoyancy is a stronger factor in a composite oil and gas body it is insufficient to cause separation in fine sands.

Hydraulic Currents.

Whilst it is extremely doubtful whether oil interspersed in a water sand will separate under static conditions, there can be no doubt that under moving conditions a complete separation is possible. Johnson [14, 1915] was one of the first to draw attention to the importance of moving conditions, and many authors have reiterated the same truth. The essential difference between moving and static conditions lies in the fact that in a flowing stream there is a definite pressure gradient in the fluid involving the traction of each oil mass by the movement in the water around it. The two can move together. During this movement there is a difference of pressure on two sides of any oil mass, causing it to retract from the capillaries on the high-pressure side and to advance into the capillaries on the low-pressure side, i.e. in the general direction of movement. If the advance continues, lobes of oil will pass forward between the grains of sand, and such lobes when free, i.e. in the broader interspaces, always tend to move upwards. Thus there is a preferential selection of the upward capillaries in the forward movement. This means that the separation of the oil is a function of the length of journey and only becomes complete after a considerable advance, a point which is supported by experimental evidence. It must also be noted that this upward separation of oil and gas from moving water is also affected by the coarseness of the sand in which the movement takes place. Where there are sudden changes in coarseness involving a fine sand overlying a coarse one, the coarse to fine interface acts as a barrier to upward oil movement and the oil is held back in the coarser strata [13, 1933]. Where, on the other hand, a coarse sand overlies a fine one, no such obstruction takes place and the oil moves upwards into the coarse sand, only to be checked where the latter is itself covered by a finer grained medium. As a result, therefore, of continuous forward movement through a large sand body containing coarse lenses, the latter filter out and retain the oil to become a series of oil-impregnated coarse sand lenses in a fine water-saturated sand. Such conditions can be claimed to occur in many oilfields, and in the earliest days of the Pennsylvanian oilfield development the term 'pay streak' was largely used for these coarser strata.

In such forward movement, so long as there is no change in coarseness within the rock, the invariable rule is that oil chooses the more upward of two alternative paths, so that where the sand is thick and of even grain size the oil tends to become the upper layer. Where the sand is horizontal this layer will be evenly distributed, but where, on the other hand, the sand is tilted or warped, the oil layer will gather in the higher zones, that is, the anticlines, while the synclines or troughs will tend to lose their oil and to become entirely water-bearing. Where the sand bodies are merely lenses the gas and oil will tend to accumulate in the upper edge of the lens, where the screening effect of the coarse to fine interface will tend to retain them in preference to water. The water flows onwards into the surrounding clays until compaction has rendered all movement impossible owing to the diminished permeability of the latter. Some authors deny that the condition of complete impermeability is ever attained. Rich considers that a certain amount of water movement occurs in all rocks and that this hydraulic sheet is continually moving. Certain of the rock types being more permeable act as the main carrier beds [28, 1931], and in these the main features of lateral oil migration take place. They are Nature's highways for oil migration. In these beds the oil and gas are flushed along by the water currents and ultimately trapped by barriers to their upward and forward movement. Such traps as terraces, faults, monoclinal domes, &c., on otherwise structureless sand sheets tend to strain out the oil from the general fluid current and become the commercial oil-pools. Whilst there is no unanimity on this occurrence of widespread lateral migration, it is none the less true that for many decades new oil-pools have been sought and discovered by the application of its tenets. As instances of such discoveries we may refer to the Cushing Pool where it was claimed by C. Beall that the whole structure had been impregnated with oil and gas by currents from the south-west. Another instance of such trapping is the East Texas field, where the wedging of the sand appears to have been the main cause of the formation of the oil-pool.

These fluid currents within the sand lenses are not always ascribed to the same factors. To many the dominant influence is attributable to the same fluid movement which causes primary migration, i.e. the compaction currents. On this reasoning the movements of primary and secondary migration are all part of one general process, the one leading inevitably to the other, and in its simplest form, the filling of a sand lens with oil, there is no necessity to separate the two processes. To others the compaction fluids are of less importance, and stress is laid on other important water movements in the permeable rocks throughout their history. Such movements may cause concentration of oil, or they may lead to dispersal of oil, according to the direction and strength of the movement.

Capillarity.

In the discussion of the possible causes of oil segregation in reservoir rocks we have already considered static buoyancy, the vehicular action of gas, and the effects of moving currents of water due to many and various causes. A fourth alternative explanation has already been considered under primary migration, i.e. the action of capillarity. Obviously, if the oil is forced into the coarser of two media because it has the lesser surface tension, it ought to occupy the coarser of two sands in contact, or lie in the coarser parts of a sand lens which is variable in grain size. The explanation fits so readily with the known facts that it

is excusable that it has attained such currency. It has, however, been pointed out above that the effect of surface tension as a whole is to prevent rather than to produce movement, and where oil-water mixtures are left in a static condition no internal adjustments take place. One of the fundamental weaknesses of almost all experiments on the effect of capillarity on oil movement is that the media used are not fully compacted and the systems are therefore unbalanced. If left to themselves, they will gradually compact, and this lack of equilibrium inevitably leads to an expulsion of oil and its interchange with the water of the neighbouring sands. It is exceedingly difficult to eliminate extraneous influences if experiments to show the effect of surface tension are carried out with mixed materials without very careful supervision of all the physical conditions. When a simple and critical experiment is carried out such as the introduction of oil drops into a converging capillary saturated with water, no movement of any kind is noted once the oil has been introduced. If capillarity were a driving force, these simple and favourable conditions for its exertion would result in the water driving the oil into the wider end of the capillary.

Adsorption.

It is asserted by some authorities that the chemical and physical nature of the constituents of reservoir rocks has an important bearing on oil migration. Certain media, in particular some of the calcareous rocks, have important adsorptive effects on oils, effects which are selective in their nature and which would automatically lead to the retention of certain parts of a crude oil during its passage through them. Clark [4, 1934] goes so far as to say that he is satisfied that no important oil movement had taken place through the limestones he has examined because of the lack of adsorbed asphalts within them. It must be remembered, however, that chemical experiments on absorption are usually carried out on the carefully prepared dry rock powder, whereas the movement of oil through these media takes place with a film of water over the grains of rock material, a very different condition. It can be shown experimentally that wet limestone or sand has practically no absorptive effect, and that even highly adsorptive earths have their adsorptive powers greatly reduced by the presence of small amounts of water.

The effects of water containing dissolved salts on the physical nature of the oil during migration have yet to be studied. There is no doubt that migration under certain conditions does involve changes in the character of the oils, but many of these changes seem to be due to the effect of physical influences such as differential filtration. Thus, for instance, in the ozokerite deposits of Boryslaw it seems clear that the wax found as veins in the shattered clays has been filtered out of the migrating oil and retained in the clays. Somewhat similar filtration effects may explain some of the thick veins of solid bitumens which have occasionally been exploited commercially.

Reservoir Pressure Changes.

It is obvious that changes in the internal pressure conditions in the water, oil, and gas mixtures will inevitably cause readjustments and some internal movement. Any factors, therefore, which alter the conditions of pressure in the reservoir must influence the course of migration.

Before discussing these factors it is important to note that the gases associated with petroleum are highly soluble in the latter and that the total volume therefore of the oil plus gas depends very materially on the quantity of gas which is in solution. At high pressures and low temperatures the whole of a given quantity of gas and oil may exist merely as a liquid with the gas in solution. Whereas at high temperatures and low pressures much of this gas may come out of solution and the total volume of oil and gas will be greatly increased. The changes in total volume thus produced by variations in temperature and pressure will lead to expansion or contraction of the oil and gas zone of a pool where the water table is free to move. This is seen in the contraction of many oil- and gasfields and the rise in edge-water conditions as production reduces the pressure within the field. On the other hand, in many sand lenses the total volume of the reservoir is limited and there is no excess water available, so that the oil-water surface remains stationary, and the space occupied by oil and gas therefore remains constant. The changes noted in such cases are limited to the gas pressures.

The natural causes of alterations in the pressure within an oil-pool after it has once been formed are:

(*a*) Changes in temperature due to increased sedimentation—causing a rise in temperature—or erosion of overlying sediments—causing a drop in temperature.
(*b*) Increase in pressure due to increase of load by sedimentation, or the reverse effect by erosion.
(*c*) The partial escape of some of the imprisoned material, particularly the gas, by the formation of permeable channels to the surface.
(*d*) Chemical changes of the gas and oil by polymerization, cracking, or other processes of chemical alteration.

All the foregoing factors have considerable influence on oil-pools in the passage of geological time, and so strong are the tendencies towards dispersal that one of the fundamental requirements for the retention of pools through long geological periods is protection from these dispersing influences, i.e. from the migratory nature of oil and gas. Indeed, it may be argued that this feature more than any other has limited the occurrence of oil- and gas-pools of great geological age to such regions as have afforded exceptional protection from oil dispersal. In these favoured areas the strata are either very little disturbed or they are covered with a mantle of some plastic impermeable material such as salt or clay. The oilfields in regions of highly disturbed structures are almost entirely confined to the Upper Mesozoic and the Tertiary, a tribute to the migratory powers of oil and gas where the rock structures are not sufficiently tight to eliminate transformational migration. In this respect it may also be pointed out that the oilfields which show the most spectacular seepages are largely confined to these same young formations, and in so far as an oil seepage indicates active oil migration, this association shows clearly how much the effects of diastrophism in disturbing the strata and opening up channels of movement lead inevitably to the dispersal of oil and gas [38, 1885]. The processes of sedimentary vulcanism, described elsewhere in this volume, are one of the extreme effects of the migratory powers of gas and oil and are conclusive proof of a process of migration which is so far-reaching as to produce rock types and structures of its own.

Lastly, we may turn to the question of the relationships between the problems of migration and those of oil accumulation. In so far as every oil-pool is considered to be the result of migration which has segregated a dispersed fluid into a commercial oil-pool, it may be asserted that

an oil accumulation owes its existence entirely to the processes of migration. All geologists, however, are not agreed on this point. There is a minority school of thought which considers that oil-pools are essentially of local origin and that the source material either is present within the reservoir rock, and therefore there has been no migration, or it occurs in the fine sediment immediately adjoining the reservoir rock so that the migration is limited to the short passage across the intervening space. To such geologists extensive lateral migration is unacceptable, and in the case of limited sand bodies their attitude has considerable grounds for support.

On the other hand, the bulk of geological evidence points to a considerable amount of migration, both lateral and transformational, and while it is probable that in the main most of this migration was upwards, it may not have been so in all cases. Fluid movements tend to be towards the zones of least pressure, but they choose the paths of least resistance and in exceptional circumstances take a downward rather than an upward course.

In the view of those who support extensive lateral migration, an oil accumulation is merely a mass of oil which has been trapped or segregated from the general fluid movement. It represents a mass brought to a standstill by some inhibiting influence, just as a log raft may be produced by an eddy or obstruction in a river. This analogy, like all analogies, must not be pressed too far, but it depicts the accumulation as but one link in a chain of events which begins with the alteration of organic matter to oil and ends, so far as we can tell, with the dispersal of the oil by erosion. The history of the changes may occupy a long period of geological time, and throughout much of this period the oil and gas may be stationary, but the forces are only in abeyance, and whether it be for the purposes of concentration or dispersal they are the same and lie within the province of a complete study of migration.

SECTION 6

NATURAL ACCUMULATIONS OF PETROLEUM

AN INTRODUCTION TO THE PRINCIPLES OF THE ACCUMULATION OF PETROLEUM

By Professor V. C. ILLING, M.A., F.G.S., M.Inst.P.T.

Imperial College of Science and Technology

An oil-pool consists of a zone of porous or fissured rock saturated with petroleum in which the permeability of the rock mass is sufficient to allow the economic extraction of the liquid impregnation. The oil is usually accompanied by gas and is under considerable pressure. It has been maintained in such a condition by an impervious envelope such as clay or water-saturated rock. As oil and gas are lighter than water there is a general tendency for them to occur on the top of the water-saturated sections of the porous rocks, a condition which prevents their loss from the base of the accumulation. In most instances dispersal of gas and oil tends to take place in an upward direction, so that protection from such action is the most important requirement in an oil-pool. This may be effected in many ways, but is usually achieved by a complete cover of impervious rock, called the cap-rock.

Any geological structure which provides adequate porosity suitably protected by an impervious seal may become an oil-pool, provided it is in contact with a source of petroleum. It is therefore obvious that there must be many geological structures which are favourable for oil accumulation.

Almost as soon as the first commercial oil-wells were drilled in the United States of America, speculation was aroused as to the geological conditions which governed the occurrence of the oil and gas. In 1861 the anticlinal theory was advocated independently by T. Sterry Hunt [2] and E. B. Andrews [1], though it is interesting to note that their conceptions were fundamentally different. The ideas of Sterry Hunt conform in principle to the generally accepted theory that the anticline provides a favourable oil structure because oil and gas float to the highest position they can attain in a water-saturated rock. Andrews, on the other hand, considered that the oil occurrences on anticlines were associated with the secondary fissuring which tends to follow the crests. This fissuring produced zones in which fluid movement could take place, and the oil and gas took advantage of such conditions. There can be little doubt that of these two conceptions the former has obtained a wider application and in its modern form the anticlinal theory is largely built up on Sterry Hunt's original ideas. It is, however, interesting to note that there are some cases of oil-pools which are much affected by zones of fissuring, and though Andrews' theory has been discarded, it has a considerable application in limestone reservoirs.

From these early ideas the geological theories of oil accumulation grew in complexity as oil discoveries ranged into new areas where the geological conditions were different. It is interesting to note that the anticlinal theory is not obviously applicable either in Pennsylvania or in Ohio where it was originally applied, and for many years it was strenuously opposed in that area by Lesley and others. However, in the year 1885 I. C. White [4] reviewed and elaborated the theory, and since that period it has received general recognition.

It was soon recognized that other structures besides anticlines were favourable for oil accumulation, and among these the structural terrace was advocated by Edward Orton [3, 1888] as being of considerable importance in areas of gentle dip. There has been a tendency of recent years to doubt whether such structural terraces are of any significance in the concentration of oil, but whether this be so or not, there was one good service which Orton rendered to geologists in the suggestion that oil accumulations were associated with the movement of water and were not merely examples of static separation. The same emphasis on the importance of water currents is discernible in all the writings of Munn and Griswold, and laid the foundation of a more dynamic theory of oil accumulation in which oil was swept into its position by moving water and held in position by the water table.

Such ideas were applied extensively in the search for new oil-pools in the Mid-Continent during the first two decades of the present century, and zones of arrested oil migration were sought on the terraces, monoclinal noses and ravines, and monoclinal domes of the great prairie plains monocline of Kansas and Oklahoma. Any important anomaly in an otherwise uniformly dipping series was considered worthy of drilling, and many oil-pools were discovered on such principles.

The underlying principles governing this search were the application of the idea that an oil-pool represented a phase of arrested migration along a porous rock. The oil and gas had been caught in the structure just as driftwood might accumulate in the back eddy of a river, and the whole technique of oil discovery in such regions of gentle monoclinal dip developed on the lines of searching for and drilling on such abnormalities in the general structure. Faults, too, became a recognized cause of oil arrest, but it was not so much in the Palaeozoic regions of the Mid-Continent as in the Cretaceous monocline of East Texas that the incidence of faulting was first recognized as a dominant influence in the formation of oil-pools. There, in what has been called the Balcones Fault region, the trapping effects of faults were so clearly displayed that there could be no doubt of their importance. The fault in this case was recognized as having created a trap structure by breaking the continuity of the porous bed and plastering its truncated edge with a down-faulted segment of impervious material.

Meanwhile in other areas geological opinion was developing independently along other lines. The structural problems were different, and the oil-pools' relations to the geology were therefore also different. Among the Tertiary fields which followed the main lines of folding there was never any doubt as to the incidence of the anticline; indeed, geologists tended to lose sight of the fact that other conditions besides anticlines could be responsible for oil-traps. The importance of faulting in fold structures was, however, so plain that it demanded recognition, and normal faults, reversed faults, and thrusts were shown to have had a marked influence on the storage of petroleum. One feature which ought to have been obvious merely from a consideration of first principles took a long time to gain

its share of recognition. This was the importance of lenticularity in all types of geological structures as a qualifying influence which limited the application of all other structural theories. This is perhaps seen best in the case of the anticline, where it is now recognized that in regions where the size of the sand bodies is relatively small compared with the size of the folds, the truth of the anticlinal theory becomes limited to the statement that it is the upper part of each sand lens, i.e. the part nearest to the anticlinal crest, which becomes the oil-bearing sector. In such regions the oil-pools may be developed so far down into the synclines that it becomes invidious to speak of the pools as anticlinal. Faulting and lenticularity play an exceedingly important part in fold fields, and many a segment in a typical anticlinal pool owes its importance to these features rather than to the folding.

In the region of the Gulf States and in Germany an essentially different type of oil-pool structure was discovered in the areas occupied by salt-domes. Here the oil was found associated with plugs of salt. It accumulated over the salt-domes or in the highly disturbed strata on their flanks, and a new technique of oil discovery, coupled later on with geophysical investigations, was developed in such areas.

In the meantime, as the more obvious structural zones were drilled up and our knowledge of the structure of oil-pools became more complete, it was realized that some of the earlier structural theories of some of the oil-pools required modification. Foremost among these was the discovery that many of the so-called monoclinal fold fields of the Mid-Continent were probably examples of sedimentation and compaction around buried ridges, and such unconformable conditions began to assume a greater importance in theories of the development of oil-pools. The incidence of such pools as Midway-Sunset had been noted, but their significance had not been stressed until the discovery of the large number of buried structures in the Mid-Continent, and finally the accidental but highly significant discovery of the East Texas pool drew attention again to the importance of unconformities. There is little doubt that the fruitfulness of such ideas has not yet been fully exploited, and oil discovery so far as the geologist is concerned is becoming more and more not merely a study of structure, but a complete study of the whole geological history of an area, a discussion of the phases of sedimentation, and the breaks in such episodes. These take their place with the effects of folding and faulting in the trapping of the oil and gas. In other words, an oil-pool is recognized as an organic whole which has been brought into being by one suite of conditions and preserved by another.

This recognition of the fundamental complexity of the history of most oil-pools and of the many independent features which have had a part in their development, makes it difficult and sometimes even grotesque to label particular pools as being due to single structural causes. Furthermore, a classification of oil-pool structures becomes a meaningless catalogue of all types of structures, for in actual fact oil-pools have been discovered in practically all types, though it is true not with equal frequency. Anticlines, faults, unconformities, the development of induced fissuring, &c., all play their parts, and often their influences are so intermingled that in some pools it is difficult to choose the dominant cause of the accumulation.

In these circumstances it is far better not to attempt an artificial classification of oil-pools, but to consider the broad effects of particular regional types of structural conditions on the formation of oil-pools. In this way the behaviour of oil and gas in different regional structures can be studied and the factors which lead to their arrest in particular areas can be carefully weighed.

THE POROSITY OF RESERVOIR ROCKS

By S. E. COOMBER, A.R.S.M., B.Sc., D.I.C.
Imperial College of Science and Technology

In order that a rock may be an effective reservoir two conditions must be satisfied: it must be porous and it must be permeable. Porosity implies the presence of void space within the rock, whilst permeability connotes the ability of the rock to permit passage of fluid through it. The two terms are therefore not synonymous. A permeable rock must be to some extent porous, but a porous rock need not be permeable. As an illustration two cases may be cited, that of pumice and that of a loose, unconsolidated sand. Pumice is very porous, but its pores are isolated one from another and therefore it is impermeable. A loose sand, on the other hand, is also very porous, but there is free communication from pore to pore, and therefore it is very permeable. The permeability of reservoir rocks is dealt with elsewhere in this volume (G. L. Hassler, pp. 198 207), and only those factors relating to the porosity of a rock will be considered here.

The porosity of a reservoir rock is defined as the relative volume of void space in the rock and is usually expressed in the form of a percentage. Its significance lies in the fact that it is a measure of the volume of fluid which may be stored within the rock. The study of porosity involves an examination of the types and extent of the voids, and two distinct measurements are possible—that of the relative volume of the total void space in the rock and that of the relative volume of only those voids which are in intercommunication throughout the rock. The first measurement is termed the total or bulk porosity of the rock, and the second is termed the effective porosity. When dealing with reservoir conditions it is the effective porosity which is significant.

Petroleum reservoir rocks are, with few exceptions, sedimentary in type, and the greater number are sands, sandstones, limestones, or dolomites. There are some cases where accumulation has taken place in finer grained rocks such as shales; more rarely, igneous rocks have become reservoirs of petroleum. These rocks vary considerably in structure and texture, and since their porosity is related to those factors it will be convenient to discuss them from that point of view. They fall into two main groups, unconsolidated rocks and consolidated rocks. Unconsolidated rocks are an aggregate of loose particles and are typified by sands and gravels. In a consolidated rock the particles are tightly packed and held together by some form of cementing material so that the mass as a whole has coherence. Sandstones, limestones, and shales are typical consolidated rocks. A table is appended giving representative figures for the porosity of some typical reservoir rocks.

Unconsolidated Rocks.

Unconsolidated rocks are essentially an aggregate of particles which are predominantly siliceous. These may vary in size from pebbles, or even larger, down to the finest silts, whilst their shape may vary from tabular to spherical. In general, however, most oil sands fall within much narrower limits both with regard to the size and the shape of their constituent particles. The distribution of particle sizes in any particular rock is very variable. In a well-graded deposit the greater number of the particles are of the same order of size, whereas in a poorly-graded deposit there may be particles of all sizes.

It is obvious that particles of this type cannot fit tightly together as would rectangular blocks, and therefore porosity must be developed to some degree in such a rock. The extent to which it is developed depends upon the grading, the shape, and the manner in which the particles pack together. In the case of spherical particles an analysis of the properties of the aggregate is possible and details of this may be obtained by reference to a paper by Graton and Fraser [3, 1935]. An important fact emerging from such an analysis is that the porosity of the aggregate is independent of the size of the spheres provided that they are uniform. The addition of either larger or smaller spheres will, however, tend to reduce its porosity. These facts, so easily demonstrated in the case of spheres, are fundamental factors governing the porosity of sands and may be expressed simply as follows: the more even the grading of a sand, the higher its porosity will tend to be. The fact that porosity is independent of the size of the grains, except in the case of the smallest, is of especial significance in reservoirs. A fine-grained rock may be equally as porous as a coarse-grained rock, and yet the former may not be so effective a reservoir as the latter on account of the difficulty which fluids may have in passing through the very fine pores and on account of the considerably greater surface area of the particles which retains a correspondingly greater amount of fluid on it. The importance of making permeability measurements as well as porosity measurements cannot be too strongly stressed. Some departure from the rule stating the independence of porosity on particle size is experienced in the case of very small particles. Their large surface area and low settling velocity introduce factors which tend to prevent them from packing together as tightly as coarser particles, and therefore the resulting porosity is higher than one would at first sight presume.

The effect of the shape of the particles on the porosity of a sand cannot be shown so easily. It is to be expected with angular particles that bridging takes place to some extent with the formation locally of larger voids. According to Fraser [2, 1935], who conducted experiments with particles of different shapes, angularity usually causes some increase in porosity, but ordinary, moderately well-rounded sands do not vary greatly in this respect.

Compaction is another factor for which it is difficult to make due allowance since representative samples of the deposit are but rarely obtained. Samples from a borehole are merely a heap of loose grains, and it is impossible to say whether or not they are in a state of maximum compaction when in the deposit. Measurements, therefore, must be made with the sample compacted to the highest degree possible and the result recorded as being the minimum porosity of the sample taken. It is probable in most cases that this approaches closely to the true value.

The porosity of spheres of a uniform size varies between 47·6 and 26% according to the manner in which they are packed together. Fig. 1 shows spheres arranged in the most compact form. The porosity of natural sands falls generally

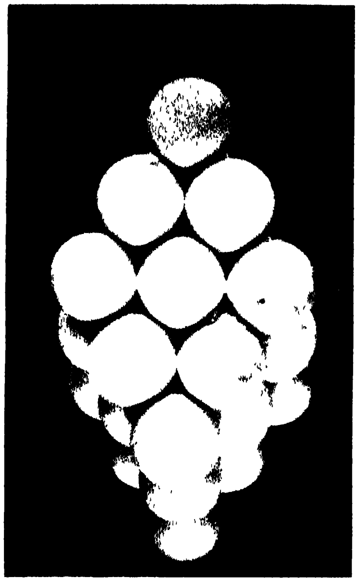

FIG. 1 Spheres arranged in the most compact form

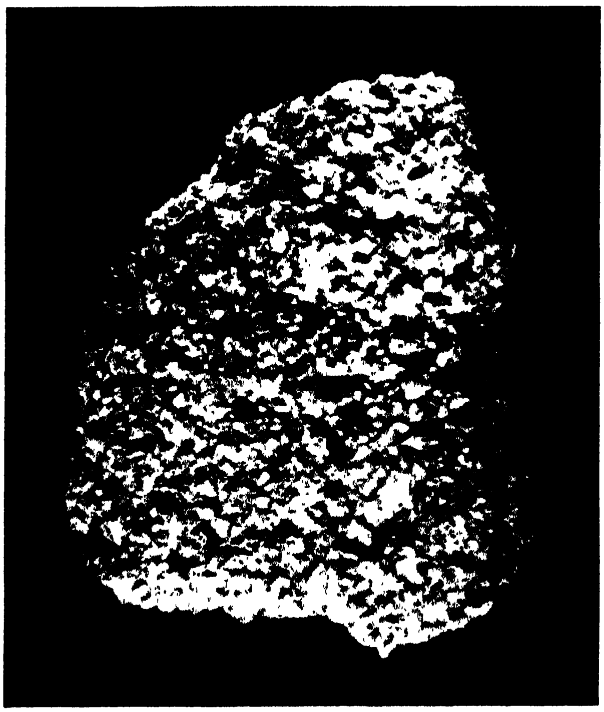

FIG. 2. Pechelbronn oil-sand. ×3

within the limits given above, and for normal, fairly well-rounded and well-graded sands it varies between 35 and 40%. Sands which are not so well graded have porosities of the order of 30%. To illustrate the effect of porosities of this order on the capacity of a reservoir the void space per acre of sand 10 ft. thick can be calculated. With a porosity of 30% it is 130,680 cu. ft. or 23,261 bbl., and with a porosity of 40% it is 174,240 cu. ft. or 31,015 bbl.

Consolidated Rocks.

The various types of consolidated rocks are best described individually, and as sandstones are more closely related in structure to the unconsolidated sands than are the other consolidated rocks, they may be dealt with first. A sandstone may be defined as a sand in the pore space of which there is sufficient cementing material, usually ferruginous, calcareous, or siliceous in nature, to give the mass coherence. The cement may either partially or wholly fill the pores. The porosity of the rock, therefore, is governed by the same factors as those governing the porosity of an unconsolidated sand, subjected to the additional factor due to the presence of the cement. A sandstone, however, is a competent rock, and as such it may be jointed and is also liable to be cracked and broken by stresses and strains of various origins. These stresses and strains may be external, the result of earth movements, or they may be internal, the result of crystallization of minerals from solutions which have entered the pores. The net result is similar and the cracks and fissures thus formed will give the rock an added porosity. In a well-cemented sandstone its porosity may be almost entirely due to such phenomena. The porosity of a sandstone may also be increased in certain cases by the leaching action of circulating waters on the cement. Some idea of the magnitude of the measurable porosity developed in sandstone reservoirs may be obtained by reference to the table.

The term 'limestone' may be extended for the present purpose to include true limestones, dolomitic limestone, and dolomites. The composition of these rocks varies widely and to some extent it has a bearing on their porosity. In certain cases a limestone may have a granular structure and so be comparable with a sandstone. The chief representatives of this class are chalk and oolitic limestones. A pseudo-granular structure is also developed locally in some dolomitic limestones due to the crystalline form of the dolomite. In other cases dolomitization may cause porosity to be increased to some extent due to shrinkage during the mineral change. This has been demonstrated by Parsons [8, 1922] in the case of the magnesian limestone of Derbyshire. The usual limestone reservoir rocks, however, have little inherent porosity, and their capability of storage is due mainly to two factors: (*a*) jointing and fracturing, and (*b*) solution.

The effect of joints and of fractures on the porosity of limestones is similar to that in the case of sandstones and other competent rocks which may have been shattered. The Asmari limestone, the reservoir rock of the Persian field, may be cited as a good example of this condition and has been described by Lees [5, 1933] as a normal, fine-grained rock with a lack of obvious porosity. A fresh core may sweat gassy oil, but mainly or entirely from cracks and small mineralized veins.

Limestones in which the porosity is due to solution undoubtedly form the most important class. Howard [4, 1928] considers that possibly 95% of the known limestone reservoirs owe their porosity to this cause. The effect of solution is varied; it may produce a honeycombed type of structure or it may be cavernous. In any case measurements are not possible.

Shales and similar fine-grained rocks present a difficult problem. In some cases the grain size is fairly uniform and they are then relatively porous. The size of the pores, however, is so fine that they cannot be reservoirs on that account. The ability of such rocks to act as reservoirs is due to the presence of bedding planes and to shattering with its consequent formation of cracks. Porosity measurements may therefore be very misleading and due attention should be paid to this point.

TABLE I

The Porosity of Some Typical Reservoir Rocks

Type of rock	*Formation*	*Field*	*Porosity*
SAND: 50% of the grains > 0·3 mm.	Upper Etchegoin, Pliocene	Elk Hills, Kern Co., California	24-35%
SANDSTONE: uniform, fine-grained, slightly dolomitic sandstone	Wilcox sand, Simpson formation, Ordovician	Gt. Seminole, Oklahoma	16%
SANDSTONE: irregular grains, average size 0·1 mm., siliceous cement	Whirlpool sandstone, Lower Silurian	Clinton-Medina fields, Ontario	10%
SANDSTONE: uniform grain size, well cemented	Bradford sand, Chemung formation, Devonian	Bradford field, Pennsylvania	11-17%
SANDSTONE: grain size mainly 0·1-0·25 mm., siliceous and calcareous cement	Woodbine sand, Upper Cretaceous	East Texas field	18-22%
SILTSTONE: siltstone and shale with numerous small lenses of sand	Bowdoin sand, Colorado Shale, Upper Cretaceous	Bowdoin dome, Montana	<10%
LIMESTONE: no signs of dolomitization	El Abra limestone, Lower Cretaceous	Tepetate, Mexico	5-12%
LIMESTONE: porous and, in some places, cavernous chalk	Selma chalk, Upper Cretaceous	Jackson field, Mississippi	5-20%
LIMESTONE: fine-grained, foraminiferal limestone	Asmari limestone, Lower Miocene	Masjid-i-Sulaiman, Persia	1-16%

As previously mentioned, igneous rocks are reservoirs in some fields. The lithology of such rocks varies considerably, but their porosity is due mainly to vesicular structure, jointing, fracturing, or any combination of those factors. As may be expected, the porosity of such a rock is very irregular and is not amenable to ordinary measurements.

In the above brief summary of the characteristics of the various types of reservoir rocks it has been shown how the porosity may vary with differences in lithology. The correct application of the results of porosity measurements is only possible when a knowledge of that variation is used in conjunction with the data available on the conditions under which the rock was deposited and its subsequent history. Thus in the case of a sand, the type of the deposit will throw some light on its horizontal extent and on the variation in grading. This in turn is of assistance in deciding to what degree the porosity may be relatively uniform and in what direction it may be expected to vary. For instance, where large sheet-like bodies of sand have been deposited off a shoreline regular conditions are usually developed parallel to the shore, whilst the greatest variations occur along a section at right angles to the shore. When dealing with cemented rocks it is more difficult correctly to apply the results of porosity measurements. A study of the lithology of the reservoir will indicate to what extent the rock is uniform. This will give some indication as to possible variations in the measured porosity. There must be considered in addition, however, the porosity induced by cracks, fissures, solution, &c., and this will figure in the measurements only in the case of the finest of the cracks. The measured porosity in such a case is therefore the minimum porosity of the rock. The history of the rock subsequent to deposition must now be considered. If it has been faulted, then the nature of the rock in relation to the degree of faulting may give some indication of the extent to which it has been cracked and broken. As already pointed out, in limestones the effect of solution is even more important than that of fractures. If there is evidence to show that the limestone has been subjected to the action of circulating surface waters, then one may expect solution, in most cases to some considerable degree, to have taken place. It is not possible to come to any conclusion concerning the porosity of such a reservoir as a whole. A similar conclusion is true in the case of shale and igneous rock reservoirs.

In view of the above facts it would seem that to strive for a high degree of accuracy in the measurements is not necessary for ordinary practice. Simplicity and ease of operation are of greater importance. Samples of consolidated rocks should be as large and as numerous as possible in order to reduce the effect of small irregularities. Many methods of making porosity measurements have been evolved, and references to these are to be found in the literature dealing with ceramics, refractories, water-supply, &c., as well as in that dealing with petroleum reservoir rocks. The basic principles are few, and it follows that these many methods are but adaptations from them, in some cases to suit special circumstances. Methods will be described here for measuring the porosity of both unconsolidated and consolidated rocks. They may be classified as follows:

A. Measurements on unconsolidated rocks.
B. Measurements on consolidated rocks.
  (1) Total porosity
  (2) Effective porosity:
    (*a*) Liquid absorption methods,
    (*b*) Gas expansion methods.

Before any measurements can be attempted it is necessary to remove what moisture, oil, and bitumen may be present in the sample. Water is removed by drying in an oven for several hours at 110° C. The oil and bitumen are best removed by extraction in a Soxhlet type extractor. Unconsolidated sands are placed in an extraction thimble of suitable size. Large pieces of consolidated rock call for a Soxhlet extractor made of metal. Extraction is continued until the returning solvent shows no sign of discoloration, a process which may take several hours. Suitable solvents are carbon disulphide or benzene.

A. Porosity Measurements on Unconsolidated Rocks.

The method recommended is similar to that described by Nutting [7, 1930]. The apparatus is merely a small cylindrical glass jar to which a flat cover fits with a ground joint—see Fig. 3. The volume of this vessel is determined

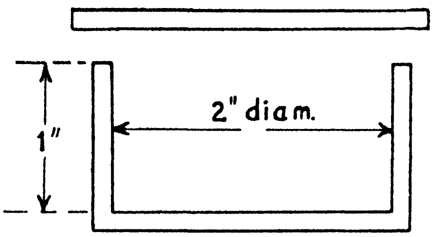

FIG. 3. Glass jar used in porosity measurements on unconsolidated sands.

and it is then filled with the sand, care being taken to compact the latter as much as possible, and its weight determined. The volume of the sand is calculated by dividing its weight by its specific gravity, and for most purposes it is sufficiently accurate to assume that the sand is entirely quartz, a value of 2·65 then being used. The volume of the vessel minus the volume of the solid particles gives the volume of the pore space.

B. Porosity Measurements on Consolidated Rocks.

(1) **Total Porosity.** The total volume of the oil- and moisture-free sample is determined by mensuration in the case of specimens of regular shape or by measuring the volume of water which it will displace if it is irregular. In the latter case it must be coated with an impervious medium such as wax before immersion, due allowance being made for the volume of the wax. The volume of the solid matter in the specimen is determined by weighing and then dividing by its specific gravity. Specific gravity measurements may be made with a small sample of the crushed rock in a pycnometer.

(2) **Effective Porosity.** (*a*) **Liquid absorption method.** This method, in brief, consists in causing a known volume of the rock to absorb a maximum volume of liquid such as benzene and then measuring the volume of liquid so absorbed. By this means the amount of pore space in free communication is determined. The apparatus required is a form of pycnometer, the method being described by Thomas, Chisholm, and Cameron [9, 1935]. A suitable form of the apparatus for general use is illustrated in Fig. 4. The specimen is placed in the vessel which is then evacuated to the highest degree possible. It is next inverted with the tube from the stopcock immersed in the liquid and the liquid allowed to enter. By means of weighings it is possible to determine the weight of liquid displaced by the solid rock and the non-effective pore space, and hence the volume of those items may be calculated. The total

volume of the specimen is determined as described in the method of measuring total porosity.

This method is suitable for hard, well-cemented rocks. If the rock is at all friable it will tend to disintegrate when liquid enters its pores, and hence for such rocks the gas expansion method should be used.

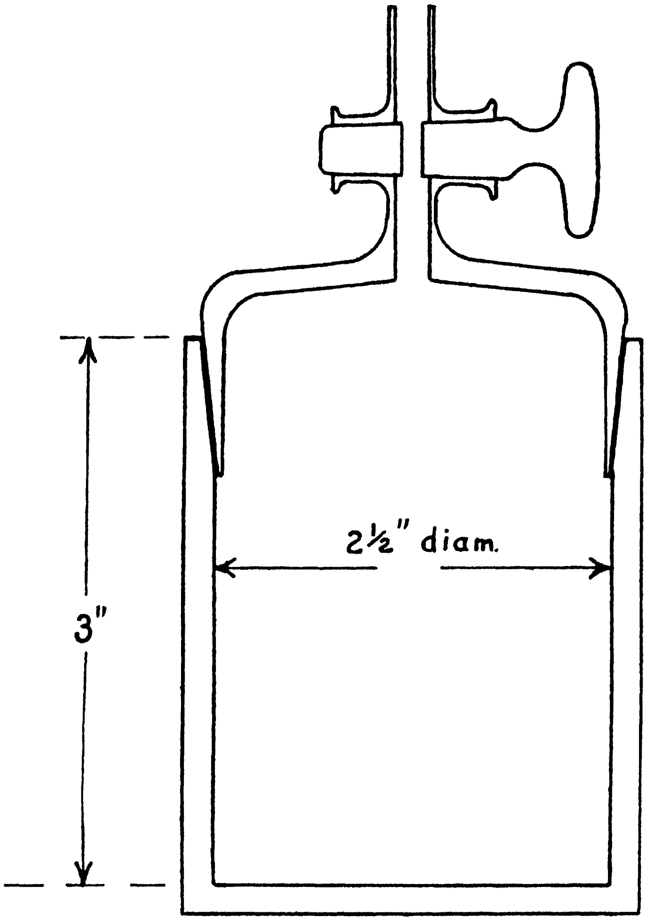

FIG. 4. Vessel for measuring porosity by the liquid absorption method.

(*b*) **Gas expansion method.** This method is an application of Boyle's law regarding the expansion of gases. If two vessels contain a gas at known pressures and the volume of one of the vessels be known, then the volume of the other may be calculated if the two vessels are placed in communication and the resulting pressure noted.

Many descriptions of suitable forms of apparatus have appeared, notably in publications by Coberly and Stevens [1, 1933], MacGee [6, 1926], Washburne and Bunting [10, 1922], and others. They may be classified into two groups, those in which the initial pressure difference is produced by compression, and those in which it is produced by exhaustion. An excellent example of the former type is described by Thomas, Chisholm, and Cameron [9, 1935]. The compression type of apparatus, however, has the disadvantage that the cover of the chamber containing the specimen needs to be secured in position by bolts, thereby causing the difficulty of ensuring that its volume shall not alter each time the cover is replaced. If, instead of compression, exhaustion be used, then a very simple apparatus may be designed, a suitable type being illustrated in Fig. 5. The main factor in design is the ratio between the volumes of the two vessels. With the specimen in place the volume

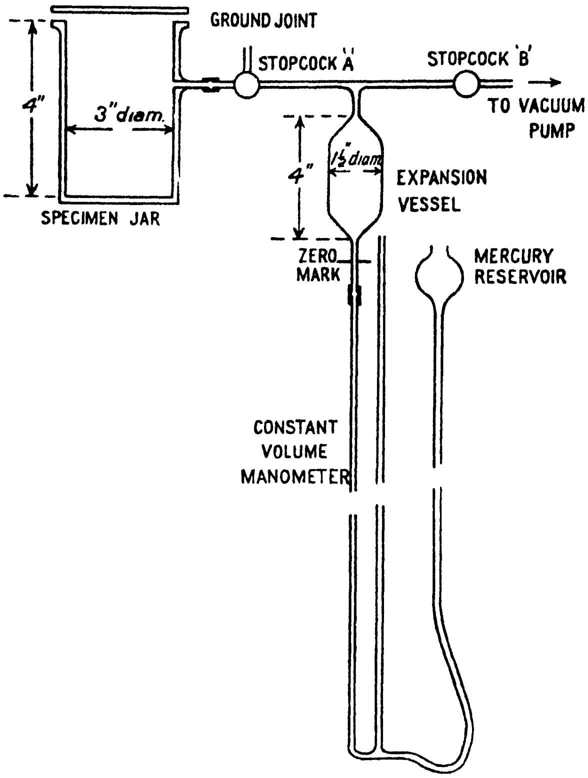

FIG. 5. Gas expansion apparatus for porosity measurements.

of free air space in each vessel should be approximately equal in order to minimize errors due to inaccurate pressure readings. The specimen should as far as possible fill the vessel, and therefore the second vessel should have a volume comparable to the effective pore space of the specimen. For general purposes this should be assumed to be 10–15%. If it is not possible to obtain a specimen which fills the vessel, the remaining space may be filled with sand and allowance made for its volume in the subsequent calculations. Care should also be taken to ensure that the specimen is quite dry, for otherwise considerable errors may be introduced by vapour. As in the case of the liquid absorption method, the volume of the solid matter plus the non-effective pore space is obtained. The total volume of the specimen is determined by mensuration or by the displacement of water.

THE ORIGIN OF PRESSURE IN OIL-POOLS

By Professor V. C. ILLING, M.A., F.G.S., M.Inst.P.T.
Imperial College of Science and Technology

THE normal oil-pool is an association of gas, oil, and water in a porous rock. The gas may be entirely dissolved in the oil or it may exist partly in this state and partly as free gas above the general oil zone. The oil lies above the water, and usually the line of demarcation between the two, the 'edge-water' line, is clearly defined. The whole of this liquid and gas is under considerable pressure, which is usually sufficient to force the oil to the surface in the early stages of a developing field. Various terms have been used for this pressure: rock pressure, formation pressure, reservoir pressure, &c. Probably the term reservoir pressure is the most appropriate to a discussion of the pressures within the reservoir, for such terms as rock pressure may be used more strictly to indicate pressures within a rock mass by virtue of its own transmission of pressure. It must be admitted, however, that there is no common agreement on this point, and the terms are often used synonymously.

Before proceeding to a discussion of the origin of these pressures it is advisable that some attention be given to the actual conditions in individual fields and more particularly to the pressure declines which occur as these fields are exhausted. The gas, oil, and water in the reservoir are subjected to the same physical laws throughout their confinement, but the conditions are necessarily complex and changing, and it is this variability which determines the behaviour of the reservoir contents at different periods.

As a general rule the pressures within a given oil-pool tend to increase with depth, so that as deeper formations are penetrated the reservoir pressure of each successive older formation tends to increase. Thus it becomes, in a very general way, a function of depth.

In the Muskegon field of Michigan the following data illustrate the relationship of depth to initial reservoir pressures [9, 1935]. The fourth column gives for comparison the calculated pressure of a water column at the same depth.

TABLE I

Formation	*Depth, ft.*	*Initial pressure, lb. per sq. in.*	*Calculated hydrostatic pressure, lb. per sq. in.*
Upper Traverse	1,590–1,650	630	691–718
Lower ,,	1,810–1,890	710	787–822
Dundee	1,960–2,030	920	850–881
Monroe	2,160–2,230	940	942–972

As a further instance of the increase of reservoir pressures with depth the case of a gas-well at Clarksville in Arkansas may be cited [3, 1935].

TABLE II

Sand	*Depth, ft.*	*Rock pressure, lb. per sq. in.*
Russell	2,875	770
Qualls	3,025	810
Kirwin	3,165	1,125

There are, however, too many exceptions to this general rule to allow it to be regarded as more than an approximation. Depth alone cannot be the sole determinant of rock pressure. The following reservoir pressures were measured on one lease of the Seminole field, Oklahoma [8, 1931].

TABLE III

Formation	*Depth, ft.*	*Pressure, lb. per sq. in.*	*Equivalent head of fresh-water, ft.*
Miscrer Sand	3,967	988	2,276
Hunton Lst.	3,980	1,520	3,520
Simpson Dol.	4,068	1,152	2,654
1st Wilcox	4,124	637	1,467
2nd Wilcox	4,217	800	1,843

It will be noted that the deeper Wilcox Sands have much lower pressures than the overlying formations and, furthermore, there are large differences in pressure in formations separated by only a few feet of sediments.

Variations from the normal pressures may be either upwards or downwards. Heroy [5, 1928] quotes Orton as having noticed an instance of a pressure of 1,540 lb. per sq. in. in a well only 2,370 ft. deep which he was unable to explain as due to artesian head. Other cases of abnormally high pressures will be given later. Instances of abnormally low pressures are widespread. In the Cleveland field of Ohio the initial reservoir pressure for the Trenton Limestone at a depth of 4,500 ft. was only 37 lb. per sq. in. [4, 1931]. In the Panhandle field the reservoir pressures are subnormal [2, 1935], being usually less than one-half of the normal hydrostatic head. Krejci-Graf [7, 1930] gives an instance at Boldesti, Roumania, where the pressure of a sand at 1,541 metres was 185 atm., whereas that of a deeper sand at 1,681 metres was only 89 atm., equivalent to an increase in pressure with depth of only 23·7 lb. per sq. in. per 100 ft.

As an actual fact there is no constancy in the rate of pressure increase with depth. The following instances indicate this point [4, 1931].

TABLE IV

Pressure Changes During Production.

The history of the pressure changes as a field is being developed may depend on a number of circumstances. In some gasfields the decline in pressure appears to be directly proportional to the depletion of the gas in the reservoir. Such a pool acts as though it were a limited quantity of gas compressed into a container of fixed volume. The gas seems to be the seat of the pressure, and as the gas is

exhausted the pressure drops proportionally. This condition can be more closely followed in a simple gas-pool than in one containing both oil and gas, for in the latter the conditions are complicated by gas dissolved in the oil. As the pressure declines with gas depletion a certain amount of replenishment takes place by gas coming out of solution and the pressure decline is therefore partially checked. Here again, however, the conditions are governed strictly by physical laws, but the introduction of an additional phase, solution, into the conditions merely adds to the complication.

There are, however, some oilfields where the drop in pressure during the exhaustion of the oil and gas is not at all commensurate with the depletion of these materials. The wells change from oil-wells to water-wells with very little change in pressure, and in certain extreme cases the whole field goes progressively to water without any marked decline in the pressure. Such fields are in strong contrast to those considered above, and it is difficult to believe that the control of the pressure is the same in both cases.

The two conditions referred to above are symptomatic of the behaviour of most oilfields. As a general rule their behaviour lies between these two extremes, but there is on the whole a tendency to approach the first condition rather than the second. In other words, the depletion of the oil and gas leads to a gradual decline in pressure. The source of the available pressure generally lies in the gas rather than in the liquids, and this reserve of energy is conserved as far as possible in modern methods of exploitation.

It may also be noted that the two types of pressure conditions in oilfields appear to be closely related to the freedom of movement of the edge-waters. In most oilfields this movement is distinctly limited. Partial exhaustion causes a rise in the edge-water table, but complete exhaustion leaves the field with a considerable area under negligible pressure into which the edge-waters have not penetrated. There are only a few oilfields in which water completely displaces the oil and gas in the last stage of exhaustion, just as there are only a few fields in which the pressure is maintained throughout the life of the field without artificial means of pressure maintainance. As a counterpart to the latter condition there are some oil-pools in which no edge-water movement of any kind can be noted throughout the exhaustion of the field. In such fields the seat of pressure obviously cannot lie in the water.

These two types of behaviour in oilfields find a simple explanation in the physical conditions which control the gas, oil, and water.

An oil-pool is a quantity of gas and oil lying in a porous receptacle and usually associated with a variable quantity of water. The reservoir rock is both porous and permeable and it is usually completely enclosed in an impermeable envelope. There is one important and very variable factor in all reservoirs, i.e. their relative size. Some may be quite small and the total void space can be measured at the most in a few thousand barrels. They may be too small to provide sufficient oil for a single commercial well, in which case only a succession of such bodies can create a successful field. Other reservoirs are merely portions of widespread rock masses in which the volume of pore space in physical continuity may exceed in volume by many thousands of times the volume of oil and gas in the reservoir. The excess volume in such a case is occupied by water.

The variation in the volume of the reservoir and in the ratio of the combined oil and gas volume to water have an important bearing on the behaviour of the oil and gas during exhaustion of the reservoir. An oil and gas zone in a limited reservoir will obviously occupy a considerable proportion of the reservoir capacity. The depletion of the oil and gas will leave nothing but the water to occupy the space, and the supply of water being limited, there is a resulting drop of pressure in proportion to the gas and oil depletion. On the other hand, an oil-pool in an almost unlimited reservoir rock bears but a small ratio to the total void space in intercommunication. There are extraneous factors which may affect the pressure within this reservoir rock, and these will communicate themselves to the water zone in addition to the pressure due to the gas- and oil-pool. The edge-waters of such a pool are therefore under pressures from several sources, and if the oil and gas in the pool are removed, the extraneous sources of pressure cause water movement until a new equilibrium is attained.

Thus the variable behaviour of different pools may be largely explained by the differences in size of the reservoirs, and when it is remembered that the permeabilities of the latter may also differ very markedly, the variable time lag required for these readjustments finds an adequate explanation.

It is important to note that oil and water are relatively incompressible. They cannot, therefore, in themselves maintain a condition of pressure if even a slight expansion be allowed in their volume. They can only exert continuous pressure where they transmit pressure from a contiguous source such as a connected gas-pool, or by the replenishment of the fluid pressure by access of further liquid, as occurs in artesian conditions.

Some slight alterations are possible in the pore space of reservoir rocks, but these are likely to be small or at any rate their variations will be slow. No sudden change in pressure can therefore be produced by sudden changes in the pore space, though there is reason to believe that in some rocks changes in the porosity may be induced by collapse as a result of diminution in pressure.

Gas, whether free or in solution, is the important medium whereby pressure can be fossilized and maintained. The enormous volume changes associated with alterations in pressure conditions enable the gas to portray the pressure conditions to which it has been subjected, so long as pressure relief has not been allowed to intervene. When, therefore, we inquire into the origin of reservoir pressure in oilfields, a considerable part of the discussion centres on the origin of the gas pressure.

Possible Sources of Pressure

Pressure due to a Water Column.

The simplest and most obvious source of pressure in a rock within the earth's crust is that due to the head of water filling the pores of the rock and in communication with the surface. Such a water column must exert its equivalent pressure and will produce a corresponding flow if the pressures in the water zone are not balanced. The simplest example of this is the condition in an artesian well where a water-saturated permeable rock folded into the form of a basin gives a high pressure in the bottom of the basin due to the weight of the water column on the flanks.

Edward Orton, in one of the classics of petroleum literature [10, 1888], made out a strong case for this theory. He pointed out that the gas, oil, and water are under pressure and the oil- and gasfields are surrounded by rocks saturated with water under pressure. The rock in the case he was discussing outcropped some distance away and must have

been fed with meteoric water at the surface. It is interesting to note the inferences which he drew as to the probable attributes of pressures due to such conditions. The rock pressure will increase with depth and will depend on the differences in height between the reservoir rock and its corresponding outcrop. The pressure will continue with unabated force until the last stages of production, and the gas and oil will ultimately be replaced by water. The supplies of oil and gas will be limited, and once the water column has risen in the field the life of the latter is at an end.

Applying these conclusions to the history of oilfields in the period since Orton first put them forward, it is interesting to note that they apply in full to only a few cases, though they are partially applicable in a number of fields. In some of the Mexican oilfields the pressures appear to show very little decline during production and the oil is rapidly replaced by salt-water as the edge-waters rise. The ultimate movement of the latter is very considerable and the whole field tends to become flooded. In most oilfields some edge-water movement occurs during production, but the movement is more restricted in its general scope. There can be little doubt that the rapid pressure declines in many oilfields have resulted from faulty methods of production, but that does not alter the fact that the normal course of most oilfields is for there to be a drop in pressure as the field becomes exhausted, until finally the pressure becomes negligible. This, and the limited nature of the edge-water movement, indicates conclusively that for such fields the seat of the pressure cannot lie in the water which surrounds the pool. Furthermore, the examples cited above of the anomalies in the pressures of neighbouring sands and the variable rate of pressure increase with depth indicate that some other sources of pressure must be available. Within a limited sand lens surrounded by clays it is difficult to see how a water head could be developed unless we ascribe a condition of permeability to the formations, which is in conflict with their physical properties. The majority of oil reservoir rocks are somewhat limited in their lateral extent, and in such bodies artesian pressures are unlikely to occur. In the case of the extensive reservoir rocks there is no reason to exclude the development of pressures due to head of water. In such cases it is inevitable that the extensive water sheet will be under pressure, but whether it will be entirely due to the head of water or to other conditions will depend on the circumstances. The fact that edge-waters are normally saline, while artesian waters are fresh, does not prove that the pressures in the former cannot be due to a head of water. The flushing of the saline waters out of the formations can only take place when there is sufficient erosion to involve extensive circulation of the waters within the formation.

Pressures due to the Weight of Sediment.

During the early stages of sedimentation the argillaceous beds undergo compression as the overlying sediments add to the load. This diminution in volume is associated with the expulsion of water and any other fluid or gas which may occur in the clays. The compression is resisted by the gel strength of the clays and by their increasing impermeability, which limits the ease of water movement. The pressures within this compacting medium must therefore reflect the weight of the superincumbent mass, and as the fluids can only escape along certain restricted paths, the pressures on the clays will be partially transmitted to the fluids within them. As the process of compaction advances the outflow of the compaction fluids becomes more difficult, so that the pressures in the fluid and in the sediment itself become practically identical.

The plastic clay and its own compaction fluids develop a pressure gradient downwards by virtue of their combined weight, and the pressures of the liquids or gases in any completely enclosed sand bodies will be determined by this pressure gradient even though the sand itself may not be compressible. There are some oilfields in exceedingly young strata which appear to simulate these conditions. At Goose Creek in the Gulf States fields of Texas the formations are young and poorly compacted [11, 1926]. The clays contain as much as 30% of water, and the sands are soft, poorly consolidated, and lenticular. Thus the general fluid movement is greatly limited by the clays. Commercial oil production has been obtained at depths varying from 1,000 to over 4,000 ft. in strata varying in age from Pleistocene to Upper Oligocene. During the extraction of the oil and gas subsidence of the surface has occurred coinciding with the area of extraction. The amount of subsidence is approximately one-fifth of the volume of extracted materials. This appears to be a case of accelerated compaction due to the loss of pressure in the oil sands caused by drilling. The lower pressures thus induced have allowed further compaction in the clays around the sands, and the surface has in consequence subsided.

So long as the general mass of sediments is plastic the pressures are commensurate with the weight of the overlying materials, and both fluid and rock substance contribute to the pressure. In this case the term 'rock pressure' would give a true picture of the conditions. The fluids within this medium find it difficult to force an exit, and their pressures are therefore closely comparable to that of the enclosing medium. If, however, there be a sand body or other extensive permeable rock which provides an easy passage for fluids out of the compacting medium, the pressures within this sand body may be considerably below the average pressures for an enclosed lens at the same depth. The presence of such a sand body may create a low-pressure system within the fluids in the neighbourhood. In other words, the pressures within the sands depend in part on the pressures within the compacting medium, but they are also influenced by the ease of egress of the compacting fluids. This latter point will explain some of the differences in the pressures in neighbouring sands. A limited sand mass surrounded by a thick sheath of clays will reflect more truly the actual pressure in the clay medium than a sand mass which extends into regions of lower pressure and which will therefore be controlled by the latter.

It has been said that the pressures built up in this manner will be commensurate with the weight of the overlying material. If the substances were true liquids the pressures produced would be equivalent to the head, but the materials are not liquid, and as they get more compressed they depart more and more from this condition. The result is that the rock pressure produced is but a fraction of the weight of the sediments, and as the rocks become more rigid this departure becomes more pronounced. Turning our attention for a moment to the fluids within the sediments, we may consider that the pressures within them are dominated by two factors, the compression due to compaction on the one hand, and the resistance to outflow on the other. These tend normally to grow together so that the pressures in the fluids also grow, but compaction becomes more difficult in the later history of the sediments, and it is then that the

effects of differences in the ease of exit become more marked. Some reservoirs, completely enclosed in impervious material, may build up pressures to abnormal extents, whereas others from which fluid egress is possible have more limited opportunities for pressure increase.

Summarizing the above conditions, the theory of compaction pressures presupposes a condition of limited permeability within a mass of sediments compressing under their own weight. The gas, oil, and water trapped within limited reservoir rocks are subjected to a pressure which reflects this compression and is a function of the total weight of the overlying sediments. The ratio of this pressure to the total weight depends on the circumstances of enclosure of the reservoir.

Pressures due to Diastrophism.

The pressures within the earth's crust are the result not only of the weight of the overlying rock mass, but they also reflect the conditions of stress within the crust itself. Where such stresses are compressional the rocks are deformed unless they have sufficient strength to resist the stresses. Lateral pressure, therefore, continues the process of rock compression begun by compaction, and the clayey strata may be still further squeezed with a resultant diminution of the pore space. The effects will simulate those of compaction, and so long as the rocks are not disrupted and new exits for fluid opened, the pressures built up may be abnormally high. Some interesting examples of abnormally high pressures may be due to this influence. At Khaur the pressures recorded are about 3,000 lb. per sq. in. in excess of the normal hydrostatic head [6, 1934]. The theory of inherited water pressure requires the Murree Series to have been some 6,000 ft. below their level of exposure at the time when the fluids were sealed off. It seems more likely that the pressures are due to the influence of the stresses indicated by the isoclinal folding north of Khaur.

When diastrophism proceeds to the stage at which the rock masses become fractured and fissured, the new zones of permeability give relief of pressure to the imprisoned fluids. Extreme folding, therefore, except in the case of exceedingly plastic formations, leads to excessive vertical migration and loss of pressure. This is largely the result of the gradual change in the physical character of the rock masses involved. The plastic characters become replaced by solidity, and the more rigid materials fracture under extreme stresses.

It is important to note one other aspect of the change in rock character from plasticity to that of a true solid. The strength of the clays is greatly increased by this process, and they become capable of resisting exceedingly high pressures. Not only can they protect the gas and oil in an enclosed sand from increase in pressure, but they can also prevent its depletion. This results in a condition of fossilized pressure wherein individual sands can be protected from loss of pressure during denudation by the compactness and strength of the surrounding rock mass.

Pressures due to the Generation of Oil and Gas.

While a mass of sediment is plastic and contains fluids in a state of movement it cannot retain within itself a condition of local high pressure. When, however, it has become more rigid and the permeability within the mass has become restricted, local conditions which lead to the generation of pressure can exert a permanent influence.

The possible causes of such local generation of pressure are: the formation of oil and gas; the increase in total volume of the hydrocarbons due to molecular break-down, or the reduction in pore space by cementation, &c. On the other hand, a reduction of pressure could be due to: the polymerization of hydrocarbons to types of higher molecular weight; chemical alterations such as asphaltization, or reduction in water content by the absorption of water into the clays to form new minerals.

Dealing first with the changes due specifically to the oil and gas content, it is reasonable to suppose that if oil generation continues after compaction has attained its maximum there will be considerable generation of pressure in the formations as a result of the volume increase which takes place when organic matter is changed into oil and gas. The writer is inclined to doubt whether the processes of oil generation occur at so late a stage, but there is a large body of geological opinion which supports these views, and until the matter is settled there can be no reason to preclude this as a fundamental cause of gas and oil pressure. If the process of oil generation takes place in a confined space and the rocks are sufficiently strong to support it, there will be an automatic increase in pressure as oil and gas are formed, for the process involves an increase in volume. Such pressures could only be preserved in a medium which was surrounded by an impervious envelope. If this were not the case, the pressure effects would be dissipated by fluid movement. It is for this reason that the writer would exclude from consideration any accumulation of pressure arising from processes of oil generation during the early phases of compaction. If oil and gas are formed by destructive distillation of organic matter within the crust, a considerable amount of pressure will be generated as a result of the chemical changes. The writer is not concerned here with the question whether such processes do take place, or whether the metamorphism is due to temperature or pressure. These matters belong to another field of inquiry.

Once the oil and gas have been formed in the sediments there are still many processes of molecular change which may and probably do take place in them. These include a further break-down of the higher molecular weight hydrocarbons accompanied by the formation of a large proportion of gas. There has always been a school of thought which considered that this process has been responsible for a larger proportion of gas in the Lower Palaeozoic fields than in the younger formations. The process would be analogous to the cracking process in a refinery, though the conditions would not necessarily be the same.

The processes of chemical alteration in oil and gas over long periods of time have not been thoroughly investigated. Barton [1, 1934] has investigated the Gulf Coast crudes and concludes that deep and prolonged burial results in the break-down of naphthenic hydrocarbons and the production of normal paraffin types. Such changes would undoubtedly be associated with volume changes and would affect the pressure in a restricted reservoir. There is also the possibility that polymerization rather than dissociation may occur in some reservoirs, in which case the pressure will be correspondingly reduced. We are on firmer ground when it comes to a discussion of the changes which occur in a reservoir as a result of deep-seated weathering. These matters will be referred to later.

Effect of Temperature Changes on Pressure.

There is one important aspect of the reaction of oil and gas to physical changes in the reservoir which must have a considerable effect on the pressures. This lies in the

changes in temperature to which the gas must be subjected by increase in sedimentation causing a rise in temperature or by denudation causing the reverse. If we assume that the normal rise in temperature in such sediments is 1° C. for 200 ft. of cover, the addition of 10,000 ft. of sediments would increase the temperature by 50° C., which would increase the pressure of any confined gas by about 20%. If, furthermore, the gas is associated with oil, it will come out of solution and the pressure will be correspondingly increased. Temperature changes modify the gas pressures in accordance with normal physical laws, but by altering the gas solution equilibrium they also change the quantities of free gas available in the reservoir.

The effect of denudation will obviously be in the reverse direction to that of sedimentation, and there must be slow, but none the less definite, changes in the pressure of an oil and gas pool as the thickness of the cover is reduced.

Other causes of temperature changes in the rocks—diastrophism, igneous intrusion, radio activity, &c.—will have corresponding influences. Igneous intrusion has occurred only in a few oilfields, of which Mexico is the best example. It is probable that in this case the effects of intrusion have not been limited to normal temperature changes, for there have apparently been metamorphic effects which have altered the volume of the pore spaces in the reservoir rock, and the peculiar chemical constitution of the gases associated with the oil which contain large quantities of carbon dioxide may be ascribable to the igneous activity. It is probable that in these Mexican examples the normal oilfield conditions have become modified by the proximity of igneous activity, and the pressure conditions due to both sets of phenomena are merged in the oilfield reservoirs.

Pressure Changes due to Mineralogical Alterations in the Oil-bearing Strata.

Once the sedimentary strata have been thoroughly compacted and the clays, &c., around the porous reservoir rocks have become impervious, the pressure in the latter must be a function of the quantity of water, oil, and gas available and the volume of the pore space. Any factor which alters either of these two features will alter the pressure.

We have considered already the alterations in the oil and gas. There remains, however, the consideration of any possible changes in the pore space of the reservoir and the quantity of water within it, on the principle that the oil and gas must occupy the void space unfilled by the water.

The volume changes in the pore space may be produced by the precipitation of cements or salts in the pores of the rock. The volume of free water may be reduced by the adsorption of water into the surrounding clays to form low-temperature micas.

The first of these processes needs no comment, but it is probable that it will only occur to a limited extent unless there is complete freedom of movement in the water, a condition which is not allowable in most cases. With regard to the adsorption of water into the clay bodies, there are in certain oilfields, notably Pennsylvanian, constant references to so-called 'dry sands'. In these sand bodies the water pressure has been so reduced that the sands act as water absorbers and their fluid pressure is negligible.

Whatever may have been the original condition of the sands, it is clear that the pressures have fallen considerably. The explanation of such conditions in an enclosed reservoir is not easy to find, but it seems possible that there has been an absorption of water into the clay mass. If this took place over a sufficiently wide area, even to only a limited extent, the water sand would automatically lose pressure unless the loss were counterbalanced by the inflow of further oil and gas. There are good reasons to believe that there is considerable scope for mineralogical reconstitution of the clays within the earth's crust, and, once the water held in the clays has been exhausted, the water in the neighbouring sand bodies will be drawn upon for the process. Such changes in water content would have no effect on the pressure unless the whole mass of sediments were compact and free from connexion with extraneous water bodies. If these conditions obtained, the pressures in the sands would undoubtedly drop. One of the curious features about nearly all oilfields is not that the pressures are so high, but that they are considerably lower than we should expect on the principles set forth in the earlier sections. This water adsorption may be a more general process than has been recognized, and it may be a general process of pressure reduction in reservoir rocks. If this is so, it may have some bearing on the anomalous pressures in sands, for the subsequent pressure reduction due to water adsorption would depend on the volume of the reservoir and the nature of its clay envelope.

Pressure Reduction due to Denudation.

In the preceding sections the various factors which have built up and subsequently modified the pressures in oil-bearing formations have been discussed. There remain to be considered the general processes of pressure reduction which are associated with denudation.

It is normal to consider weathering and denudation as a superficial process, but in so far as it affects oil and gas it may penetrate thousands of feet into the crust. Many an oil and gas seepage is connected with oil at great depth, and many an oil sand has been altered to a tar sand to a considerable depth underground by processes of change comparable to normal weathering.

The changes are aided by the presence of fractures or other channels which allow gas and oil to escape, and permit the introduction of water carrying bacteria or salts in solution which react with the oil and gas to form asphalts.

Intense diastrophism which folds and fractures the rock masses greatly facilitates the escape of the oil and gas, and therefore it leads indirectly to large drops in pressure. However, the production of new zones of permeability works both ways, and the incursion of water from the surface, which is accelerated by such conditions, leads to the development of water pressures due to the normal hydrostatic head. Indeed, there are many cases where the presence of hydrostatic pressure is probably a secondary phenomenon introduced by the progressive effects of denudation and succeeding the condition of original enclosed pressures which was associated with the formation of the oilfields.

SHORELINES AND LENTICULAR SANDS AS FACTORS IN OIL ACCUMULATION

By JOHN LYON RICH, A.A.P.G., A.I.M.M.E.

Associate Professor of Geology, University of Cincinnati

ANCIENT shorelines may be significant in connexion with the accumulation of oil and gas either as being places where exceptionally rich organic sediments are deposited, or as being places where porous sand deposits are formed which may later become oil or gas reservoirs.

The problem of the occurrence of oil accumulations in lenticular sands is closely bound up with that of the relationship of oil to ancient shorelines, because many of the sand deposits close to shore are characteristically lenticular.

Is it true that deposits laid down close to the shore are characteristically rich in organic matter which might become the future source of oil and gas? Several geologists have thought so (Jones [8, 1920], Branson [3, 1926]), and have even argued—on account of the supposed restriction of oil accumulations to the vicinity of rich organic source materials and of the supposed richness of near-shore deposits—that prospecting for new reserves is hazardous except in regions where the sediments to be tested were deposited in a near-shore environment.

A world-wide study of the organic contents of recent sediments by Trask [19, 1932] has shown that rich organic 'source materials' are by no means confined to the neighbourhood of the shoreline. Trask's results have such an important bearing on our problem that some of his most pertinent observations and conclusions are abstracted briefly in the following paragraphs.

First, it is important to bear in mind that the place where marine life is most abundant is not necessarily the place where the richest organic sediments accumulate, for organic life is light in weight and can be transported easily by currents to points that may be far removed from the localities where the plants or animals originally lived. Furthermore, on account of its lightness the inorganic matter tends to be deposited with the finer organic materials in places least disturbed by waves or currents.

Consider first the distribution of marine life. The shallow water near shore teems with life—both plant life and the animals that feed upon it. The larger forms of marine plants—the marine algae, or seaweeds—live mostly in the shallow water near shore through which sunlight can penetrate. The microscopic plants and animals, however, are not so closely restricted. They swarm in the near-shore waters, but are even more abundant off shore wherever there is an upwelling of cold water from the depths of the ocean such as occurs along the margins of ocean currents flowing parallel to the shore; along the outer margins of the continental shelves; or over other submarine escarpments. In short, life which might be the source of rich organic sediments may be as plentiful a hundred miles or more out to sea as along the shore.

As to the actual distribution of sediments rich in organic matter, Trask found that the abyssal deep-sea sediments are uniformly lean in organic matter, but that on the continental shelves and generally within 100 to 500 miles from shore, depending on the topography of the ocean bottom, no correlation could be made between richness in organic matter and nearness to the shore. The rich deposits within that zone are characteristically in the deeper basins or in any other places protected from wave and current action. In these protected spots the light-weight organic material accumulates with the finer inorganic sediments. Lagoons behind off-shore sand bars contain rich organic sediments in some instances, and in others they do not, depending on a variety of conditions affecting life and sedimentation.

In the light of Trask's results, it seems safe to say that in so far as the generation and accumulation of oil and gas may depend on the presence of sediments rich in organic matter, there is no reason to expect such accumulations to be confined to sediments deposited near the shore. Oil- and gas-pools may be expected to occur anywhere in a belt which is *within reach of migration* from adequate deposits of organic sediments whether those were laid down in lagoons close to shore or in deeper basins many miles out to sea.

In the case of shallow epi-continental seas such as those which covered much of North America during the Palaeozoic era, it is probable that no part was deep enough to be out of the zone in which rich organic 'source' sediments might accumulate. It is even probable that in many instances the deeper spots may have been the most favourable for the deposition of such sediments because of their being less disturbed by wave and current action. Trask found such to be the case in several relatively shallow enclosed seas such as Lake Maracaibo.

Relation of Lenticular Sands to Shorelines

The wave, current, and tidal activities characteristic of a shoreline produce concentrations of sand of lenticular character which, in so far as they are formed in the region where rich source rocks are also likely to occur, are especially favourable sites for the accumulation of oil and gas.

Lenticular sand bodies developed along a shore may be classified into (*a*) shore bars, spits, and hooks; (*b*) off-shore bars, generally separated from the mainland by shallow lagoons; and (*c*) sub-aqueous bars formed by the strewing of sand along the sea bottom by currents, and perhaps in some cases by wave action during the greatest storms.

Off-shore Bars or Barrier Beaches

The off-shore bar is commonly formed along gently shelving shores. Such bars are straight and long, generally rather narrow, and are interrupted at intervals by tidal inlets. Because prevailing winds are often diagonal to the shoreline, off-shore bars commonly are offset at the tidal inlet in such a way that the bar on the windward side of the inlet lies a little farther out to sea than that on the leeward side. Individual bars range in length from a mile or two to a hundred miles or more along modern coasts, and presumably they had a similar range along ancient shores.

The preservation of off-shore bars so that they can later serve as reservoirs for oil and gas requires somewhat special geological conditions. In the ordinary evolution of a coast-

line, if the land is slowly sinking, the bars tend to be pushed gradually backward rather than to be buried and preserved. If the land is slowly rising, the bar becomes exposed to erosion and new bars are built farther off shore. Preservation of such bars and their burial when the sea again returns over the area requires either that the wave action be very weak as the sea returns, or that the bars settle and become buried by alluvial material before its return. Whatever the process, it is evident that such bars can be buried and preserved, for we actually find them, as, for example, in Greenwood county, Kansas.

Sub-aqueous Bars

Sub-aqueous bars are not so well known. Soundings record areas off shore in which the bottom is composed of sand and other areas in which it is mud. These areas tend to be elongated and distributed parallel to the shore, but they are more irregular than off-shore bars.

Considerable evidence indicates that storm waves stir the bottom to depths as great as 600 ft., and in 200 ft. of water pea-sized gravel has been found in suspension 24 ft. off the bottom after a gale (Borley [2, 1923]). Whenever sand is lifted off the bottom by wave action it can be carried along, at least for a short distance, by any tidal current or undertow that happens to be moving. Thus it comes about that even weak currents are capable of strewing sand over the sea bottom, presumably stringing it out more or less in the direction in which the currents are moving.

Charts of the North Sea bottom accompanying Borley's report show a distinct corrugation of the ocean bottom off the English coast which appears to represent sub-aqueous bars trending approximately parallel to the shore. They are on a larger scale than most of the sand lenses with which the petroleum geologist has to deal, but it seems probable that they are formed in the same way.

The sub-aqueous bars cannot be expected to be as definite in form or as thick as the off-shore bars, nor to show the definite thickening at the top characteristic of off-shore bars.

Irregular Shore Bars and Spits

Minor shoreline deposits such as spits, hooks, tombolos, and cuspate forelands are commonly built out into deeper water, and consequently at least their bottom parts are likely to be preserved (Johnson [7, 1921]). These would form isolated lenticular sand bodies of variable, and in general unpredictable, form, dimensions, and distribution (Brewer [5, 1928]). As Johnson has pointed out, they would appear in many cases as nodes of thicker sand projecting downwards below the base of a sheet sand.

Tidal Inlets

Along a coast defended by barrier beaches, the individual sand bars are broken at intervals or separated from each other by tidal inlets through which the lagoons behind the bars are filled and emptied twice each day. On account of the restricted width of the inlets, the currents through them are swift and scour deeply. If physiographic conditions change so that an inlet is abandoned and silted up, a thick body of sand may be preserved which will lie at right angles to the trend of the bars; will have a channel form; will cut down deepest and may be thickest in the middle of its length; will be relatively short; and may merge, on the lagoonward side, into the irregular sands of a tidal delta.

Channel Sands

Another type of lenticular sand body not so closely restricted to the shore, though generally formed in an environment not far from the shore, is the channel sand.

Channel sands may be the fillings of river channels, delta distributaries, tidal channels in lagoon deposits, or of channels formed by the deep scouring which is common at tidal inlets.

Each type of channel has a distinctive configuration which can be used in determining its type. This, in turn, is essential information if one is tracing the course of such a channel by means of well records. The tidal river or delta distributary channels swing in broad, smooth curves and maintain their width for long distances; tidal channels meander intricately, branch, and are likely to taper out abruptly; the tidal inlet channel is short, deep, deepest in the middle of its length, and is disposed more or less at right angles to the shore at the time it was made.

Dune Sands

Another type of sand deposit which may make lenticular sands is the sand dune or the sand-dune area. Such deposits, if buried without serious modification, are irregular in pattern. The sand is highly irregular in thickness, and is characterized by an irregular top without distinctive pattern, except that of hummocks and hollows, and by a relatively flat bottom. A portion of the Parker pool in Robinson county, Illinois (Fig. 1), is perhaps such an accumulation.

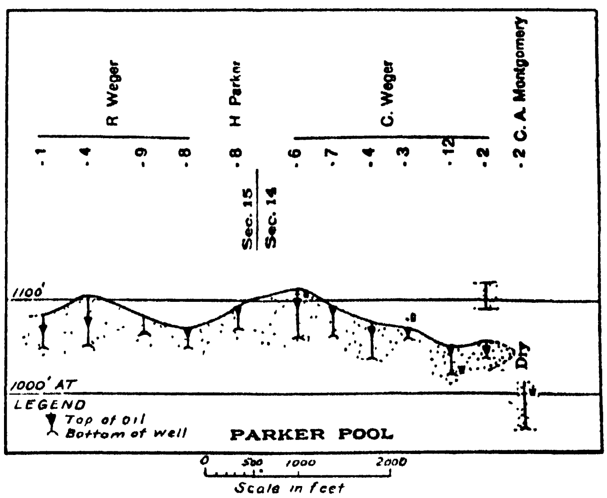

FIG. 1. A sand body whose cross-section suggests dune origin.

In continental deposits lenticular sands might represent river channels, sand dunes, or the braided channels of broad alluvial fans.

Channel sands are more easily preserved than shoreline sand bars because only sinking is required to permit their burial and preservation. Thus, probably, they are much more common than lenticular sands of the off-shore bar type.

Examples of Oil-pools in Lenticular Sands

The literature on the detailed nature of the sand bodies serving as reservoirs for oil- and gas-pools in 'lenticular sands' is not extensive. Mention of lenticular sand is common, for such sands produce oil in many fields in all parts of the world, but only under rather exceptional conditions

can the sand bodies be traced sufficiently far by drilling to reveal their true nature and extent. On localized anticlinal structures where production is confined to the upper part of an anticline it is commonly easy to recognize that sands are lenticular, but the type of lenticularity often cannot be determined because drilling is stopped at the limits of the productive area, and consequently the sands are not followed out for their whole extent.

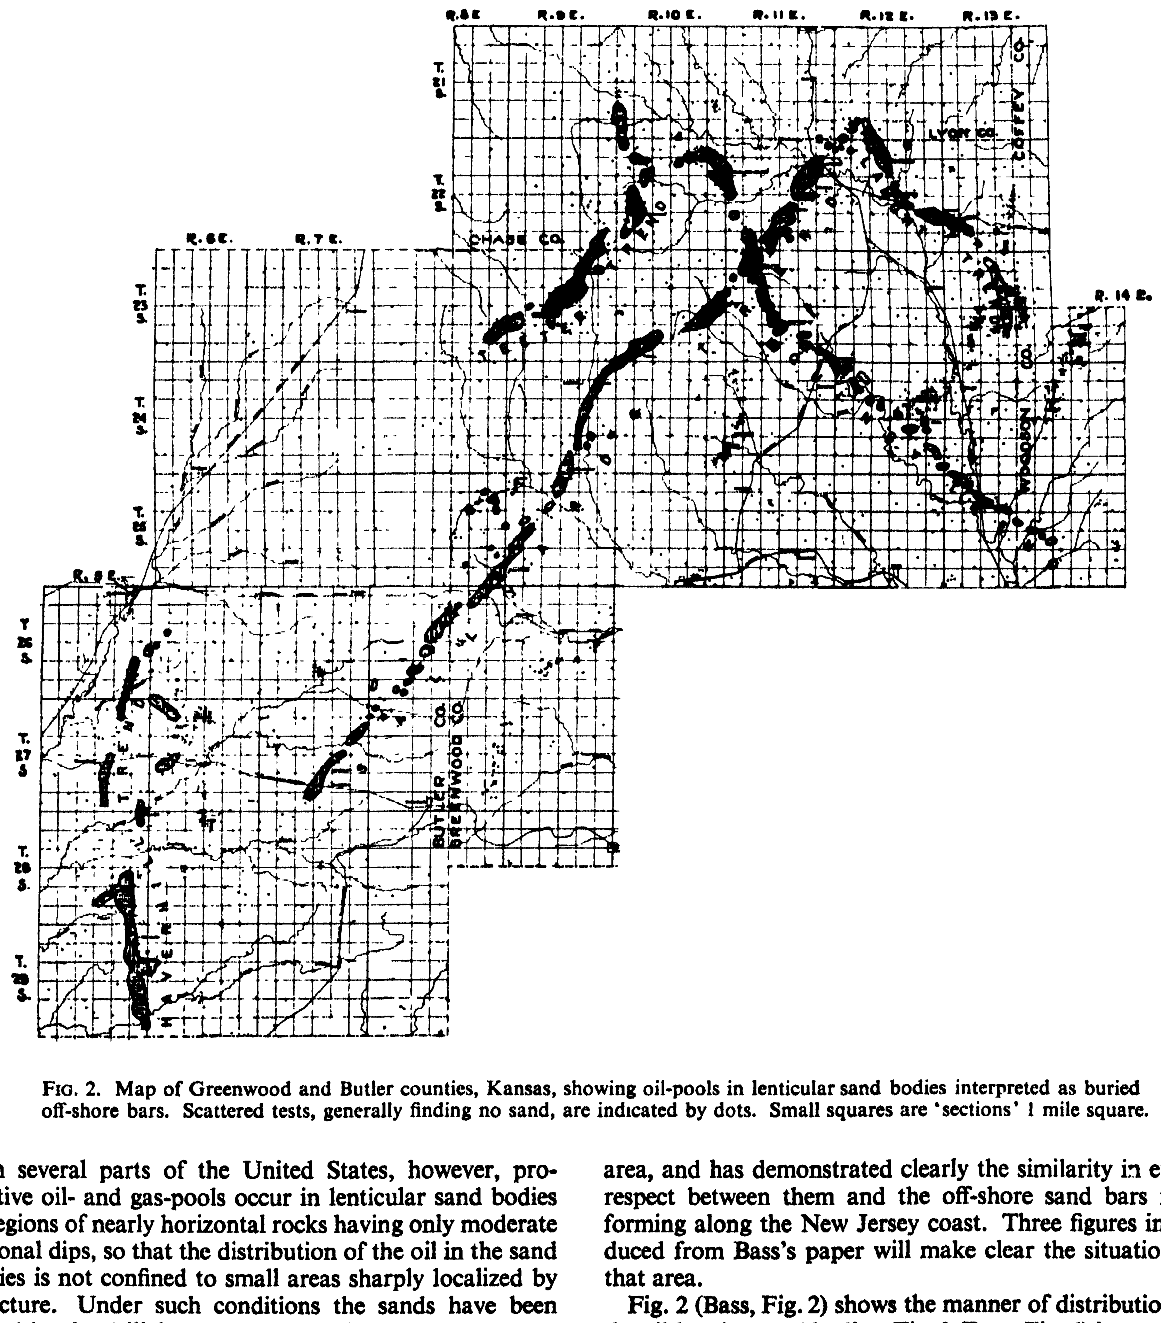

FIG. 2. Map of Greenwood and Butler counties, Kansas, showing oil-pools in lenticular sand bodies interpreted as buried off-shore bars. Scattered tests, generally finding no sand, are indicated by dots. Small squares are 'sections' 1 mile square.

In several parts of the United States, however, productive oil- and gas-pools occur in lenticular sand bodies in regions of nearly horizontal rocks having only moderate regional dips, so that the distribution of the oil in the sand bodies is not confined to small areas sharply localized by structure. Under such conditions the sands have been traced by the drill far enough for their form and pattern to be accurately determined from well logs.

Several such areas illustrating various types of lenticular sand bodies are described in the following section.

Off-shore Bar Sand Bodies in Eastern Kansas

In eastern Kansas, particularly in Greenwood county and parts of adjoining counties, are the best-known examples of buried off-shore sand bars serving as reservoirs for oil accumulation. On account of the richness of these pools and the fact that, over most of the county, oil occurs in the bar sands wherever they are found, drilling has been active, so that the shape and extent of the sand bodies has been determined in detail over a large area.

Bass [1, 1934] has recently made a thorough study of these sand bodies in the Greenwood and Butler county area, and has demonstrated clearly the similarity in every respect between them and the off-shore sand bars now forming along the New Jersey coast. Three figures introduced from Bass's paper will make clear the situation in that area.

Fig. 2 (Bass, Fig. 2) shows the manner of distribution of the oil-bearing sand bodies; Fig. 3 (Bass, Fig. 6) is a stereogram of the sand body of a typical sand-bar oil-pool about $3\frac{1}{2}$ miles long and 1 mile wide; and Fig. 4 (Bass, Fig. 10) shows a side-by-side comparison on the same scale between the buried sand bodies in the Pennsylvanian shale of Greenwood county and present sand bars along the New Jersey coast.

The salient features brought out by Bass's study are:

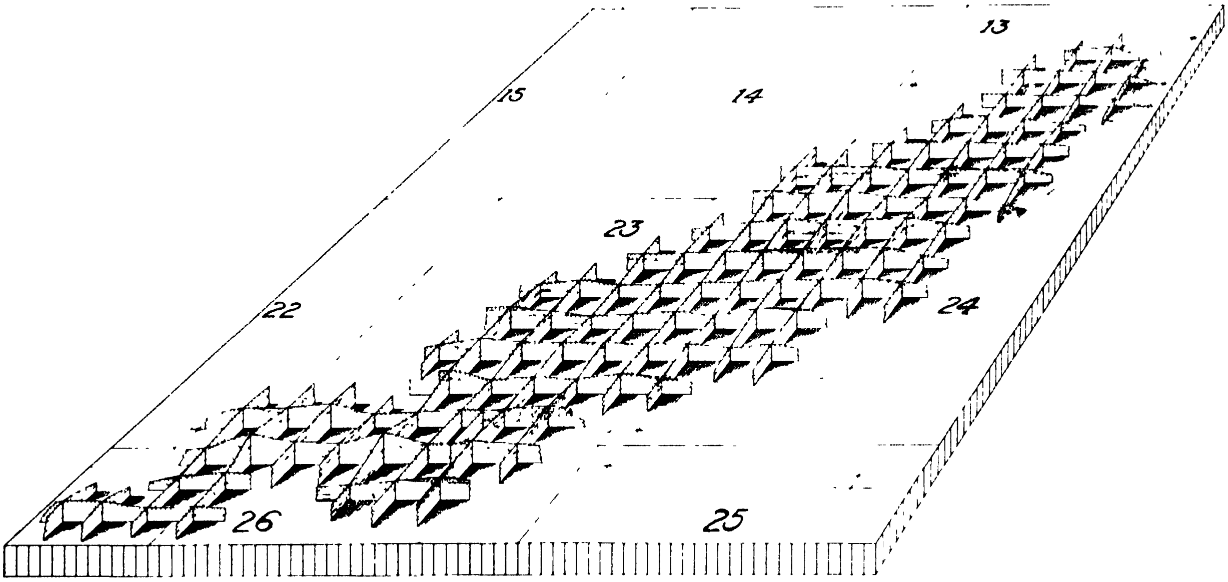

FIG. 3. Block diagram of Bartlesville sand body in Burkett oilfield (T. 23 S., R. 10 E., Greenwood Co., Kan.). Vertical lines at intersections represent wells. Dotted pattern represents Bartlesville sand. Dashed pattern represents shale at Bartlesville horizon. White band below sand represents underlying shale. Light line encircling diagram represents approximate boundary of sand body if projected. Sand body is 75 ft. thick in central part of field. Wells are spaced 660 ft. apart. Symbol represents dry holes. Section lines shown by dashed lines.

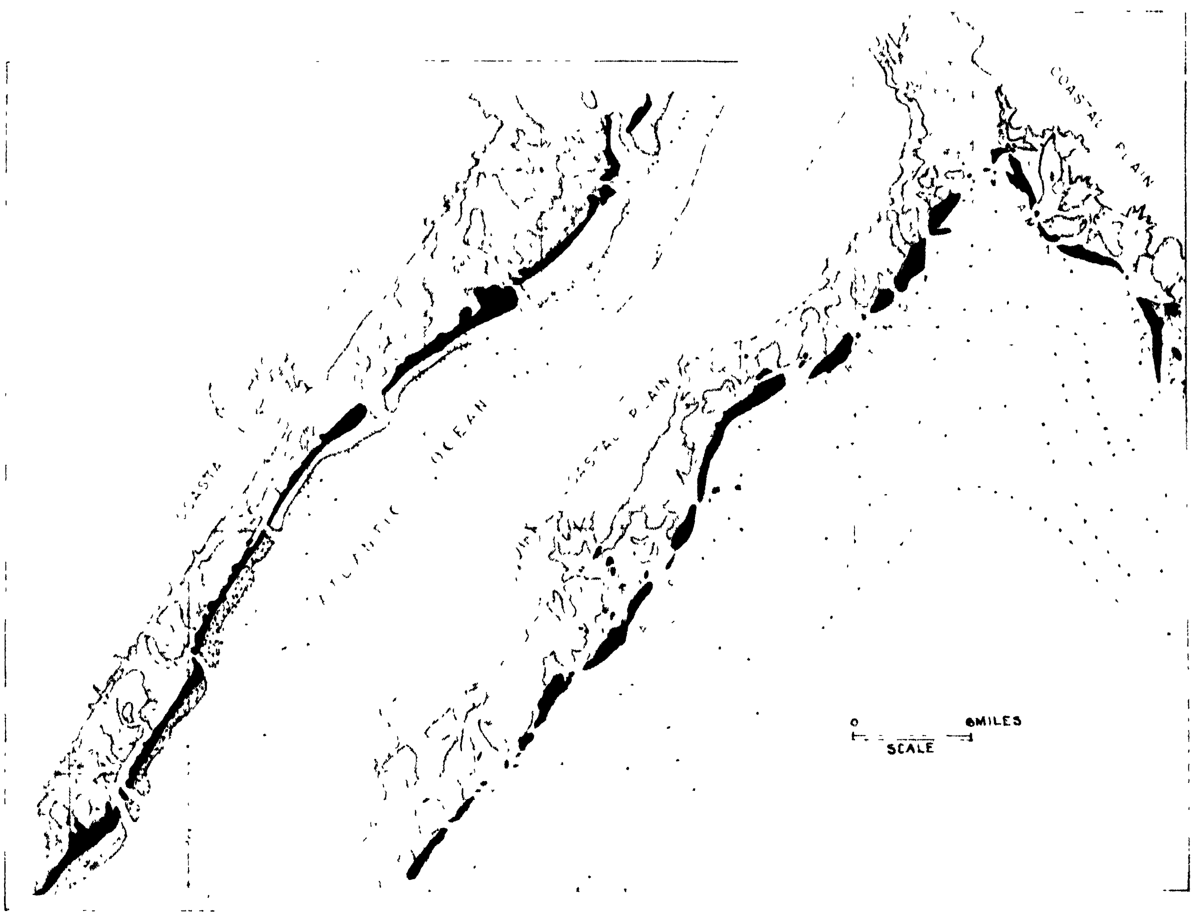

FIG. 4. Left: Sketch of part of New Jersey coast (After *U.S. Coast and Geodetic Survey Chart 1217*). Dotted-lined area represents Atlantic Ocean; solid black with adjacent stippled areas represents offshore bars, shaded area at left of bars represents lagoons with coastal plain farther left.

Right: Sketch of part of shoestring-sand area, Greenwood County, Kansas. Dotted lines represent Cherokee sea; solid black represents Bartlesville sand bodies; shaded areas represent lagoons. Squares are townships 6 miles square

(1) the distribution of the lenticular sand bodies in long, relatively straight 'trends', of which two sets are recognized. These are believed to mark successive positions of the strand line along the border of a shallow sea which underwent moderate tilting in the interval between the deposition of the two sets of bars; (2) the pod-like shape, and the discontinuity of the sand bodies within the 'trends'; (3) the offsetting of the individual sand bodies in the same manner as sand bars are offset along the present coasts; and (4) the characteristic shape of the sand bodies in cross-section. They thicken at the top and in the middle, and pinch out low at the edges in a fashion typical of sand bars, but quite different from channel deposits.

Channel Sand Bodies in Eastern Kansas

In the eastern counties of Kansas many oil-pools are found in long, narrow sand bodies which have been interpreted as channel fillings. These 'shoestring' oil-pools have been described by Rich [14, 1923; 15, 1926] and by Charles [6, 1927]. A map of an area near Garnett, Anderson county, where the channel sands are well developed, Fig. 5, shows that the sand bodies extend for many miles—in the case of the Bush City shoestring it is over 14 miles without a break—in broadly swinging curves. The sand thickness averages about 50 ft. in the central part of the channel, and the width varies from about 1,000 to 1,500 ft. A typical cross-section near the west end of the Bush City shoestring is shown in Fig. 6.

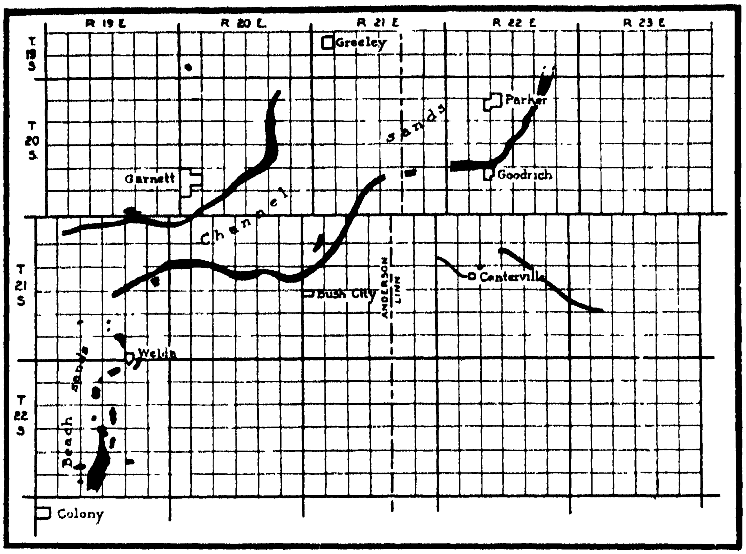

FIG. 5. Oil-pools in the 800-ft. or 'shoestring' sand of Anderson and Linn Counties, Kansas. The sand bodies fill ancient stream channels except at the south-west corner of the map where the streams seem to have emptied into open water and shore bars were formed. (*Base map, after Rich*)

The channel bottoms are nearly flat; the sides are abrupt; the tops are nearly flat, but may sag slightly in places; and thin bodies of sand occur at the edges of some of the channels at a level a little higher than the top of the main sand body. These are interpreted as former natural levees. The channels are cut sharply into marine shale of Cherokee age (Pennsylvanian).

Within the channels the porosity of the sand is variable. Parts are clean, relatively pure sand, and others are muddy. As a rule the sands tend to be cleaner and the channel bottoms a little deeper on the outsides of the bends. Outside the channels no sand is found except for the thin, natural-levee sand that is sometimes found close to the channel as already described.

An analysis of the possible origins of these channels leads to the conclusion that they were formed by consequent streams which cut into a flat, slightly raised, coastal plain resulting from moderate temporary withdrawal of the Cherokee sea. Lamination of the sand, as revealed

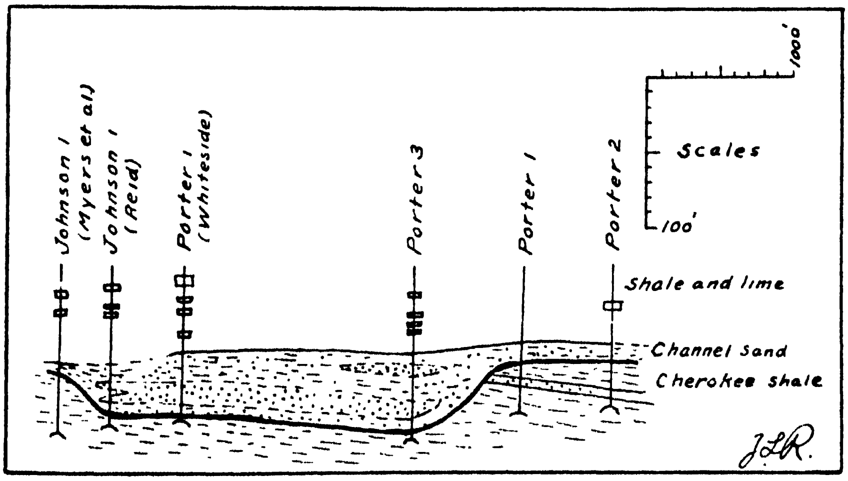

FIG. 6. Cross-section of Bush City channel sand body, Sec. 13, T. 21 S., R. 19 E., Anderson Co., Kansas. Shows sand-filled channel cut sharply into Cherokee shales, also irregular distribution of sand and sandy shale within the channel.

by drill cores, is of a type suggesting deposition under conditions of ebb and flow, indicating that at the time the channels were being silted up their water was subject to the tides.

At least two instances have been recognized in Anderson county where channel sands merge into sand bodies of the beach type trending approximately at right angles to the channels, indicating that the streams emptied into bodies of open water where the sands were strung out along the shore.

Criteria for distinguishing between Buried Channels and Buried Sand Bars

In the paper on the shoestring sands of eastern Kansas (Rich [14, 1923]) and in the report on the Birds quadrangle of Illinois (Rich [13, 1916]) the author has given criteria for distinguishing between channel sands and sand bars. The channel sands are continuous and thicken at the bottom; the bar sands occur in lens-shaped patches along a more or less definite trend, and thicken at the top. The sand bodies of the bars are commonly unsymmetrical. Their tops are likely to slope down smoothly on the seaward side, but to be broken and extend out in fingers into the shale on the landward side (Fig. 7). Coal also has been found in several instances on the landward side, indicating contemporaneous filling of the lagoons behind the bars with vegetable matter.

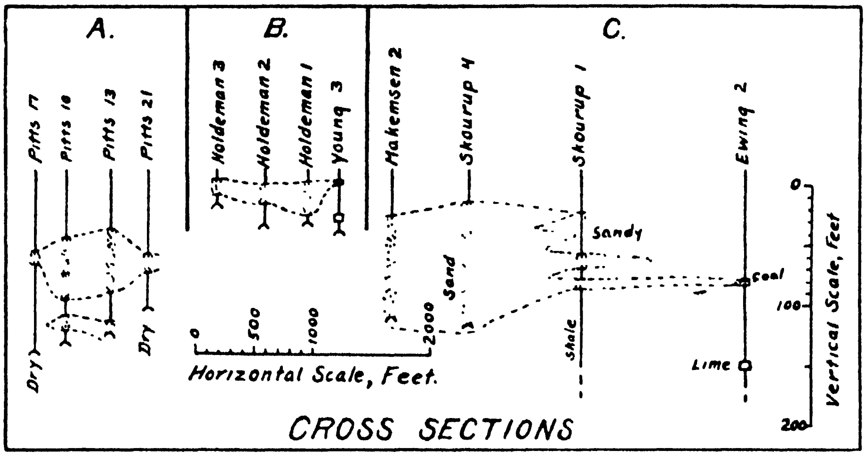

FIG. 7. Cross-sections of typical Kansas 'shoestring' sand bodies. Section *A*, Elmore shoestring, shows thickening at bottom indicating probable channel origin of the sand. Section *B*, Sec. 15 and 16, T. 23 S., R. 18 E. A typical channel sand body. Note thickening at bottom. Section *C*, east side of Colony sand body at Colony, Kansas. Shows thickening at top and also fingering and coal on eastern (lagoonward?) side. These features suggest that the sand body is a buried off-shore bar.

Tidal Inlet Channels in Eastern Kansas

What are believed to be tidal inlet channels have been recognized in the Greenwood county area of Kansas already mentioned. The cross-section of one of the clearest of these is shown in Fig. 8, taken diagonally across what is believed to have been a tidal inlet at the south-eastern end of one of the sand-bar oil-pools shown on Bass's map, Fig. 2. At the left in the cross-section are the convex-topped bar sand body, and at the right the flat-topped channel type of sand body at a lower elevation which is believed to represent the filling of a tidal channel between two bars.

Lenticular Sands in the Illinois Oilfields

Much of the oil produced from the Pennsylvanian formations in the Illinois oilfields comes from lenticular sands of one or another of the types mentioned. It was in connexion with a detailed study of that area (Rich [13, 1916]) that many of the principles used in the interpretation of the lenticular oil in sand reservoirs were first worked out.

The portion of the Illinois fields referred to lies on the broad, flat crest of the La Salle anticline in Crawford and Lawrence counties. On the larger regional structure the detailed distribution of the oil and gas in several of the productive sands is controlled almost entirely by the distribution of the sand bodies. In the report mentioned, the criteria used in differentiating various types of sand bodies are discussed and illustrated by cross-sections constructed from well logs. Sand bodies believed to represent shore bars, filled tidal inlets, and buried sand dunes were recognized.

Clinton Sands of Ohio

The so-called 'Clinton' sands of central Ohio have yielded a large amount of gas and some oil from the up-dip edge of a sedimentary wedge on the eastern flank of the broad Cincinnati arch (see J. R. Lockett [9, 1927]). Over part of the area production is from a sheet sand, but in other parts, especially in the northern half of the productive belt, the sand occurs in irregular lenses or patches several miles long and from a fraction of a mile to 2 or 3 miles wide (Fig. 9). Except, perhaps, along parts of their western margin, these lenses are not arranged in definite trends like the off-shore bar sands of Greenwood county, Kansas, described by Bass (loc. cit.). They are more irregular and the sands are generally much thinner than in the Kansas area. Nevertheless, the lenses show a decided parallelism in trend which is believed to correspond in direction with that of the shoreline, or at least with the axis of the embayment, at the time they were deposited. They show, therefore, the features which would be expected of sands of the sub-aqueous bar type. Further more detailed study will be required before the exact origin of these sands can be more definitely established.

Lenticular Sands in the Appalachian Fields and their relation to the Shoreline

Most of the oil in western Pennsylvania and in adjacent parts of Ohio and West Virginia occurs in irregular lenti-

cular bodies of sand or in patches or streaks of soft, porous sand within more widespread sheet sands. (See U.S. Geological Survey, folios, nos. 121, 134, 144, 146, 176, 177, 178, and *Bulletins*, nos. 318, 354, and 356.) The oil occurs in the central part of the Appalachian geosyncline at or near the western limits of the various sands where they become thin and patchy before pinching out into shale. Towards the east the same sands thicken and become coarser towards their source in the old Appalachian land mass. In the oil-producing area all the sands, except, perhaps, the the pattern would, of course, be much simpler, and from it some idea might be had of the conditions of deposition when that particular sand was laid down.

In order to bring out the pattern for one sand, the accompanying map, Fig. 11, of the oil- and gas-pools in the 'Hundred-foot sand' was compiled from the folio maps. The pools are superimposed on the structure map so as to bring out to what extent they are dependent on structure and to what extent on sand distribution. In the 'Hundred-foot' sand in that area the oil and gas accumula-

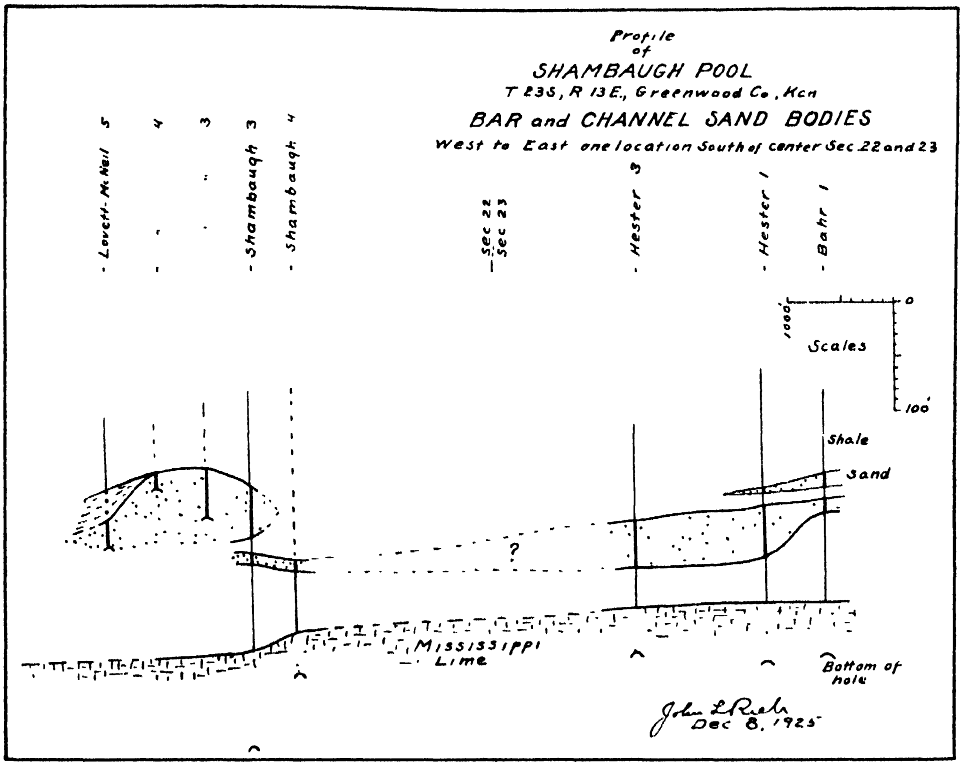

FIG. 8. Cross-section showing an off-shore sand body at the left associated with a sand body of the channel type which is believed to represent a partly filled tidal inlet between sand bars. Greenwood county, Kansas.

upper ones of Pennsylvanian age, are marine. They seem to have been deposited in the open water of an embayment formed by the sinking of the Appalachian geosyncline between the Cincinnati arch on the west and the Atlantic highland on the east.

In general, and for most of the sands, the evidence indicates that the belt where the sands become patchy in distribution or in porosity marked their farthest extension seawards, and that their lenticularity was probably caused by the actions of currents following the Appalachian embayment, more or less parallel to the general shoreline.

The Berea sand, however, higher in the section than the Devonian sands forming most of the pools, thins out to the east, suggesting that it was derived from the western side of the trough. Details of shape and pattern of certain of the Devonian sand bodies suggest that some of them, also, were deposited along the west side of the embayment, but the evidence is not conclusive.

The pattern of distribution of the oil-pools of the Appalachian fields, and their relation to the major folds of the region, are well shown on the accompanying map of western Pennsylvania, Fig. 10, but in reading this map it must be borne in mind that oil- and gas-pools at several different horizons are superimposed. For any one horizon tions are controlled mainly by streaks of porous, conglomeratic sand in a thick and widespread sand body, though some of the pools seem to be at the western margin of the sand where it pinches out into shale.

Neither the pattern of the Appalachian pools as a whole nor that of the pools in the 'Hundred-foot' sand suggests deposition as off-shore bars such as have been described in Greenwood county, Kansas, or as channel sands. A distinct alinement is, however, visible, and on the map of the 'Hundred-foot' sand, Fig. 11, three fairly distinct 'trends' or lines of pools can be made out, though the individual oil-pools are quite irregular. Unfortunately for our purpose, the map shows only the outline of the oil and gas accumulations, and not necessarily the limits of the porous sand streaks, which may or may not be similar. For the most part, however, the published discussions of the area indicate a fairly close correspondence between the outlines of the pools and the extent of the porous sand streaks.

It seems certain that these sand trends do not represent the actual shoreline, especially in the 'Hundred-foot' sand area shown in Fig. 11, for they are merely especially porous streaks in a widespread sand. They are believed to represent the results of assortment and strewing of coarser

material along the sea bottom by currents, but it is possible that the water was shallow enough for wave action during exceptional storms to have affected the bottom and to have been in part responsible for the 'trends'.

Neither of the pattern maps of the Appalachian pools, Fig. 10 or Fig. 11, reveals any close relation between production and structure. All geologists who have reported on the region agree that the distribution of porosity of the sands has had more influence than structure in determining the location of the oil- and gas-pools.

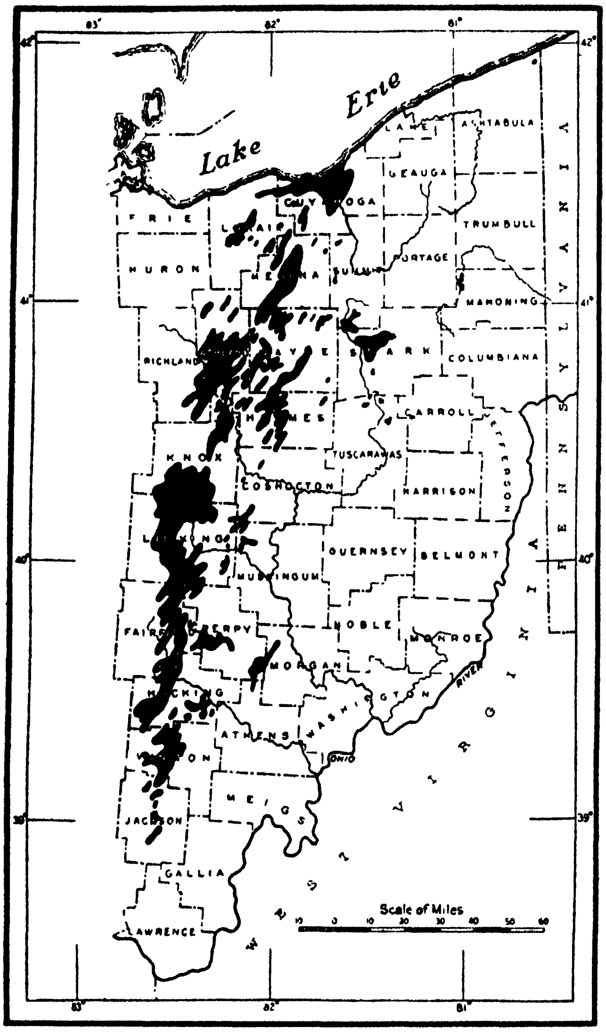

FIG. 9. The 'Clinton sand' fields of eastern Ohio. These fields occur along the up-dip edge of the 'Clinton' sand where it becomes lenticular before pinching out into shale to the west. *(Map by J. R. Lockett)*

In detail, within the limits of any one of the porous areas, structure undoubtedly plays a part. Gas may be in the highest part of a given lens, and water in the lowest, if both are present, but in many instances there is no water, and the oil is in the lowest places it could reach.

Jones [8, 1920] has pointed out the rather striking trend of the Appalachian oil- and gas-pools, approximately parallel to the general trend of the Appalachian geosyncline and presumably of the Appalachian shoreline, and the fact that these trends are not coincident with the structural axes. From these features and from the assumption that oil is derived from rich bituminous source materials and has not migrated far, he has argued that the 'present position and shape of the pools closely conforms to the underlying or overlying source of supply', which he believes to have been lagoonal areas close to and generally parallel with the coast line at the time of deposition, '. . . each line of pools corresponding to successive shore lines, with generally barren belts intervening'.

Jones's observation that the trend of the pools has a depositional rather than a structural origin is certainly correct, but the correlation of the pools with strips of bituminous lagoonal sediments is open to question. A correlation with strips of porous, reservoir-making sediments seems more nearly to fit the facts, especially as the correlation between oil-pools and streaks of porosity in the sands has been made by most of the writers who have described those pools. Besides, the sands appear to be of the subaqueous bar rather than the off-shore bar type such as should have been associated with coastal lagoons.

Torrey [18, 1934] believes that the reason that the oil is found mainly in the western, thinning edges of the various sand horizons is that, there, the sands were deposited in quieter waters farther from shore and are interbedded with marine shales rich in organic matter, whereas eastwards, towards the shorelines, the shales between the sands become more sandy and contain less organic source material. Thus, according to Torrey's ideas, it is not the belt close to the shore that is most favourable for oil, but one farther out. Torrey argues against extensive migration of oil and against its generation by geodynamic agencies. Those questions do not concern us here except that the occurrence of oil in lenticular sand bodies is cited as an argument against migration.

How oil and gas may have found their way into the lenticular sands is a puzzling question which can only be touched upon here.

Migration and Accumulation of Oil in Lenticular Sands

The common occurrence of oil in lenticular sands is often cited as proof that oil is formed essentially in place and does not migrate laterally into its reservoirs.

If a sand lens is entirely surrounded by impervious shale not broken by any joints or other fissures, it is conceivable that oil could be squeezed up or down into it from the adjacent shales as they are compacted, but lateral migration to the sand of the lens from any considerable distance seems out of the question.

Yet certain facts of distribution of oil and gas in lenticular sands suggest so strongly that extensive migration has occurred that we seem justified in questioning the assumption of complete isolation of the sand lenses.

The strongest evidence indicating extensive migration to the lenticular sand reservoirs is that in many regions the accumulations of oil in lenticular sands are on regional 'highs' where they would be expected if the oil had been free to migrate. As examples may be cited the pools on the Bend arch of Texas; the Greenwood county shoestring pools of Kansas; the lenticular sand pools of the Illinois oilfields; and the 'Clinton' sand-pools of Ohio—the latter on the up-dip side of a pinching sand body.

If the oil has not migrated into these lenticular sand-pools, why should they be found in places that are so situated structurally that oil would have migrated to them if it had been free to do so? In the case of the Greenwood county shoestring pools the evidence seems especially strong, for the accumulations are in an area that was regionally high during the Pennsylvanian and Permian

periods when the oil is believed to have accumulated (Rich [17, 1933, p. 804]). In the regionally high areas most of the sand lenses are entirely filled with oil, though a few miles to the north, off the 'high', similar sand bodies occur at the same horizon, but are filled with water instead of oil.

Two possible ways in which oil might migrate to the lenticular sands and accumulate in them under the control of structure may be suggested. One is that the sand bodies may be more effectively connected with each other underground than we suspect; and the other is that oil may migrate to the regionally high areas through continuous porous 'carrier beds' lower in the section and then find its way up through fissures to the lenticular sands (Rich [16, 1931]).

The discovery by Price [12, 1935] that the nature of the waters in the shallow lenticular sands of the Corpus Christi region of Texas indicates relatively free intercommunication between sand lenses, suggests that, at least in the early stages of burial, the sand lenses may not be so thoroughly isolated as has commonly been supposed.

An interesting relation noted in some of the oil- and gas-pools in the 'Hundred-foot' sand of Pennsylvania is that one sand lens may contain only gas while an adjacent one contains only oil. This condition is well shown on the oil and gas map of the Burgettstown-Carnegie folio, no. 177. Although the subject has not been specifically discussed in the reports on that area, it seems reasonably certain from the maps that the condition is fairly common. One may well ask why one sand lens should be entirely filled with gas while another, near by, is filled with oil to the apparent exclusion of gas. One possible explanation is suggested below, tending to bear out the idea that oil and gas utilize fissures for their migration to a greater extent than has generally been realized.

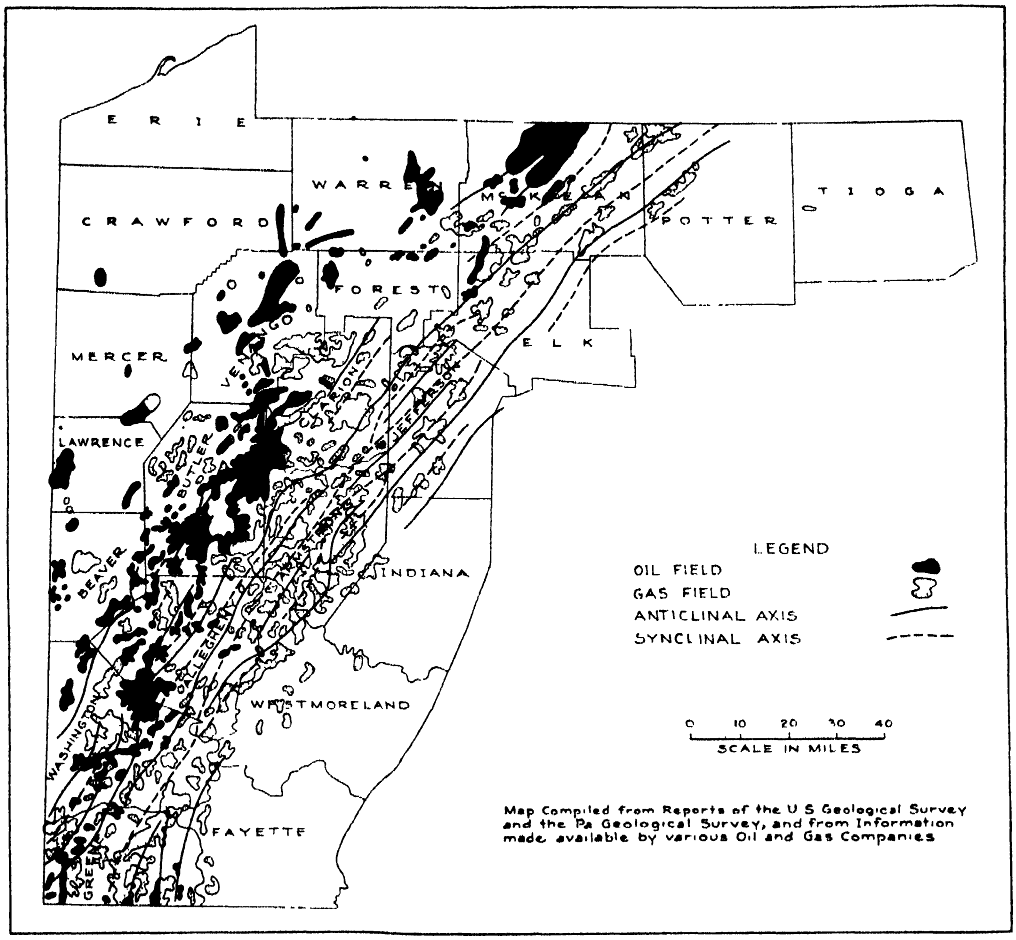

FIG. 10. Map showing oil- and gasfields and principal structural axes in western Pennsylvania. (*Map by Paul D. Torrey*)

Mills and Wells [10, 1919] have given good reason for thinking that gas in large quantities has at some time escaped from the oil- and gas-bearing regions of Pennsylvania and has carried with it so much water-vapour that some of the sands have been almost completely desiccated, and in the remainder the water has been so reduced by evaporation into the escaping gas that it has been changed into a concentrated brine.

If we grant that at some time, perhaps soon after the deposition of the rocks, large quantities of gas moved through them, carrying with it or driving before it more or less oil, as Mills has shown it will do, we have a mechanism capable of filling some of the lenses of sand entirely with oil, while others near by and at the same horizon are filled only with gas, for if we conceive of one lens being tight, so that there is little passage of gas through it, that lens would presumably fill completely with gas at an early stage and would now contain only gas. If the seal over another nearby lens were broken by joints or fissures, or for any other reason was imperfect, that lens might well serve as a channel for the passage of gas and its entrained oil. If conditions were just right, the oil might be differentially

screened out, while the gas, being able to escape through smaller openings than the oil, continued on its way. Thus a large accumulation of oil without free gas might be formed. Mills reports (oral communication) that in experiments conducted at the Bureau of Mines gas often broke through and escaped, leaving the oil behind.

Tracing Lenticular Sand Bodies

Applications of the principles of physiography can contribute much to aid a geologist in tracing lenticular sand bodies.

The first step is to determine, either by pattern or cross-section, the type of sand body. If it is a channel filling, the sand body may be expected to be continuous, of approximately uniform width, and to curve first in one direction and then in the other after the fashion of a meandering stream. The curves may be very broad and open, however, for such curves are characteristic of delta distributaries—a type of channel commonly to be expected.

If the sand body is of the off-shore bar type, it may be expected to be pod-shaped—tapering at the ends—and the units of a series of such sand bodies strung out in a 'trend' along the old shoreline may be expected to be separated from each other by barren areas representing tidal inlets between bars. Individual bars are likely to be offset somewhat *en échelon*, and may have hooks pointing lagoonwards at the ends.

If one is dealing with sub-aqueous bars formed of sand strewn along the ocean bottom by tidal or other currents, the problem is not so simple. The sand bodies may be thinner and are likely to be more irregular in pattern than the channel or shore-bar sands. General trends, or prevailing directions of elongation of sand lenses, may, perhaps, be recognized.

Finally, whatever the nature of the lenticular sand bodies, the relationship of oil or gas production in them to local structures must be ascertained. In some regions the lenticular sands carry gas or oil where they cross local 'highs' and water in the 'lows'; in other regions, as in eastern parts of Kansas, oil may be found in the lowest parts of the lenses, while gas or dry sand is in the 'highs'.

For best results in tracing lenticular sand bodies, an intimate knowledge of the local conditions, both structural and palaeogeographic, is essential.

THE RELATIONSHIP OF BURIED HILLS TO PETROLEUM ACCUMULATION

By JOHN L. FERGUSON and JESS VERNON
Amerada Petroleum Corporation

Introduction

AFTER 75 years of intensive development of the world's petroleum resources, the search for undiscovered oil-pools is still strongly guided by precedent. Cautious advances in development are made from conditions under which oil is known to be commercially available towards those conditions where the results are more problematical. The pioneer tests have been made adjacent to well-defined seepages, with subsequent extension of development as new precedents and methods are developed, to the more obscure indications of accumulation. Among the most obscure of the indications are buried hills, which by themselves or through their influence create one of the most important groups of petroleum reserves.

Up to the present, buried hills have been very little exploited throughout the world, due largely to the cautious manner in which the search for petroleum under new conditions progresses.

This hesitancy arises most particularly from the lack of *direct* evidence of the presence of oil-pools, but also from the vague knowledge of the principles governing the origin and accumulation of petroleum.

Each new productive province has its own problems of accumulation which can, as yet, be solved only by the development of new precedents based on trial and error, or the adaptation of certain precedents from other provinces. Those provinces which have the most obvious indirect indications, such as oil seepages and gas blow-outs, have received the earliest development with later activity, on less obvious indications, depending on diverse factors. In certain provinces, such as the Caspian area, Burma, Dutch East Indies, and Venezuela, in which strong seepages or simple anticlines in unconsolidated sediments indicated large accumulations of oil, development of the resultant oilfields has been adequate to care for the market requirements, and search for more complex producing conditions has been retarded. In areas like the Golden Lane of Mexico and the San Joaquin Valley of California, exhaustion of pools resulting from testing of seepages has forced the search into areas where more obscure indications of oil accumulations have resulted in the development of new reserves. Certain provinces were found early in the search for oil to have such highly developed anticlinal structure in their surface beds that the development sequence began with exploitation of these indications, and has not yet extended far beyond them. The principal examples of this type are found along the salt structures of Roumania and Germany, and the canoe-folds of Pennsylvania. Many other areas in which petroleum reserves have not yet been established may well ascribe this to the lack of obvious indications of oil accumulations. At a later date less obvious indications will reveal commercial oil-pools in certain of these provinces.

Of the major producing areas of the world, the central portion of the United States is the only one which, through a fortuitous coincidence of geological and accumulative conditions, geographical situation, and market demand has been able to follow the development sequence through in more or less orderly fashion. Starting with the discovery of oil-pools near seepage oil indications in south-eastern Kansas in 1889 and at Corsicana, Texas, in 1896, development spread to simple surface anticlines and other obvious indications. As these more easily evaluated features approached exhaustion, the search for more obscure indications was directed towards buried hills. This new field for investigation was sponsored by Sidney Powers in two papers published in 1917, 'Granite in Kansas', *Amer. Journ. Science*, 4th ser., **44,** 146–50 (1917), and 'The Healdton Oil Field', *Economic Geology*, **12,** 594–606 (1917), following the discovery of granite hills underlying the production along the Eldorado line of folding in Kansas, and of Ordovician hills underlying the Pennsylvanian sand production at Healdton, Oklahoma.

Following his conception of the importance of buried features, the area from the Rocky Mountains to the Mississippi River and from Nebraska to the Gulf of Mexico is being intensively prospected with core-drill, microscopic studies, geophysics, and the drill in search of buried hills, which will yield sufficient oil to take care of the ever-increasing demands upon the area.

Buried Hills

Buried hills, as broadly interpreted by American petroleum geologists, are either remnants of elevated topography or unroofed anticlines, against and over which younger sediments have been deposited unconformably, with or without contemporaneous arching. These buried features, then, fall into two groups—buried topography and buried structure—each having distinctive characteristics and exerting typical influence on the accumulations of petroleum associated with it.

Border-line cases inevitably arise between the two groups, due to their common origin in local upwarping. The buried topography group was either so highly folded or so deeply eroded following uplift that the importance of the original anticline was lost as far as oil accumulation is concerned, and the group remains important because of the influence of its topography. The buried structure group, on the other hand, was folded and eroded in such a manner that the oil accumulation in the original anticlinal structure is still present in large part, and is the dominant petroleum accumulation of the buried feature. Such pools as the Golden Lane of Mexico, Hurghada Oilfield of Egypt, Garber and Tonkawa in Oklahoma, are definite border-line cases, in that accumulation is found in the buried anticlines, but is also closely associated with the unconformity surface.

Buried Topography

Of the two groups of buried hills, buried topography was first recognized as a distinctive influence on petroleum accumulation. In Kansas, intensive drilling in Eldorado, Augusta, and smaller oilfields showed clearly that following the Early Pennsylvanian upwarping of the basement granite and overlying pre-Pennsylvanian formations in the

Nemaha Ridge, there was long erosion with the removal of much of the sedimentary section from the crest of the ridge, leaving rounded granite knobs exposed at some places.

Subsequent broad submergence brought a long period of Pennsylvanian deposition, with sediments gradually filling in along the flanks of the ridge and finally covering it entirely. During the regional settling, however, there was continual upwarping of smaller amounts along the old line of weakness which had produced the Nemaha Ridge. This movement, together with the greater compaction under increasing load of the thicker prisms of sediments on the flanks, maintained anticlinal structure over the buried ridge during much of the period of Pennsylvanian and Permian monadnock during the deposition of the younger formations.

These superposed anticlines frequently cover a large area and have produced large quantities of oil and gas. The oilfields of Eldorado, Augusta, and Oxford, Kansas; Braman, Thomas, and Garber in Oklahoma, along the Nemaha Ridge; and the world's largest gasfield in the Panhandle of Texas, are striking examples (see Fig. 1).

The sealing of sands deposited on the flanks of the buried ridge is of less importance, due to the generally erratic character of the production. However, part of the 'granite wash' oil production of the Texas Panhandle is of this type.

Secondary porosity developed in the surface of the high topography by weathering and erosion prior to its covering

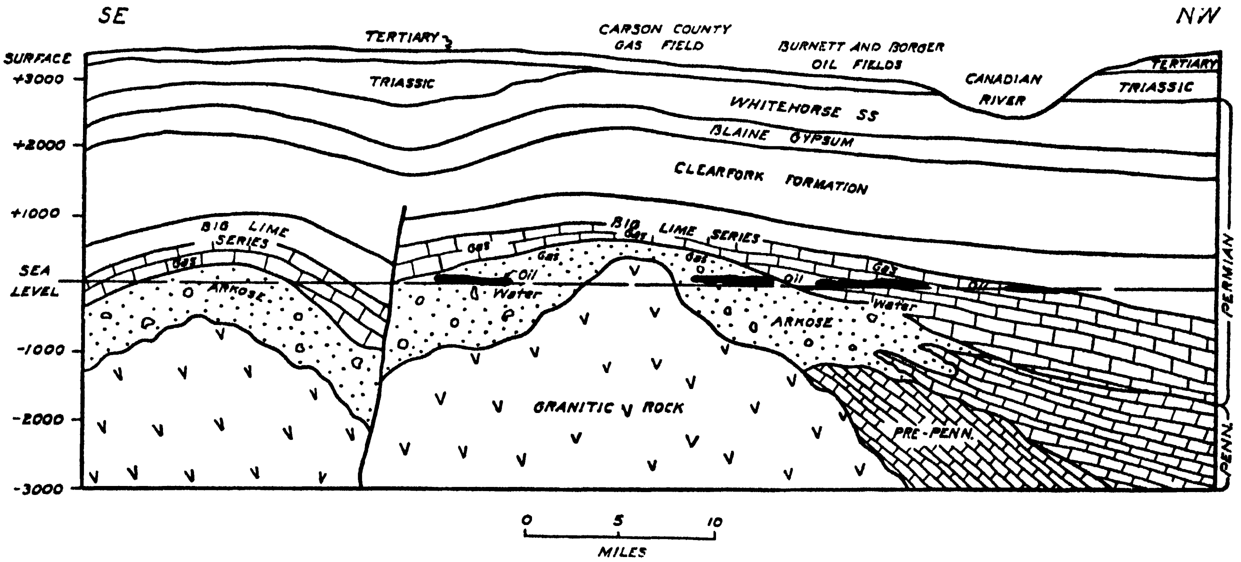

FIG. 1. Cross-section of the Panhandle buried ridge, Carson-Hutchinson Counties, Texas. Reflected buried topography, with oil and gas accumulations in the superposed anticline, in dolomites of the 'Big Lime' series and arkosic sands. Flanking arkosic sands are also productive.

deposition, beyond which time information is lacking. Later regional upwarping, which brought the area above sea-level finally, was again locally intensified along the buried ridge, leaving a pronounced surface anticline in the Permian rocks overlying the crest of the ancient granite ridge very closely. This Nemaha axis is a typical reflected buried hill, and its history corresponds very closely with that of many other similar features, such as Healdton and Hewitt, Oklahoma, the Panhandle fields of Texas, Sweet Grass Arch in Montana, and the Gebel Zut Oilfield in Egypt.

The Healdton field of southern Oklahoma differs from oilfields along the Nemaha Ridge in that the pre-existing island around and over which the present oil-producing formations were deposited was a highly folded complex of Ordovician sediments. In both cases, however, the topographical feature and its influence on the adjacent sediments were the important factors in petroleum accumulation.

Buried hills of the high topography group gain their importance by arching up sands deposited over their crests, by contributing in varying amounts to the petroleum recovered from adjacent beds, by providing reservoirs in their highly weathered buried surfaces, and by sealing off monoclinal sands deposited on their flanks. The most important of these functions is the anticlinal structure produced in overlying oil-bearing formations through compaction of the sediments and by upward movement of the buried by younger sediments is of considerable importance, where exceptional porosity has been developed in limestone hills. The enormous production of such wells as the Potrero No. 4, Casiano No. 7, and Cerro Azul No. 4 of the Golden Lane of Mexico, which have averaged better than 90,000,000 barrels each from the weathered El Abra limestone, give an idea of the possibilities of this accumulation. Gas and oil are found in smaller quantities in the weathered granite core of the Panhandle Ridge in Texas.

Finally, minor amounts of oil may be yielded to flanking and superposed sands by oil-bearing sedimentaries which have not lost all their oil content during the high folding and denudation prior to the deposition of the covering sediments.

In general, the influence of buried topographical highs on accumulation of oil and gas is of less importance than that of buried structure, though several prolific oil- and gasfields have been found in the Mid-Continent area of the United States on this type of structure.

Buried Structure

The buried hills of the second group are buried unroofed anticlines which may have existed as low topographical highs at the time of submergence, but which find their importance as centres of oil accumulation mainly through their original anticlinal structure. The earliest structure of this type which received prominence was the Cushing anticline in

Creek County, Oklahoma, one of the large oil-producing folds, which was an unroofed pre-Pennsylvanian anticline with the Simpson formation (Ordovician) exposed on the crest. This fold was submerged in Middle Pennsylvanian times during regional sinking, but local upwarping during this movement developed the overlying anticlinal structure. Production on this structure was found in the buried Ordovician anticline after the superposed anticline in the Pennsylvanian had also been found to be highly prolific.

Buried structures may be reflected in the surface beds, as at Cushing, or they may be entirely concealed by later serves of petroleum made available. The Permian Basin folds of West Texas and New Mexico; Van in East Texas; Marshall, Lucien, and Covington in Oklahoma; Voshell and Burrton in Kansas; 'Tamasopo' Ridge in Mexico; Maidan-I-Naftun in Persia; and Gemsah in Egypt are highly productive unreflected buried structures. Big Lake, Reagan County, Texas, is a striking example of a twice-buried structure, for it produces from an Ordovician anticline which is unrevealed by the overlying Pennsylvanian and Permian beds and from the Permian anticline which is unrevealed by the overlying Cretaceous beds, the two

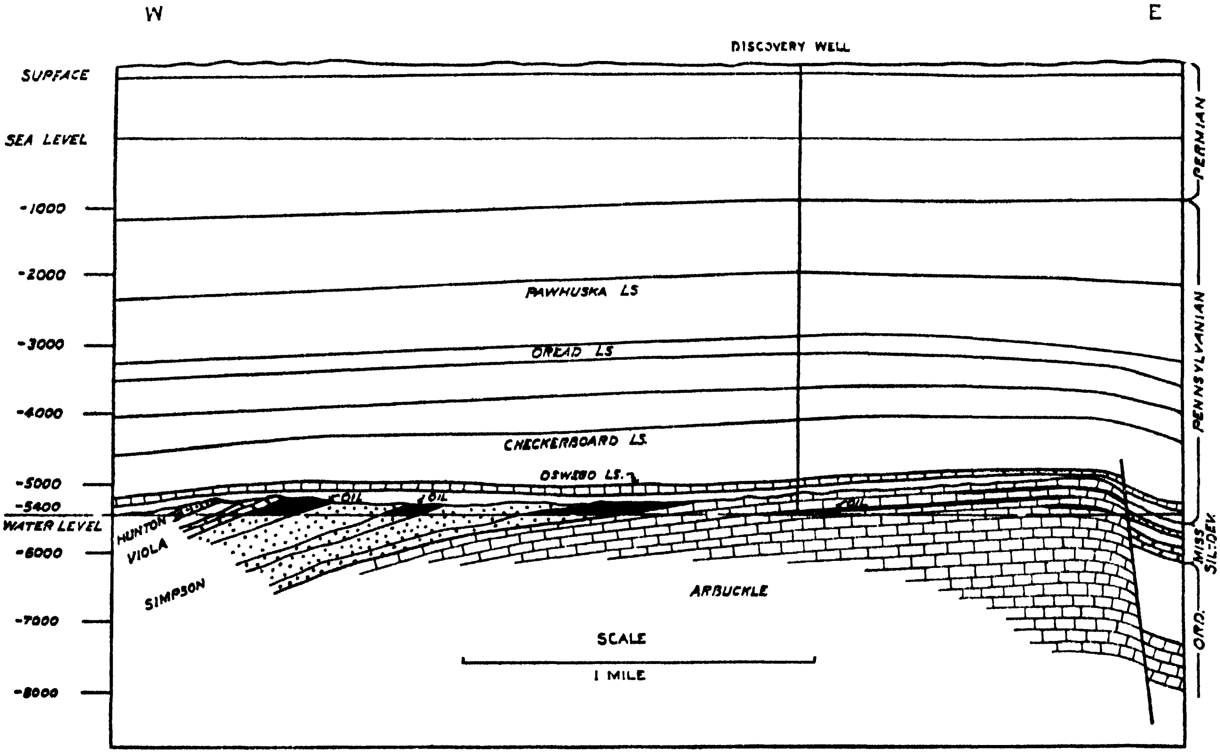

FIG. 2. Cross-section of the Oklahoma City field, Oklahoma County, Oklahoma. A reflected buried faulted anticline, with oil and gas accumulations in porous members of the Arbuckle limestone several hundred feet below the unconformity, in truncated sandstone members of the Simpson formation at the unconformity, and in anticlinal Pennsylvanian sands above the unconformity.

deposition during which there was no recognizable rejuvenation along the old lines of weakness, as at Seminole City, Oklahoma.

Many reflected buried structures, through the recognition of a low anticline at the surface, were tested and revealed early in the search for petroleum accumulations in the Mid-Continental United States. Such fields at Tonkawa, Garber, Yale, Oklahoma City, in Oklahoma; Fairport, Gorham in Kansas; Bend Arch and Yates in Texas, had ample surface expression to justify testing, and the discovery of oil in the reflected buried anticline resulted. Recently a more complicated surface structure was found to overlie the buried Ordovician fold at the Fitts Pool, Oklahoma. The inevitable testing of any suspicious surface structural indication led ultimately to the discovery of unreflected buried structures of the type found on the Seminole Plateau—such as Seminole City, Bowlegs, Little River, Earlsboro. These proved to be very prolific producers from the Ordovician, although their anticlinal nature was not indicated by similar structure in the Pennsylvanian beds on the surface. Through the advent of subsurface correlation, core-drilling, and geophysical instruments, further buried structures have been located and large re- producing areas overlapping but not coinciding in direction or location of apex.

Buried structures are important in the accumulation of petroleum largely through the anticlinal structure of the buried fold. The oil, accumulated in porous strata under typical conditions, is available for production well below the unconformity. In Oklahoma and Kansas the formations generally found below such unconformities are sands in the Simpson formation or the Arbuckle dolomite, both of Ordovician age; while in West Texas and New Mexico they are dolomites of Permian age. In all instances the pre-unconformity horizon has much better porosity than the horizons above the unconformity.

In certain cases the erosion of the anticline has proceeded far enough to uncover the oil zone before the submergence. In such cases the oil will migrate, at least in part, into the superjacent beds, and permit secondary accumulation of important reserves above the unconformity.

Of lesser importance on reflected buried anticlines is the oil found in the induced anticlinal structure in younger beds above the unconformity, although excellent production has been secured from such superposed anticlines in many fields.

An excellent example of a reflected buried anticline is the Oklahoma City pool in Oklahoma (Fig. 2). This pool yields oil in large quantities from porous horizons well within the Arbuckle limestone (Ordovician) core of the fold, as well as from the eroded Simpson sands on the flank, which have also supplied small quantities of oil to the debris material at the unconformity. Several sands in the Pennsylvanian section in the anticline above the unconformity have been tested for commercial oil and gas production, although these have not yet been developed, due to the greater yield of the Ordovician horizons. Such a structure producing from several different sources of accumulation makes a very prolific and valuable reserve.

Conclusion

In the present stage of world development, the central United States is the most important province in which large accumulations of petroleum have been developed in buried hills. These obscure features, which are to be found largely through greater zeal in exploration under the driving force of urgent demand, will be found more abundantly than at present suspected in many oil provinces which are still finding sufficient oil adjacent to the more obvious indications of accumulation. They remain, with unreflected buried salt-domes, the major unexploited reserve of the petroleum industry.

LOCATION OF OILFIELDS IN TECTONIC BELTS

By H. DE CIZANCOURT, M. Inst. P.T., Memb. A.A.P.G.

Paris

In a recent publication Professor Illing has shown that the regional distribution of oilfields is influenced by the following three factors:

(*a*) distribution of source-rocks,
(*b*) reservoir-rock conditions of accumulation,
(*c*) chances of preservation.

Distribution of Oil Facies

An examination of the petroliferous regions in the world shows that, almost without exception, these can be divided into two groups: fields located on the edge of mountain chains, and fields situated in subsidence basins. In these two groups the facies of the oil series change considerably; with the exception of continental facies, oil accumulation is encountered not only in purely marine deposits, but also in lagoonal or deltaic formations. Their sedimentary conditions are characterized by the enormous thickness of accumulated deposits, while in epi-continental seas and oceanic depths a reduced sedimentation took place during the same space of time This special type of facies is characteristic of subsidence basins. Subsidence by itself, a factor which must be considered in order to explain the thickness of deposits, fails, however, to account for the tremendous accumulation of detritic sediments, and the existence of an intense and continuous erosion in adjacent continental areas has to be admitted.

Such conditions are typically represented in the case of troughs in the foreland of mountain chains: the gradual rise of the chain is accompanied by a deepening of the foreland; at the same time active erosion has the effect of wear-down the rising mountains. Many oilfields are located in zones of this type. The case of subsidence basins is very similar to the previous ones, for in such cases tectonic phenomena, and especially isostatic readjustments take place.

As the result of the above-mentioned considerations a first point should be emphasized. There is a close relationship between the different features of tectonic zones and the distribution of oilfields. This connexion is only an indirect one, since shown by the facies of the deposits.

Role of Structure

A second factor to be taken into consideration is the direct influence of structure on the distribution of oilfields. The influence of general environments (large areas of uplift, synclinal basins, &c.) and of local features (anticlines, salt-domes, &c.) which have a local and definite influence on the distribution of the fields must be considered here.

In every case, however, stratigraphy and tectonics are so intricately related that it is absolutely impossible to separate these two factors. The influence of structure is not merely confined to the last periods of diastrophism. On the contrary, tectonic movements have taken place over long periods of time, and the deformation of the beds has been progressive. Consequently, *conditions of accumulation were not as they are to-day but have varied continuously.*

The distribution of oilfields at the present time should therefore be considered as the last term of a succession of varied stages of equilibrium. It should be necessary theoretically to take into consideration, in every case, another factor, time. Such a consideration is unfortunately impossible, but it is clearly involved, since oilfields correspond to different stages of evolution.

(*a*) **Unfolded Zones.** Subsidence basins of the type of the Gulf of Mexico show a series affected by a gentle dip towards the centre of the basin. The distribution of the fields seems at first sight erratic, but a closer study shows a concentration of oilfields in certain special areas. In the Gulf province the Sabine uplift, and in the Mid-Continent the Bend Arch, seem to have played an important role in the distribution of the fields. These features have probably not only a tectonic influence but also a stratigraphical one, through variations of the facies.

In these flat-lying series, the *oil is distributed in a great number of small structural irregularities*, and this type of accumulation may be considered as an older form.

By rotating the oil series through the angle of dip, until they lie in the horizontal plane, the small irregularities of the actual monoclinal surface appear as proceeding from elevations and depressions of the old depositional surface and oil accumulations correspond to the former. In some cases the sediments of the elevations are of a coarser type, which agrees with the studies of P. D. Trask on actual sediments.

These facts show the influence of this old depositional surface, which determines simultaneously the local facies and the distribution of the domes.

Where the continuity of the reservoir allows for migration, this type of deposit shows a remarkable instability. It can be supposed that, owing to tilting due to subsidence, deepening of the basin, or to erosion which will facilitate the motion of waters, a time comes when the previous state of equilibrium will be destroyed. *Oil will then migrate to more suitable 'traps'* and specially towards the higher regions of the reservoirs. Some barren structures in producing areas may be explained in this way.

Levorsen has previously emphasized the role of the tilting of the reservoirs in the secondary migration of oil. Such movement will vary with the nature of the reservoir, being a maximum in uniform deposits, and a minimum in the case of lenticular reservoirs. In the latter case, however, too strict an interpretation would prove to be erroneous. In many instances experience shows that ill-defined connexions may have existed between certain lenticular sandstones. For instance, the anticlinal disposition of many producing levels in certain small Carpathian fields, where the stratigraphy shows deposits of the 'flysch' type, is a definite proof. Wells drilled in synclinal zones have found insignificant traces of oil and salt-water only.

(*b*) **Folded Zones.** The 'embryonic folds' had the effect of remodelling progressively the monoclinal zones of the previous type. These folds have played an important role in the disturbance of a previous state of equilibrium and in the building of a new one. Through the tilting and folding of the reservoirs, as in the preceding type, the

closures will become insufficient for retaining the oil, which will *abandon its former zones of accumulation and migrate towards new locations on the folds.* The problem of eroded reservoirs is closely related to these facts. In many cases, where oil is not coming from beds overlying the reservoirs, subsequent accumulation of oil in the higher zones of the reservoirs may be due to folding. This folding has destroyed accumulations of the older type in zones which have not been eroded and permits a further migration of the oil into higher zones, eroded and covered subsequently by a transgressive cap.

(*c*) **Overthrust Zone.** The succession of orogenetic movements increase progressively the complexity of the structures, and their final stage results in overthrusts and nappes. Very few illustrations of fields of the last type are to be found, the chances of preservation becoming more and more precarious for oil. However, Canada, Poland, and North Africa have oilfields of such a type. The writer has been able to study the two last countries and gives here the result of his own observations.

Conditions of accumulation are extremely complex. Some structures, in spite of their regularity and their large drainage area, have proved to be entirely barren, whilst others, which would be condemned at first sight, on account of their unfavourable position and tectonics, have given production. These anomalies can be explained by a close examination of tectonic conditions.

A good illustration is given by the Boryslaw field in the Polish Carpathian Mountains. It corresponds to an axial rise of the frontal zone of a nappe. A few kilometres to the north-west a similar and even more important rise, at Nahujowice, is barren. A close study of the tectonics reveals that Boryslaw corresponds to an area of regional uplift where the different folds have been compressed against an elevation of the basement. The trend of their axis shows that this zone of compression, from which they escape to the north, forms a virgation.

The Nahujowice fold, on the contrary, has its origin in the depression and contains no oil. Its present rise is a secondary phenomenon due to the following factors. The fold, previously low, could advance freely, and at the same time rise on an inclined overthrust surface, but, during these tectonic movements, oil was already concentrated in the Boryslaw dome and remained there.

The same relationship exists between the Majdan and the Bitkow areas, the latter corresponding to an elevation of the basement, as proved by geophysical measurements.

In conclusion, it is possible to state that the present stage of oil accumulation results from a very complex evolution and is not only related to the present state of tectonics but had earlier and simpler stages. During the evolution, local readjustments naturally took place and resulted in a small accumulation of very light oil in the barren anticlines.

Destruction of Accumulations

The final distribution of oil is not only dependent upon the process of accumulation, but also upon the chances of preservation. This distribution is also modified by the destruction of some fields through erosion. The most radical process consists in the erosion of the reservoir which was very effective in every folded area.

Water circulation is another factor; a partial erosion of the reservoir permits the infiltration of surface waters and the flushing out of the oil. The Wyoming district offers typical illustrations of this phenomenon. Some seepages, which result in oil mixed with an enormous quantity of water being brought to the surface, may be due to a similar process, for instance Hit on the Euphrates River.

Finally, regional metamorphism will cause the disappearance of the hydrocarbon accumulations.

The Carbon Ratio Theory

As a conclusion to the present study, it is necessary to discuss briefly the 'carbon ratio theory', which offers an interesting solution to the problem of the distribution of oilfields.

Various observations have shown that in the Mid-Continent and in the Appalachians, oil accumulations are situated between certain isocarb contours. These isocarbs express equal proportions of fixed carbon in the coals of that area. The conclusion has been drawn that they are an index of the degree of regional metamorphism and especially of the point where oil first, then gas, would disappear. At first the carbon ratio theory was received with much favour by many scientists, but nowadays, owing to many contradictory facts, it is a matter of controversy.

The carbon ratio theory postulates:

> 'Coal beds are assumed to have the same original composition over their whole lateral extension, consequently every change in the composition of these beds is due to subsequent modifications in the environments, i.e. to regional metamorphism.'

Recent work on the composition of coals has given results which do not support the above-mentioned theory. In Europe observations made in the Franco-Belgian Coal Basin have shown that the variations in the percentage of fixed carbon in coals are essentially due to the nature of the detritals composing the different varieties of coals, which in turn are dependent on their position in the basin, i.e. on general conditions of sedimentation. Cuticle coals are found in the centre, whilst cellulose-lignin coals are deposited on the edges. To these factors must be added the effect of an early 'diagenetic process', representing the influence of environment on the carbonization phenomenon. The isocarb-contours, consequently, reflect the general sedimentary conditions.

American authors, on the other hand, hold contrary views. They consider that the composition of detritals is approximately constant for any given bed over the entire area of the basin. The absence of cuticles or of lignin or cellulose is due to their disappearance during the process of carbonization.

Recent studies made by Stadnichenko have shown that the increase of fixed carbon has no relation to the nature of the detritals. Duparque and White, starting from two different hypotheses, have shown the importance of an 'early diagenetic process' in the differentiation of the various types of coals. This diagenetic process is due to variations in the conditions in the different lagoons where the transformation of vegetable matter took place and is dependent on the degree of aeration of water which in turn is controlled by changes of depths and currents.

According to a prevalent opinion, the influence of regional metamorphism is not due entirely to temperature (below 160° C. no transformation is observed and it is necessary to reach 250° C. to obtain a transformation of about 2% in the proportion of carbon) but to pressure. In the Franco-Belgian Coal Basin observed facts are not in accord with this opinion: no relationship is found between faults, overthrusts, &c., and the trend of the isocarbs.

The above-mentioned considerations show how weak is

the basis of the carbon ratio theory. The isocarbs result, in the author's opinion, from three factors: grading of the vegetable detritus, diagenetic processes, regional metamorphism. The first two are sedimentary factors. The relation of the isocarbs to the regional distribution of oilfields may, therefore, be considered as expressing, first, the role of the sedimentary conditions and, secondly, the influence of regional metamorphism.

OILFIELDS IN FOLDED ROCKS

By W. A. J. M. VAN WATERSCHOOT VAN DER GRACHT, Dr.jur., D.Sc., M.E., F.G.S.
Netherlands Bureau of Mines, Holland

To a large extent, oilfields occur on gentle structures, in areas of comparatively very little folding. Such tabular regions are chiefly the 'forelands' of relatively more recent orogenetic zones. The tablelands themselves may have been subjected to earlier mountain building movements, but have become so solidified that they were not or only slightly affected by more recent movements. They formed the framework against which the later folds were directed.

Accumulations of petroleum are not only formed, but they are also frequently destroyed by subsequent geological events (cf. the article on the Stratigraphical Distribution of Petroleum). Within strongly folded mountain belts, the chances against preservation of oil deposits are very much greater than in relatively more quiet regions. For this reason oilfields are comparatively rare in strongly folded rocks. They are far more frequent in the foothills of the exterior zone of the chains, where folding is much reduced, or on the only gently warped tabular foreland. Other gentle structures often occur within depressions in the interior parts of mountain systems, which are filled by less disturbed later sediments. The reasons for the frequent destruction of oil deposits within strongly folded mountains are the following: (*a*) *erosion*, and (*b*) *dispersion.*

(*a*) Although high elevation is not necessarily the result of folding, which generally occurs at some depth in the crust, and mostly in submerged geosynclinal areas, a period of folding is usually succeeded by emergence and often even by strong regional elevation, during which erosion carves the highlands into a mountainous topography. The 'mountain building forces' may, therefore, primarily have been compressive folding, but the actual building of the mountains was strong regional uplift, followed by valley-cutting erosion. An enormous quantity of material is thus eroded and carried down by rivers and glaciers, first into valleys or interior depression basins, but afterwards spread as an extensive blanket over adjacent plains or sea bottom. The very basement of the interior chains is finally bared, denuded of its mantle of sedimentary rocks. Whatever deposits of petroleum may have been present in the latter are destroyed. For this reason oilfields are extremely rare in the heart of mountainous belts. Practically, they only occur within wide intramontane depressions, filled by a great thickness of sediments, which have merely been slightly affected by the later, less intense phases of the orogeny (the San Joaquin Valley and the Los Angelos Basin of California are good instances).

b. The violent dynamic thrust within the orogenetic zones, often accompanied by a downward buckling of the crust into considerable depths, and resultant injection of igneous rocks or mineralized solutions and vapours, cause chemical changes in the strata, which are called metamorphism. This may occur to a very variable degree. It may be so intense that the entire mineralogical aspect of the strata is profoundly changed. Even comparatively recent sediments can thus be transformed into crystalline rocks—schists, marbles, and quartzites—which cannot be distinguished petrographically from pre-Cambrian formations. In other cases metamorphism is so slight that silicates and other rock-building minerals are not visibly affected. We now know, however, that bitumina and coals are much more sensitive to chemical influence of this nature. The world's known oilfields all occur in unmetamorphosed or only slightly metamorphosed sedimentary rocks, but natural gas is found able to survive a somewhat greater alteration. Strongly metamorphosed rocks are barren of oil deposits. For the same reason source rocks could not remain in existence if depressed to depths exceeding 5 to 6 miles.

Where the strata affected contain coal-seams, these can effectively be used to indicate the amount of the very moderate metamorphism which is not strong enough to affect inorganic minerals. Slight metamorphism turns bituminous coals into harder varieties with less volatile constituents, and finally into anthracite. This is clearly demonstrated in the Appalachian coalfields of the eastern States of North America, where the gradual changes in the same seams of coal can be traced from the undisturbed foreland to within the heart of the mountains. The same process is, however, more or less clearly, in evidence all over the world. A map showing the regional carbon-ratio variations in Pennsylvania, Maryland, Virginia, West Virginia, eastern Ohio, and eastern Kentucky and adjacent regions, was published by David White and Ely in 1925 [1].

We now know that petroleum is affected in a very similar manner. The result is similar to the cracking processes used in petroleum refineries for the conversion of heavy oils into lighter varieties, chiefly gasoline, where the surplus carbon is left in the form of petroleum coke. In nature the effect of progressive regional dynamic alteration is also marked by a concentration of hydrogen in the distillates and a concentration of carbon in the residual debris. Metamorphism, consequently, lowers the specific gravity of the oils, so much that in the more strongly affected zones only gasfields remain and, finally, where metamorphism becomes more intense, no trace of oil or even gas is left, although general conditions remain equally favourable for the presence of oilfields. All this takes place within zones where there is not yet any trace of visible change in the rock-forming minerals of the sediments. Where coal is present in the oil-bearing section, as in the Appalachian oilfields, it can, therefore, sometimes be used effectively as a natural recorder of the local intensity of the metamorphic action to which the associated strata have been subjected, and the quality of coals can be used as an indicator for the position of the metamorphic 'dead-line', limiting the occurrence of commercial oil-pools. The contents of fixed carbon are used, as shown by proximate analyses of coals, calculated to the ash-free basis.

This so-called 'carbon ratio theory' is often used to estimate the promise of possible oil-occurrence in unprospected territory, but it has to be applied with circumspection; it has by no means such validity that a certain carbon ratio in some coal excludes all possibilities of finding commercial oil deposits in the vicinity. We are still less permitted to state that a certain degree of folding excludes the possibility for the preservation of oil deposits. Orogenic

pressure may have been relieved locally by the yielding of the beds in folds or faults, especially in overthrust zones. Metamorphism is not only a result of dynamic thrust, but also of temperature, arising from depth of burial. In an area of local and irregular thrusting, incompetent rocks, which have ridden passively on competent beds, or have been shielded from direct thrust by nearby faults, can be intercalated with other formations, which have been strongly compressed and more intensely metamorphosed. In this way patches of still oil-bearing strata may occur in checkerboard fashion between other areas with a high degree of alteration (for instance, oil seepage at Rose Hill, Virginia, and Stony Creek oilfield of New Brunswick). Accumulated geological observation, however, substantiates in a broad way that very strong folding, especially when found seriously to affect the carbon ratio of any coals present, adversely affects the chances of making important discoveries of oil within such areas as a consequence of the effect of local metamorphism.

That important oil provinces may occur in very intensely folded regions, within the overthrust front of major mountain systems, is illustrated in somewhat further detail by the following two examples: (1) the Turner Valley gas- and oilfield of Alberta, Canada, and (2) the Polish oilfields in front of the Carpathian Mountains (Boryslaw, &c.). Furthermore, a few remarks can be added on (3) the curious folding and upthrusting associated with saline formations (salt-anticlines and salt-domes), which often are connected with important oilfields.

1. **Turner Valley** is structurally probably the most complicated oilfield so far known in North America. It is a highly folded and faulted compound anticlinal overthrust sheet, bordering the outer foothills of the Canadian Rocky Mountains. It involves Palaeozoic limestones, dolomites, and shales, Jurassic shale, and Cretaceous rocks. The major overthrust fault, which underlies all of the structure, is of considerable magnitude and appears to have been subsequently warped. The thrustsheet is divided into a great number of individual slices. The adjoining cross-section, Fig. 1, perpendicular to the strike of the mountains, after T. A. Link and P. D. Moore [2, 1934], probably presents an essentially correct picture. The character of the overthrust structure is fully proven by 178 wells, notably by the McLeod No. 4 well (7,751 ft.), which reached the Cretaceous substratum, after having passed through the Palaeozoic, and demonstrated the tremendous drag on the underlying beds by the position of the Cretaceous *cardium* sandstone, inverted at the 6,300-ft. level, and in normal position at the 7,735-ft. level. In all cases, where cores were taken below the major thrustplane, high dips were observed to prevail in the strata. The warping of the thrustplane was proven by the varying elevations at which the fault was encountered in numerous wells.

Production is found in a dolomitized zone in the Palaeozoic limestone, which is generally found bituminous in places farther away from the mountains, and gives some oil-pools in the vicinity. Small amounts of oil and gas are obtained from Mesozoic sandstone at shallower depths.

As to the source of the oil, it is not improbable that the source rocks are in the Palaeozoic. In the Moose Mountain section, 20 miles north-west of Turner Valley, dark bituminous limestones and shales (Banff Shales) occur in the Lower Carboniferous. The Devonian is partly saliferous under the plains of southern Alberta (wells at McMurray on the Athabaska River), and has bituminous shales at the top. The Jurassic, which unconformably overlies the Palaeozoic, is confined to the Cordilleran geosyncline, and rapidly wedges out farther east; it is only thin at Turner Valley. It contains black bituminous shales of euxinic facies (cf. article on Stratigraphical Distribution of Petroleum). The Cretaceous is probably not an important source rock; the famous Lower Cretaceous subaerial tar sands on the Athabaska River are certainly no source beds and may have been impregnated either from the Devonian, or by tar washed into them from a remoter source (Cretaceous?).

As would be expected with dynamic forces of such intensity, the oil is a very light gravity naphtha (73·6 Bé. = 0·6899 sp. gr.), with large volumes of gas. Somewhat heavier oils are found in the younger formations and show a progressive decrease in specific gravity with depth. In the Kevin-Sunburst field, on the extremely gentle Sweetgrass Arch, on the Canadian border in Montana, the oil is found on the Jurassic-Palaeozoic contact, and in the same (Madison) limestone, and is 30 Bé. = 0·8762 sp. gr. To January 1934 the total production of the Turner Valley field has been 6·5 million barrels of naphtha and more than 600,000 million cu. ft. of gas.

For further details the reader may be referred to the cited paper by Link and Moore [2, 1934].

2. **The Polish Oil Province** is located in the frontal zones of the northern part of the Carpathian loop; the region extends south-eastward into Roumania, but becomes less and less productive in this direction. The oil-bearing zone extends over a length of some 500 km.

The Carpathian ranges form a strongly folded and overthrust mountain system, including very complicated structural forms. The petroliferous zone, however, occurs exclusively along the frontal belt, but extends a considerably greater distance into the more strongly deformed zone than is the case in the Appalachian Mountains of North America, where production is confined to the only very gently warped foreland.

Like all major systems, the Carpathian chain is bordered by an outer depression in the foreland, a structural 'foredeep', in front of the actual ridge. This sub-Carpathian region is only gently undulating country; it narrows to the south-east, where it is confined by the Podolian Plateau: to the north-west it expands more widely. Partly saline Miocene formations prevail on this foreland, largely obscured by Quaternary surface deposits. Carpathian folds, consisting of Oligocene strata, however, are concealed at depth. There is unconformity between the Upper and the Lower Miocene. The actual mountain front is made up of a series of overthrust masses, which are again divided in several slices ('skiby'). The mountains consist of Cretaceous, Eocene, and Oligocene rocks, which have been thrust over the Miocene foredeep. Three major overthrust masses can be distinguished: the 'Marginal' belt of the outer front; the 'Median' belt, marked by a distinct longitudinal depression lying behind the slightly more elevated Marginal zone; and finally a more central elevated ridge in the south-west, the 'Magura zone', which passes into Czechoslovakian territory.

The oil production in the Marginal belt is derived from Oligocene and Cretaceous strata, in the oilfields of Schodnica, Boryslaw, Tustanowice, and Mraznica. In the Median belt production is found in Eocene and Cretaceous beds in the oilfields of Kleczany in the west, the Jaslo-Protok-Krozno group of oilfields in the centre, and some eastern outlying fields at Wankowa and Pajskie-Polana. In the central Magura zone only unimportant occurrences are known: Ropica and Ropianka. About 100 known oil- and

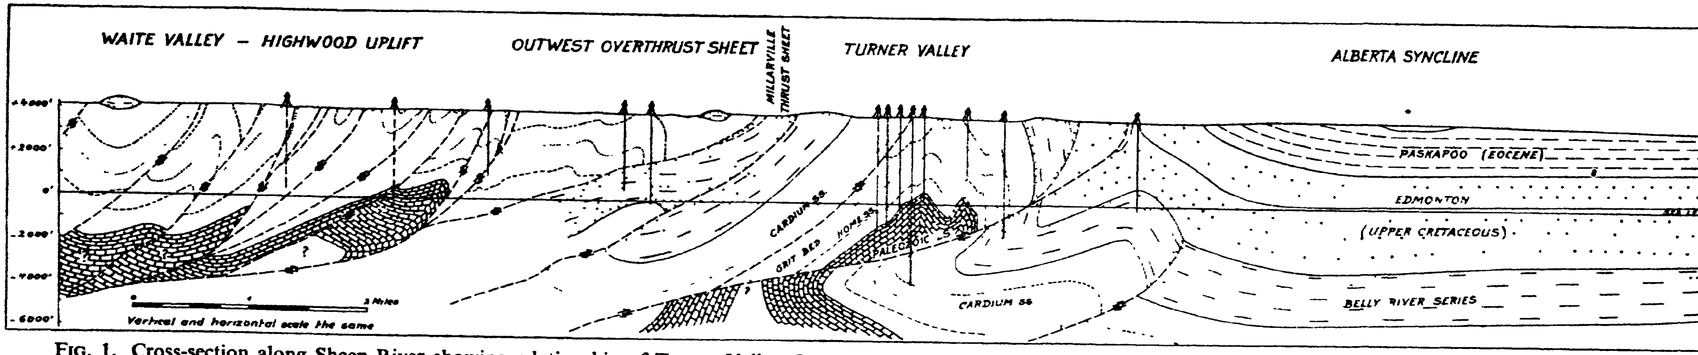

FIG. 1. Cross-section along Sheep River showing relationship of Turner Valley, Inner Foothills, and Alberta Syncline. After Th. Link and P. D. Moore (*Bull. Amer. Assoc. Petr. Geol.* **18** (1934)).

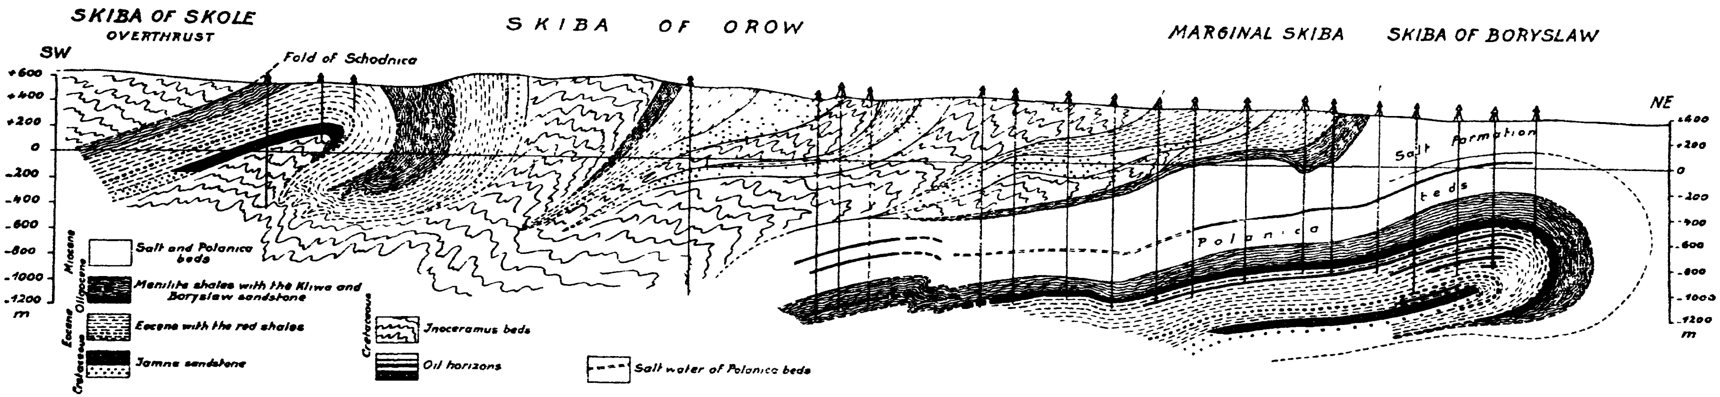

FIG. 2. Geological section, showing structure of Northern Carpathian Range in Boryslaw region. Length of section from Dinar 382 at south-west to Magda at north-east, and is approximately 9,900 metres or 6 miles (Carpathian Geological Survey). After K. Tolwinski (*Bull. Amer. Assoc. Petr. Geol.* **18** (1934)).

gas-producing areas are scattered over the total area. Only a 'dry' gasfield has so far been found on the actual foreland: Daszawa gasfield, east of Stryj. Exploration of this region, however, with its folded and obscured substratum, is still incomplete.

The long slices, or 'skiby', of the front may be compared to those known from the Appalachian Mountains; they are long, generally parallel thrustblocks which may extend for hundreds of kilometres. In the Boryslaw district the outer slice, largely obscured by the foreland Miocene, is 'the Boryslaw skiba'; it is over-ridden from the south by 'the Marginal skiba'; this in turn by the 'skiba of Orow', and over this, farther south, the 'skiba of Skola' is thrust (this latter slice already belongs to the Median belt). These skiby consist of folded Cretaceous, Eocene, and Oligocene rocks. Petroleum deposits occur in the Cretaceous Jamna Sandstone, a fine-grained porous sandstone of varying thickness, up to 30 metres. The main production is found in the Boryslaw Sandstone, a fairly porous sandstone, averaging 20 metres, with variable porosity and hence erratic production, near the base of the Oligocene Menilite shales. The Eocene shales are somewhat creviced and may contain oil or gas on joints and bedding planes, but good reservoir sands do not occur. The element of the outer Boryslaw skiba extends for a long distance to the north-west and south-east, along the entire mountain front, and yields production 100 kilometres to the south-east of Boryslaw, at Bitkow. The number of individual folds varies in this skiba. The Miocene foreland contains beds of rock-salt, which cause diapir folds in the southern, more intensely folded belt (cf. sub. 3). Farther away from the front the folds become broader and flatter (Daszawa gasfield).

Fig. 2, after K. Tolwinski [3, 1934], gives a south-west to north-east section through the overthrust and drag-folded complex which contains the Boryslaw-Schodnica oilfields, in the Marginal zone. In the Jaslo district in the western Carpathians, 140 km. north-west of Boryslaw, oil is produced from long narrow and steep anticlines in calcareous clays and sandstones of Oligocene age, with an Eocene and Cretaceous core (Potok anticline). The reservoir rocks are here in the lower-Eocene and upper-Cretaceous sandstones.

The little oil produced in the Magura zone of the Jaslo district is of a density 0·720–0·870 (= 65–31° Bé.); these fields are on the margin of the Magura mass, where it is thrust on the Median complex, and are evidently derived from the latter.

In the Median zone of the Jaslo district the oils vary still more widely in density: from 0·700 to 0·950 (= 70·5° to 17·5° Bé.), but are mostly around 0·850 (= 35° Bé.) in the more important productive areas.

In the Marginal belt, in the Boryslaw area, the oils average 0·850 in density (= 35° Bé.); at Bitkow in the south-east; *c.* 0·810 (= 43·2° Bé.).

All the oils are generally of paraffin base.

The comparatively heavy nature of many of these oils is still more surprising for a zone of more intense deformation than at Turner Valley, in Alberta. It proves that metamorphism is by no means necessarily a consequence of strong dynamic thrust. It is true that the primary origin of the Carpathian oil is still in controversy, and that the accumulations in the strongly folded and thrust strata may have migrated into them from below, after the diastrophism. However, the substratum of the Carpathian thrust-sheets must also have been subject to tremendous stress and drag, under a terrific load. According to Petrascheck, coals occurrin below the Carpathian thrustsheets are totally unaffected by metamorphism, a condition greatly differing from the Appalachian coalfields, and explaining why oil has been preserved in the substratum.

Oil has been produced for a long time in the northern Carpathians: at first from natural seepages and hand-dug pits; modern development dates from about 1860. Prior to 1916 most of the considerable amount of gas associated with the oil was allowed to escape; at present there are gas-lines (150 km. to the city of Lwow and 77 km. from Jaslo to Tarnow), and some 25 natural gasoline extraction plants. Boryslaw has produced from 1886 to 1932, 23,500,000 tons (174 million barrels) of oil and more than 5,000 million measured cu. metres of gas (176,500 million ft.), from 1916 to 1935. The total quantity of gas wasted prior to 1916 is estimated at 10,000 million cu. metres (353,000 million ft.).

The gas-oil ratio is about 60 cu. metres of gas per 100 kilograms of oil (= about 3,000 cu. ft. per barrel). Natural gasoline produced amounted to 38·8 million kilograms, from 251 million cu. metres of gas treated, equal to about 1·5 gallon per 1,000 cu. ft. of gas.

For further information the reader may be referred to articles by Ch. Bohdanowicz [4, 1933], and K. Tolwinski [3, 1934].

3. **Saline structures** are frequently associated with oil deposits. Since they result in intense dislocation of strata, these structures may be mentioned when discussing oilfields in folded rocks. They occur when a stratigraphical sequence contains intercalations of rock salt, anhydrite, or gypsum, or even mere shaly strata with a considerable admixture of salt grains. Rocks of this nature behave as a plastic material whenever they are subject to pressure, either through orogenic thrust or through the weight of mere overburden.

Saline formations occur in all geological periods, from the Lower Cambrian (Hormuz Series of the Persian Gulf region) to Recent. The most important bodies of water in which salt is now being deposited are inland lakes, such as the Great Salt Lake of Utah and the Dead Sea. Contemporary marine saline lagoons are in all cases marginal to larger bodies of normal sea like the Red Sea, the Caspian, or the Gulf of Mexico. A classical example is the Qara Bughaz in Transcaspia. It would seem that the climatic conditions of the present time are nowhere sufficiently severe to cause such widespread marine concentration as has evidently occurred at some times in the past, notably in the Permo-Triassic and Middle Tertiary periods.

When a salt formation is buried under as little as 2,000 ft. of sediments, the pressure (about 170 kg/cm.^{2}) already begins to render the salt plastic, as is shown by its behaviour in salt-mines (Mines Domaniales of Alsatia). When the formation is more deeply buried, the extra pressure forces the plastic salt and gypsum through the cover of overlying rocks: it bursts through as circular intrusive plugs (salt-domes), entirely comparable to volcanic necks. The mechanics are evidently very similar. This is another case of 'sedimentary volcanism'. Tangential pressure does not seem to be required for the formation of these circular vents: the mere weight of the overburden (between 20–30,000 ft. for the Iranian salt-domes, at least 15–20,000 ft. for the American Gulf Coast) appears sufficient. Fulda has assumed that a thickness of overlying sediments of about 11,000 ft. is necessary before a neck of salt can burst through overlying competent strata by the sheer weight of rock pressure. Once a vent is formed, isostasy may keep the salt moving upward until equilibrium is

attained. Thus a salt-dome can rise above the surrounding topography.

When, in addition, tangential pressure, caused by orogenetic thrust, acts on a sequence containing a saline formation, the salt beds behave like a lubricant and are responsible for a sliding and independent crumpling of the overlying rocks leading to an extreme structural discordance between them and the underlying rocks. Sliding and independent folding of this nature explains the structure of the Jura Mountains of Switzerland and France, where the thrust of the Alps appears to have sheared the entire blanket of Upper Mesozoic strata off its pre-Triassic crystalline base; it was compressed into folds, whilst sliding over the Triassic saline formation that underlies the mountains. The structure of the front of the Iranian Mountains of Iran has been found to be something similar. Since the rigid Asmari Limestone, 1,000 ft. thick, underlying the saline Lower Fars formation (Lower Miocene) is the prolific oil reservoir of this petroleum province, the task of the geologists is the detection of suitable covered structures in this presaline formation. There it was soon discovered that the surface folds offer no guidance: that superficial anticlines have been thrust over synclines, and that the violent contortions and faulting have no counterpart in the broad simple folds of the limestone basement. The plastic salt and anhydrite have moved from some parts of the structure and have been massed to considerable thicknesses in others (the so-called Omega-fold of Busk). The rather involved structure following the northern and western edges of the Harz Mountains, and elsewhere in the north German plains, very probably had a similar cause.

When upthrusts of salt and tangential pressure act together, very complicated diapiric salt anticlines result in which the saline beds are thrust through the crest of the anticlines. Beautiful examples of such structures are described from the southern front of the Carpathian arc in Roumania. Circular salt plugs, however, also occur in previously folded regions (for instance, in Iran and in Moldavia) and clearly show the independence of such vents from normal folds, and also that the age of the uprise of the salt is not necessarily related to periods of folding of the strata they have pierced. In Iran the salt-domes are in general associated with anticlines, but they are not regularly located on the highest part of such structures, but rather on the pitching ends or on the flanks, quite indifferently. Some few are situated in synclines. Also, rarely are there visible lines of dislocation or major faulting which could account for the distribution of the plugs. This independence indicates that it is not so much tangential pressure that causes the salt necks to rise, but rock pressure by weight; sometimes these agents act simultaneously, in other cases they may be entirely unrelated and take place at different times.

The columns of salt contain an enormous amount of material. A salt plug which emanates from a stratum 20,000 ft. deep, and has an average diameter of a mile and a half (which is the order of size of very many salt-domes), would have its salt requirements satisfied by the material contained in a bed of salt 150 ft. thick over a square with a 15-mile side. Since in many regions salt-domes are very numerous and close, it is very probable that the entire original supply of salt has been exhausted and that many deep-seated domes, such as are known on the American Gulf Coast, have not been able to reach the higher levels on account of a lack of supply. If it were possible to reach the parent salt horizon by drilling, no salt would be encountered. Some plugs appear to have been pinched by lateral pressure and assumed an overhanging mushroom shape. They may even have become disconnected from their base and been squeezed upwards independently, and may now be rootless.

Saline domes occur wherever saline formations are buried at sufficient depth. We know them from America (Texas-Louisiana, Utah, Mexico, Bolivia), from Germany, Spain, Roumania; from North Africa, Egypt, Palestine, Arabia, Transcaspia, Iran, India; and continuously new finds are being reported. The Cambrian salt-domes of southern Iran are probably the most spectacular in the world. More than 100 of them are mentioned by G. M. Lees. Their average size is about 3 miles in diameter, and in some cases they form mountains as much as 4,000 ft. above the surrounding country. They present some unique evidence on the plasticity problem. In the case of several of the higher domes the salt has even commenced to *flow* downhill as a 'salt-glacier', whilst the rock-salt remains solid, with its normal banded structure, and is totally distinct from a slide of debris. Evidently, the salt continues to rise within the plug and thus supplies this overflow. Since rock-salt is known to acquire an exceptional plasticity when wetted, the occasional rains of the region (yearly rainfall about 3 in.) play a part. Even 'gypsum-glaciers' are reported by A. Wade from the northern Red Sea area.

Not all salt-anticlines and salt-domes are associated with oil deposits. They can only carry oil if an adequate supply from source beds is present in the area. Since the saline facies is generally favourable to the genesis of petroleum (see article on the Stratigraphical Distribution of Petroleum) we find many commercial oilfields connected with saline structures, the latter having favoured migration and accumulation in reservoir rocks. The upthrust of the salt core, either in diapiric folds or in salt-domes, has often dragged the adjacent beds, sealing their upper ends against the salt, and thus created good reservoirs in strata of favourable porosity. Sometimes the salt plug is covered by a cap-rock, often a dolomitic, more or less cavernous mass of cemented residue remaining after partial solution of the salt. If oil can find access to a rock of such nature, it finds an excellent reservoir, and a prolific oilfield may result (Spindletop, &c.). As in all oilfields, a series of favourable circumstances and events must coincide, i.e. genesis, migration, accumulation, and, last but not least, preservation of petroleum.

For further information, the reader may be referred to the Symposium on Salt-domes [5].

THE ROLE OF FAULTING IN THE ACCUMULATION OF OIL AND GAS

By Professor V. C. ILLING, M.A., F.G.S., M.Inst.P.T.

Imperial College of Science and Technology

A FAULT is a fracture in the earth's crust resulting in a relative displacement of the rocks on either side of the fault-plane. Unless the fracture takes place along the bedding-planes it involves a break in the continuity of the sedimentary layers, and if the stratigraphical displacement is sufficient the broken edges of a stratum are completely separated at the fault-face. Should this involve the juxtaposition of two formations which are essentially dissimilar in their physical nature, the resultant effect is to introduce an anomalous condition in the neighbourhood of the fault which will greatly affect the flow of liquids through the rock masses in its neighbourhood.

There are three physical and geological effects associated with faulting which require consideration. Firstly, the physical continuity of the beds is disturbed so that fluid movement along them is affected in the neighbourhood of the fault. Secondly, the physical nature of all the competent rocks broken by the fault is liable to be altered by secondary fissuring which will increase their permeability. In the third place the formations close to the fault-plane are liable to suffer secondary warping or fracture which alters their attitude and results in anomalous structures near the fault.

The incidence of these three alterations in the physical condition of the strata may produce the following effects so far as oil movement and accumulation are concerned.

(*a*) *Trap Structures.*

Where the fault displacement completely breaks the continuity of a porous horizon and the torn edges of the latter become plastered with a mass of plastic and impervious material, the continuity of flow through the porous rock is broken. Should the fault lie athwart the line of oil and water migration, the area adjoining the fault becomes a zone of stagnation and an oil trap may be produced. Where the displacement merely throws one porous horizon against another the changes in permeability are not important and no trap will result.

(*b*) *Associated Trap Structures.*

A fault represents a reaction to a local condition of strain. The resulting fracture is not usually the only reaction, for the strata may be warped as well as broken. This distortion near the fault usually involves some longitudinal and considerable cross-folding. Such readjustments to the local stresses may produce trap structures in themselves apart altogether from the main fault.

(*c*) *Induced Permeability.*

Where the fault-plane intersects rigid formations there is often considerable fissuring of such strata. This provides additional porosity and at the same time greatly increases the permeability of the formation as a whole. Such features may greatly increase the productive capacity of the formation.

(*d*) *Vertical Migration.*

The induced fissuring associated with fault-planes may lead to extensive oil and gas movement wherever such fissures remain open. In many cases this has led to the escape of oil and gas at the surface. In other cases the movement produces secondary accumulations at higher horizons which are in communication with fault-planes.

(*e*) *Contact Enrichment.*

The fault displacement may bring a rock into contact with a source rock. In this case oil-flow may occur across the fault-plane and a commercial accumulation may be produced in the porous rock.

Fault Traps (*a* and *b*).

A normal strike fault produces the simplest type of trap structure in so far as migration of oil and gas are usually up dip, and such a fault will lie athwart the movement. Where a porous reservoir is covered by an impervious and plastic cap and the latter is downthrown on the up-dip side, the plastic rock seals the reservoir on its upper truncated edges and a perfect trap may be produced. The sealing effect of such fault structures is greatly enhanced by the longitudinal closure with which they are usually associated. The zone of maximum faulting in the middle of the up-faulted block has often developed sufficient up-warping in itself to form an anticlinal trap, and the resultant structure is both a faulted and folded one. Luling is an excellent example of a structure in which faulting alone is the cause of the accumulation. The structure of the down-dip side of the fault is unaffected by folding, and the oil in the Edwards Limestone has been trapped by the down-faulted clays of the Taylor Marl [2, 1929] (Figs. 1 and 2). On the other hand, the Mexia structure is also associated with considerable warping of the crest of the structure close to the fault-plane, and an appreciable amount of closure must have been induced by these folded conditions [3, 1929]. Both of these examples are probably cases of the trapping of oil during lateral migration, and there is little evidence to support the view that they represent oil accumulation produced by vertical migration up the fault-planes [4, 1934].

It is a significant feature that practically all the fault fields of the Balcones Fault Region represent up-faulted blocks with the downthrow on the western side. They may be complementary to the main Balcones Fault itself which has a movement in the opposite direction, and represents a general subsidence towards the Mexican Gulf. The fact that it is the subsidiary faults and not the main one which contain the oil accumulations may be partially due to the fact that they lie between the main fault and the source of migration, and would therefore have intercepted the oil. This, however, does not appear to be the only reason, and it is more probable that such fault structures are usually associated with longitudinal as well as transverse closure,

whereas this is not normally the case with a fault where the dip and downthrow are in the same direction.

Dip faults on a simple monocline do not show any tendency to trap oil, but where such dip faults occur on the crests of anticlines, the closure due to a combination of folding and fracture often produces important segregations of oil on these fault segments. A plunging anticline cut off by cross-faulting from the main crest may produce a local closed structure which is as efficient as the main dome in spite of the fact that it is not the highest point on the main structure.

Strike faults on folded structures may produce local traps just as they do on monoclines, the folding already present helping to increase the efficiency of such structures.

Sometimes an association of two or more oblique faults on a monocline produces a sector bounded up dip by an obtuse angled set of intersecting fault-planes. Such structures produce effective reservoirs, provided the faults are themselves sealed, for longitudinal closure is taken care of very effectively by the obliquity of the fault-planes.

Some strongly folded anticlines have their steep limb shattered by reversed faults. The resultant effect from an oil accumulation point of view is to break the continuity of the producing horizons and sometimes to repeat the latter in a vertical section, thus creating an upper and lower producing horizon separated by the reversed thrust. In most cases the thrust consists of the more plastic portions of the sequence squeezed and shattered by the intense movement, and it forms an excellent seal to the oil in the underthrust segment.

Occasionally oil is found in commercial quantities under regional thrusts of still greater dimensions, a classical example being the Boryslaw field of Poland. In this case, however, the sealing effect is due more probably to the plastic nature of the Miocene clays than to the effect of the overlying thrust.

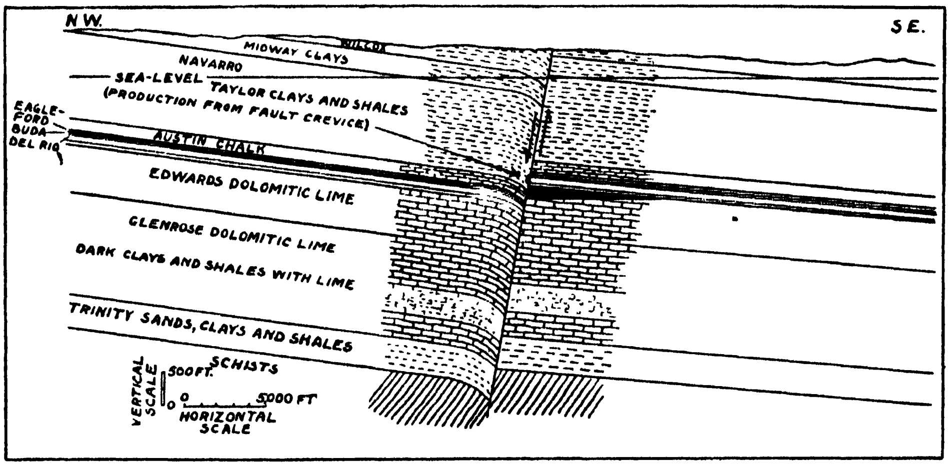

FIG. 2. Generalized north-west–south-east cross-section showing structure and stratigraphy of the Luling fault (after Brucks).

Induced Permeability (c).

In some oil-pools, particularly those containing limestone reservoirs, the fissuring produced by faulting and accentuated curvature due to torsion plays an important part in rendering the oil rock more permeable. Such open fissured conditions are commonplace in mineral lodes, but there has been a reluctance on the part of oil geologists to accept the idea that open fissures occur in these rocks. There is, however, no valid reason why such fissures should not occur, provided the rocks are sufficiently competent to maintain them. The large gash-veins filled with solid bitumen are good examples of such open fissures, and the open cracks, joint-planes, and fault fissures which have been found filled with gas-carried muds as features of sedimentary vulcanism are other examples. Wells which penetrate into such fissured conditions are liable to give abnormally high production, which is probably due more particularly to the increase in permeability than the change in the porosity.

Vertical Migration (*d*).

There can be little doubt that while faults may in some cases seal the oil in the reservoir rock, they are often more important as the avenues of extensive oil and gas movement across the strata [5, 1923; 6, 1919]. The association of faults with lines of seepages is one of the most obvious examples of this action, and lines of mud volcanoes lie more commonly on faults than on any other type of structure. Where an oil source is deep-seated this vertical migration along fault-planes plays an important part in the carriage of the oil to shallower portions of the structure, and there are numerous examples of such vertical oil movement, particularly in regions of disturbed tectonics. Such conditions lead to the accumulation of oil at successive horizons in a single structure, or a major reservoir may lose some of its constituents to minor reservoir rocks at higher levels. Occasionally the rocks caught up in the fault-plane may become highly impregnated, and a small but often very rich zone of oil may be found in the fault block. There can be little doubt that gas and oil may move in this way across thousands of feet of strata, and if such movement be given free play it forms a powerful aid in the concentration of oil in the rocks which come into contact with the fault. Admittedly, such fractures may, on the other hand, lead to the bleeding of good reservoirs and to the loss of oil and gas at the surface.

One of the most striking examples of fault accumulation with probably considerable vertical migration is the marginal accumulation on the edge of a salt-dome. The salt boundary is essentially a fault-face in so far as it represents the slip-face along which the salt has burst through the strata. In addition there are numerous subsidiary faults close to the salt edge, and the rich accumulations which occur locally on such margins probably result from intense oil concentration in zones of considerable vertical migration. The faults in these cases have probably focused the oil movement and then trapped it on the edge of the salt.

Contact Enrichment (*e*).

Lastly, we have the action of faults or thrusts in bringing source rocks and reservoir rocks into intimate contact and thus leading to an oil accumulation. It is not always realized that many a potential field has failed to materialize, not for the lack of oil, but because suitable reservoir rocks were not available, for it seems probable that the conditions which produce oil do not normally produce reservoir rocks. Sometimes this association of the two rock-types has been produced by faulting and thrusting. A good example is provided by the Bustenari field of Roumania, where the Oligocene has been thrust over the Miocene and has apparently been enriched with oil from that source [1, 1912].

This brief résumé of the role of faults in oil accumulation has been restricted of set purpose to the part played by faults in forming the accumulations. There is another aspect of the subject in the part played by faulting in permitting changes in the oil and water zones, as secondary water circulation commences in the reservoir. However, it may be said that faults have, in fact, three primary functions. They produce local trap structures when the conditions are favourable. They increase the permeability of the reservoir rocks and add to their capacity to allow free oil flow. Lastly, by inducing vertical migration they bring deep-seated oils close to the surface, and though in some cases this oil is lost, in others it is segregated in shallower reservoirs where it can be produced economically.

SALT STRUCTURES: THEIR FORM, ORIGIN, AND RELATIONSHIP TO OIL ACCUMULATION

By G. D. HOBSON, Ph.D.
Imperial College of Science and Technology

STRUCTURES with salt cores of a wide range of forms occur in various parts of the world. Many have long been known, some having been worked for their salt content, whilst others are of importance on account of the oil which has accumulated about or over them. The presence of salt in some of the latter was realized before oil was discovered, but for others its presence has only been proved after a considerable number of oil-wells have been drilled. The association of oil with salt-cored structures has led to an intensive search for these at increasingly greater depths, yet much of our knowledge of their structure and origin has been obtained from salt masses which have been exploited for their salt content and near which little or no oil has been found.

In the U.S.A. the first oil-well completed on a salt structure was at Spindletop in 1901, whereas in Roumania oil has been produced from the beds around salt masses since the latter half of the nineteenth century. In Germany oil in relatively small amounts has been found around salt masses and in their exploration, and within the last few years, test bores drilled from the galleries of a salt-mine at Volkenroda encountered oil in commercial quantities in the Middle Zechstein Hauptdolomit. Oil has also been found in association with salt masses in other parts of the world. Some very prolific wells have been drilled on salt structures, and the oil production from such sources is of no mean order, for over a thousand million barrels have been obtained in the Gulf Coast region alone, and more than half that amount in Roumania.

The Structures of Salt Masses and the Surrounding Beds

A complete range of salt structures is known from a normal salt bed through salt anticlines to stock-like masses of salt, yet even in the simplest forms, where the salt closely follows the gentle folds of the enclosing beds without marked thinning or thickening, it is apt to show structures which are not present in the other beds. In salt anticlines a thickened mass of salt has arched the overlying beds into an anticlinal form and is probably itself, in many instances, on the crest of a less strong fold. The salt may penetrate the overlying beds a little. Its internal structure, while generally anticlinal, usually shows complications. The extreme form of the salt is the stock—circular, elliptical, elongated, or irregular in plan and penetrating the beds which would normally overlie it, for great distances vertically. Strong contortions and flow structures are seen in the salt. Generally the sides of the stock are steep, and it may even taper downwards. The surrounding beds usually dip away steeply, to become much less steep at a short distance from the salt, and often their dip increases with depth in any vertical section near the salt. Where the salt does not reach the surface the overlying beds are commonly domed, although there are instances where a graben overlies the salt, preserving young beds within a ring of older ones. Unconformities may occur in the beds above or near the salt, and radial and peripheral faults are probably very frequent. These faults are not always easy to detect on account of unconformities, drawing out of beds, and other structural complexities.

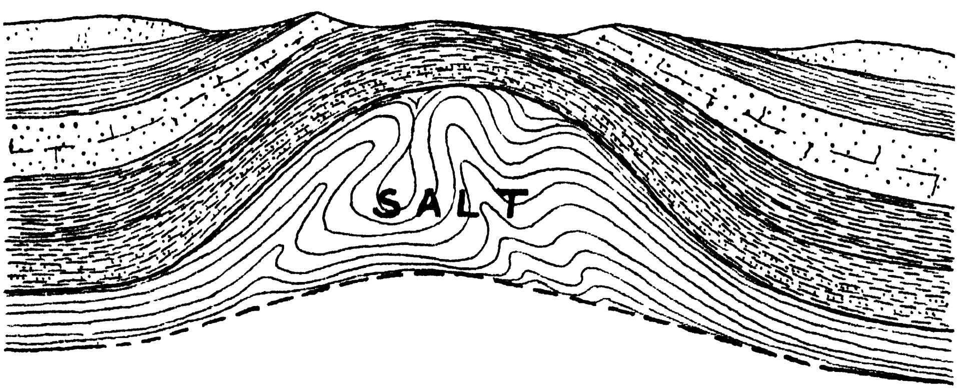

FIG. 1. Hypothetical cross-section of a salt anticline. The base of the salt is shown arched, but whether such a feature is necessarily correct is not proved.

A full range of salt structural forms occurs in the North German Zechstein Basin. The least deformed salt beds are marginal and where downward movement of the beds ceased in the early Jurassic; the salt stocks are found where the sinking and sedimentation in post-Variscan times was strong, whilst salt anticlines occupy the intermediate areas. According to Stille [17, 1926], there are cases where, in tracing a single line of uplift into the basin, the form of the anticlines goes over more and more to the form of a salt stock.

Salt masses in Roumania are widely scattered, their maximum occurrence being along the edge of the nappes. They tend to lie on curving lines parallel to the edge of the Carpathians. Usually they are elongated in plan and lie along the anticlinal crests and fault lines, but a few appear in synclinal areas or cut across anticlines. At times the salt masses seem to be overthrust and possess projections. Many have old beds at the surface on the upthrust side and

young beds on the other, but some have young beds on both sides. The salt is almost pure sodium chloride. However, there may be much mechanically infolded clay, sand, and carbonaceous matter, especially in the upper parts, and the breccias which are frequently found on the margins of are reported near Dudinsk and in the Cape Nordwick area. Little information is available concerning the salt structures of the U.S.S.R., except that it appears that they are more faulted than those of the Gulf Coast of America.

The majority of the salt masses of Iran have burst through

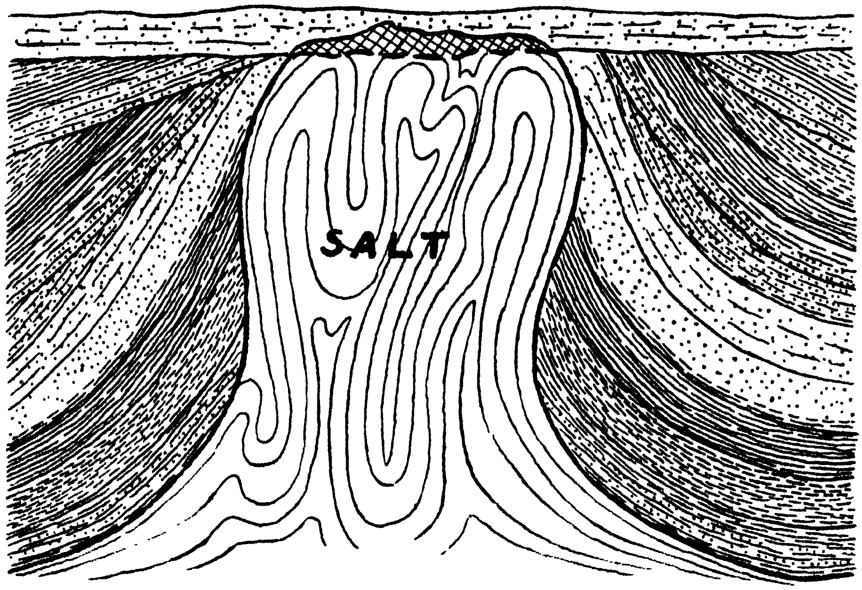

FIG. 2. Hypothetical cross-section of a salt stock, on the top of which is a salt table (cap-rock). Salt stocks range from a fraction of a mile up to several miles in breadth, and may be several miles long.

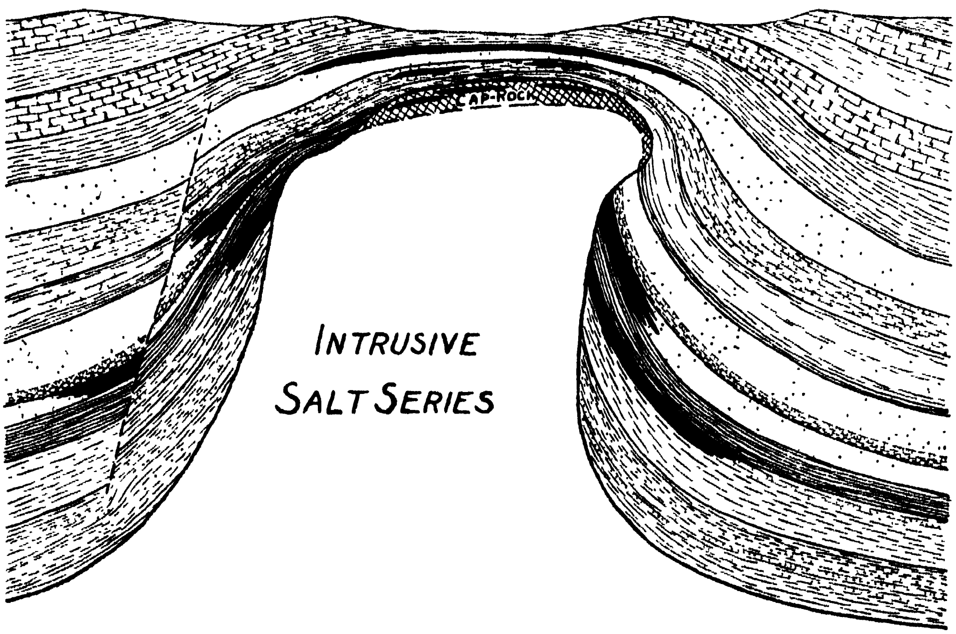

FIG. 3. Simple cross-section showing possible sites of oil and gas accumulation over and about an intrusive salt mass: super-cap, cap-rock, and various types of flank accumulation. The oil and gas are shown in full black.

the salt have been the cause of much controversy in connexion with the age of the salt [19, 1926].

Salt cores are common in the marginal folds and fractures of the Transylvanian Basin, and it is thought that they may be present at depth in the centre.

Many salt structures have been discovered by geophysical methods in the Ural-Emba region of the U.S.S.R. Others

the folded beds bordering or covered by the Iranian Gulf [8, 1931]. Some occur on the north-eastern edge of this folded zone where faults are numerous, and others pierce the Mio-Pliocene deposits of the Median mass which forms much of the high plateau of central Iran. Those connected with faults are dyke-like, although it is uncertain how far the faults are the cause or effect of the salt uprise

[12, 1931]. The others are circular or elliptical in plan. Most of the salt masses or plugs are associated with anticlines. Often they are not on the crest, but occur on the flanks or the pitching ends. The injected material is a mixture of salt, gypsum, and red shales.

Intrusive salt bodies are known in coastal Asir, Arabia, being seen in the regions of Salif, Loheiya, Guma, Gizan, and in some of the Farsan Islands [20, 1931]. A salt mass occurs at Jebel Usdum, Palestine, and others have been recorded from North Africa [3, 1932] and Spain.

A very important series of salt masses, typically of the stock type, is found around the Mexican Gulf, in the U.S.A., and Mexico. The Gulf Coast salt-domes fall into three main groups separated by barren areas—the Coastal, the Texas Interior, and the Louisiana Interior groups. The salt is covered by arched beds when it does not reach the surface. According to Hanna [7, 1934] only one salt-anticline has been delimited in the Gulf Coast province—Boggy Creek, Texas. The presence of rim synclines and overhang has been shown on some of the domes. A variable proportion of disseminated anhydrite is found in the salt, some salt cores showing as little as 1%, whilst the average is 5–10%. Elongated salt masses occur on the Isthmus of Tehuantepec.

The salt cores of the Utah-Colorado structures are generally very impure and they are connected, at least in part, with a series of parallel anticlines. In some cases the cores are plug-like [9, 1927].

In Germany, Mexico, the Gulf Coast, and possibly also in the Utah-Colorado region, it is common to find on top of the salt masses a 'cap-rock' consisting of anhydrite and gypsum. At times these are accompanied by 'limestone', dolomite, and sulphur, the sulphur and 'limestone' being a feature of the Gulf Coast salt-domes. The thickness of the cap-rock may vary from a few feet up to several hundred feet; it may cover part, or all, of the top of the salt, and on some domes it extends some distance down the side of the salt. Often it shows signs of brecciation and is highly porous. Cap-rocks are not known in Roumania.

Surface Indications of Salt Structures

When the salt approaches or reaches the surface it gives rise to a variety of features. Salt springs, depressions, marshes, and ponds are seen over some salt masses in Roumania, Germany, and the Gulf Coast. A number of the German salt structures are marked by a dropped-in mass of young beds, and some of the Interior domes of the Gulf Coast and Mexico are well expressed in the surface geology. On the other hand, surface mounds, slight or strong, may occur. In some instances in Germany there is a mound of gypsum, and the Gulf Coast domes are frequently revealed by a slight mound of sediments. By far the most striking indications of this type are shown by the Iranian salt plugs, some of which rise several thousand feet above the surrounding country, lifting an aureole of beds with them. The salt may stand above the encircling sediments, its preservation being due to the low rainfall, and may send out glacier-like tongues of salt [8,1931; 12, 1931]; or it may lie below the rim of uplifted beds, as a central depression, covered with an alluvial cloak of weathered-out clay and breccia.

Theories of the Origin of Salt Structures

The mode of origin of these salt structures is still a subject of controversy. Uptilted beds around the salt and other characteristics point to the intrusion of the salt from below. Hence, it is not surprising to find among the earlier hypotheses suggestions of a volcanic origin from analogy with some of the features shown by igneous intrusions [4, 1926]. At a later date Goesmann advanced the theory that the salt had been deposited from solution. This was elaborated by others, including Fenneman and Harris, who pictured the forces exerted by growing crystals as giving rise to the domed strata and surface mounds. According to Harris, writing of the Gulf Coast, artesian waters descended through porous beds, became heated, and took into solution salts encountered in Palaeozoic and Mesozoic beds. Under hydrostatic pressure the solutions rose at points of weakness in the beds, these points occurring mainly at the intersection of faults in the pre-Tertiary beds. Near the surface where the temperature and pressure were lower, deposition of salt set in. A core of salt formed which was pushed upwards by further crystallization of salt at its base. Thus the beds would be arched and penetrated, and near the surface the salt mass might be beheaded by subsurface waters.

Such theories are chiefly of historical interest, for critical examination shows them to have serious defects, and it is to theories based on the deformation of a normal sedimentary salt series that attention must be paid. Much of the data which has led to the formulation of the 'plastic flow' theories has accrued from observations on the German salt masses, for in that country all phases, from the undisturbed salt bed to a salt stock, are known.

Estimation of the thickness of a continuous salt bed which could supply the volume of salt present in the salt masses known in the Gulf Coast and Iranian regions, gives figures of the same order as those recorded for various salt series which are believed to have been formed in lagoons, embayments, or shut-off bodies of sea-water [6, 1920]. These salt series are complex: ideally they consist, from the bottom upwards, of zones characterized by calcium sulphate, sodium chloride, and then the more soluble magnesium and potassium salts. In particular instances only part of the full series may be present, or there may be repetitions and mixing of varying degrees of importance, depending on the detailed history of the area in which salt deposition took place. As a result of wide variations in composition, constitution, conditions of burial, and geological environment, it is difficult to generalize as to the behaviour of salt series. However, it is widely accepted that salt behaves plastically. Therefore, a critical pressure gradient must be attained before the salt will flow. This critical pressure gradient is probably affected by the thickness of the salt mass, and according to Stille [17, 1926] the carnallite zone is less plastic than the rock-salt, whilst the anhydrite is the least plastic component. (Murray Stuart [18, 1931] has put forward certain evidence in India as indicating an increase in plasticity in ascending the ideal salt series.) Consequently, in Germany the 'main anhydrite'—an anhydrite bed 40–50 m. thick and some distance up in the salt series—behaves differently from the rock-salt and potash salt. Usually it does not partake of intense folding, but shatters, and in places the more mobile salt wells up through gaps in the 'main anhydrite'. It may also be that the plasticity of the salt is dependent on the absolute pressure. If increase in absolute pressure increases the plasticity, then under the higher pressures a lower pressure gradient will be necessary to cause flow. Therefore, as the salt approaches the surface it will become less plastic and will behave more like a true solid. It is probable that the rise in temperature with depth of burial will increase the

plasticity and that the water content will be important in determining the ease of flow.

There are two main schools of thought concerning the source of the forces which cause the salt to flow and so give rise to these remarkable structures. According to one, any irregularity in the load on the salt bed which gives rise to a pressure gradient in excess of the critical value will lead to flow and uplift of the salt. The size of the requisite irregularity will depend on the relationship between the depth of burial and the plasticity of the salt, as well as on the constitution of the salt bed. Such an irregularity may arise from the accidents of deposition of the salt or of the beds above it; from weak spots in the enclosing beds; from extensive erosion of parts of the cover; or from arching of the salt and enclosing beds and erosion of the anticlinal areas. Once the salt begins to rise, then the fact of its density generally being less than that of the surrounding beds will enhance the pressure differential, in so far as the increment due to density difference exceeds the additional resistances introduced by friction, especially on the margins when the salt is penetrating the overlying sediments, and the load added in raising beds. It is likely that these two retarding influences will be relatively less important as the diameter of the rising salt mass increases. A sinking area with a growing load of sediments might, according to this theory, have salt plugs and anticlines, and these could occur, at the surface at any rate, in otherwise unfolded beds. Uplift or penetration of the overlying sediments would be dependent on their properties and on the amount of salt movement, and in the absence of faults the intrusive masses might be expected to be more circular the farther they had risen.

Kraus [11, 1923] has shown that the accepted form of some salt masses approximates to that to be expected from the lateral thrust due to a settling area.

The other school of thought maintains that the rise of the salt is due to lateral pressure in the earth's crust. Stille [17, 1926] considered the salt upthrusts as an extreme case of disharmonious folding in which the cores of anticlines had burst through the overlying beds. He conceived the upthrust less as the injection of an especially light material than as the injection of an especially mobile material. The rounded plan of many salt stocks has been taken as evidence of the absence of tangential pressure, but he pointed to the occurrence of domes in non-saline formations at the intersection of axes of uplift. In at least one salt mass in Germany there are signs of the effects of the intersection of two structural trends. Stille also found indications of the time of rise of the German salt masses corresponding with the orogenic periods. Nevertheless, at a later date he felt compelled to concede more importance to isostatic forces in Germany than he had formerly admitted, and was convinced that isostatic phenomena had played a considerable part in the upthrust of salt on the Gulf Coast.

From his study of the Roumanian salt masses Mrazec was of the opinion that they were dependent on the thrusting movements of the Carpathians, but Krejci-Graf has noted certain facts in connexion with the distribution of the intensity of folding, and the times of dying down of folding movements and maximum rates of rise of the salt masses, which seem inconsistent with this view. Krejci-Graf, therefore, has suggested that in Roumania the formation of the upthrusts was initiated by lateral pressure. This also caused the mobile salt to penetrate the overlying more competent beds at the crests of the folds where the resistance was least, whilst the final vertical rise of the extruded core was due to differential loading of the salt. Theoretically, lateral pressure could have accomplished the final stage, but he considered the field evidence to be against it.

Whatever the driving force, the theory of plastic injection of salt readily explains the contortions in the salt, the steeply dipping beds, local unconformities, the presence of radial and peripheral faults, the associated breccias, doming of the covering beds, and the occurrence of surface mounds. It is possible that a rising salt mass, which uplifts the surface sediments while sedimentation is still in progress, may affect the nature of the nearby deposits. The flow of salt from the surrounding areas, especially if the movement is due to differential loading, may be expected to create a peripheral or rim syncline, as has been indicated by Nettleton's experiments [13, 1934]. Rim synclines may increase in strength at depth.

A salt mass will cease to rise if the driving force falls below the critical value or if, due to exhaustion, development of a rim syncline, or other features, the supply of salt is cut off. The existence of rootless salt masses is possible.

In Iran, from density considerations and the elevation of the salt above the surrounding terrain, the depth of the source bed has been estimated on the assumption of isostatic balance. The figure reached is comparable with the depth of the assumed salt source in the Hormuz series, calculated from stratigraphical data. Hence, having regard to the time of rise and the general setting of the Iranian salt plugs, Harrison [8, 1931] suggested that, whilst agglomeration of the salt from an even bed into nuclei was conditioned by tangential pressure, the chief factor in driving the salt upwards was irregularity in overburden or static pressure.

Opinion is divided concerning the cause of the upthrust of salt in Germany. Romanes' [16, 1931] view is that the evidence is against any strong tangential forces having acted on the salt, for the only acute folding is in the immediate vicinity of the salt masses. He believes that folding has guided their distribution, whereas differential loading has supplied the driving force in the uplift. On the other hand, Stille and others claim that tangential pressure has played a prominent part. The tectonic setting of the Roumanian and North African salt masses is complex, and it appears that lateral pressure may have been of more importance than in some other regions. The location of the Gulf Coast salt domes in an essentially unfolded region has led to the wide acceptance of the theory that their uplift is due to differential loading. For the Utah-Colorado salt masses, intrusion contemporaneous with the folding of Late Pennsylvanian and Late Permian age has been suggested [14, 1927], but Harrison attributed much of their growth to differential loading and cited recent river cutting as a cause of the differential [9, 1927].

In many regions until there is a definite proof as to which features are causes and which effects, support may be given to one or the other view concerning the driving forces by inverting the interpretations. Tangential stresses (tensional or compressional) tend to be invoked to explain the distribution and initiation of salt uplifts. In this connexion the structure and weaknesses of the beds immediately above the original salt bed will have a dominating influence, with the result that salt masses may appear in somewhat anomalous positions in relation to the surface geology.

Origin of the Cap-rock

The origin of the cap-rock is a further matter of dispute. In Germany it has been widely accepted that if the salt rises

into the zone of circulating sub-surface waters the soluble materials at the top will be removed, leaving a more or less flat table of anhydrite, gypsum, and clay. Such solution would account for the central depressions over some salt masses, central synclines, grabens, and salt springs. On the other hand, there are geologists in America who maintain that the thickness of the cap-rock on some salt cores is too great to be explained thus, since the salt cores show only a very low percentage of insoluble matter. However, such low percentages are not necessarily a measure of the amount which may have been present in the salt which has been dissolved, assuming that solution is the correct theory. The alternative suggestions offered are that the cap-rock is part of an original sedimentary bed which overlay the salt at depth and has been carried upwards, or that it has been deposited from underground waters.

The broad divisions of the full cap-rock are, in descending order, a zone of calcite ('limestone' cap) and sulphur, a zone of gypsum, and at the base a zone of anhydrite [5, 1926]. The divisions do not consist wholly of these materials, but are merely characterized by the predominance of one of them. Gypsum may be expected to overlie anhydrite if hydration of the latter can only occur under low temperatures and pressures. 'Limestone' and gypsum are not found on the deeper domes [7, 1934], and sulphur has not been recorded in Germany. Cap-rock sulphur is characteristically associated with calcite, and its formation has been attributed to the interaction of calcium sulphate and hydrocarbons. In this reaction calcium carbonate would also be formed which has, however, sometimes been ascribed to infiltering meteoric waters.

The absence of cap-rocks on some salt masses has been attributed to the salt breaking through a developed cap or to the purity of the salt, and attempts have been made to correlate their presence or absence with the depth of the salt. Clearly, if the cap-rock is part of an original covering bed, it will be most likely to be present on the salt masses which have not risen far, whilst if it is formed by solution of salt, its presence or absence will depend on the opportunities for attack by water which have occurred during the whole history of the salt uplift.

The cap-rock commonly shows signs of several periods of brecciation and recementation, possibly due to the removal of supporting salt leading to collapse. The presence of a heavy cap-rock has been given as a possible cause of salt overhang [10, 1932].

The Age of the Salt in the Various Regions

In Germany the salt is of Zechstein age and the main uplifting movements were probably in Lower and Upper Cretaceous times [16, 1931], but they continued at later dates. The problem of the age of the salt in Roumania is not yet settled. Voitesti's interpretation of the materials in the breccias associated with the salt masses is open to grave doubt. This and quantitative considerations led him to lower the source farther and farther down the geological column until he suggested that these, and all other salt masses, arose from salt condensed from a vapour and concentrated by water in depressions on the earth's original crust. Many geologists place the age of the Roumanian salt as Upper Oligocene or Lower Miocene, and that of Transylvania as Miocene. The date of uprise in Roumania was probably Pliocene and later.

In Iran, salt of Lower Fars age has formed only one uplift where salt outcrops, although Lower Fars salt accumulations have been met in drilling. The salt and gypsum of the remaining Iranian salt plugs, together with the associated red beds, probably belong to the Early Cambrian (Hormuz series), for the debris with the salt contains fragments from the Cambrian to the Jurassic. Uplift took place as early as the Upper Cretaceous, but the majority of the plugs rose in Pliocene or post-Pliocene times.

The age of the salt of the Gulf Coast region is by no means settled and, whilst it is probable, it is not certain that it is all of one age. It is at least older than the uppermost Cretaceous [2, 1933], and there is evidence of a source at least as low as the basal Lower Cretaceous for the salt of some of the Interior domes. Some ascribe it to the Permian or Triassic, and fossil algae resembling Permian forms, though unfortunately of long time range, have been found in the salt of the Markham dome. Against a Permian age is Schuchert's contention that the Cretaceous of the Gulf Coast is underlain by pre-Cambrian metamorphics. Anhydrite and red beds have been found in the Lower Cretaceous of north-west Louisiana and north Texas, and Lower Cretaceous salt is reported at Ojinaga, Chihuahua [4, 1926]. Permian and Early Palaeozoic salt is well known some distance outside the salt-dome region. Formation of the domes was in progress as early as Wilcox (Early Eocene) time and must have continued until quite recently [2, 1933]. Harrison [9, 1927] dated the Utah-Colorado salt as Lower Pennsylvanian, but Silurian and Devonian fossils have since been found in shales which appear to have been carried up by the salt [14, 1927].

Relationships between Salt Structures and Oil Accumulations

Although it is possible that some genetic connexion may exist between oil formation and salt structures, the cases where critical examination has been possible have failed to support the idea. Andrussow [6, 1920] noted that the conditions which seem to be involved in the formation of some salt deposits, can lead to the killing of large numbers of organisms, and the organic matter may be transformed to oil in some instances. Furthermore, the earlier phases of salt uplift may have produced shallow-water conditions suitable for the rich development of organisms and may have favoured their conversion into petroleum. However, the only certain relationship is structural—that the salt in arching and uplifting the beds has provided suitable conditions for the concentration of oil into accumulations of commercial importance.

Oil may accumulate in arched beds above the salt, e.g. Humble; in the cap-rock, especially the 'limestone' cap, e.g. Spindletop. Oil production has been obtained from beds abutting against the salt, e.g. Roumania, and on the flanks beneath the overhang, e.g. Barbers Hill. Pinching out of beds due to unconformities or structural thinning will at times control accumulation and, whilst the role of faulting is often difficult to determine on account of the other structural complications, it is certain to provide traps or avenues for migration in some cases. Ritz [15, 1936] has discussed the effects of rim synclines on oil accumulation, and concludes that their strong development may divert oil away from salt-domes and cause it to accumulate on the residual 'highs' formed by interference of the rim synclines.

In particular instances oil may be found at one or more of the sites of accumulation mentioned, and since the oil may be confined to quite a small sector, a large number of wells may be necessary to prove whether or not a given salt structure bears oil.

OIL ACCUMULATION IN IGNEOUS ROCKS

By Professor E. H. SELLARDS

Director, Bureau of Economic Geology, The University of Texas

SHOWINGS of oil and gas coming from igneous rocks are known in many localities throughout the world. An extensive list of such occurrences will be found in the *Bulletin of the American Association of Petroleum Geologists*, August 1932 [8]. Notwithstanding numerous seepages and showings in wells, only a few localities have yielded commercial production from igneous rocks. The present discussion will be limited to fields which have produced in commercial quantities, the fields discussed being located in Cuba, Mexico, and the United States.

Cuba

In Cuba two fields produce from igneous rocks. One of these fields, the Bacuranao oilfield, is about 10 miles east of Havana. This field is on the northern edge of an outcropping serpentine mass 3½ miles in diameter. The oil is produced from a depth of 200 to 800 ft., and is found in fissures in the serpentine. Sedimentary formations exposed near the field are of Tertiary age. The oil from this field contains much paraffin and has a gravity of 34° Bé., although one well near the northern edge of the field produces oil of gravity 28° Bé. At the close of 1931 the field had produced 112,918 bbl. [6, 1932].

Another field in Cuba, the Motembo oilfield, likewise produces from a serpentine mass which is exposed at the surface, forming a small hill. This field, which is 34 miles east of Cardenas, rises out of flat lands, and the nature and character of the underlying sedimentary formations are not known. The oil is a naphtha produced presumably from fissures in the serpentine which is cut by igneous intrusions. The production is small, the total to the end of 1931 being about 5,000 bbl. The depth of production varies from 285 to 1,905 ft. The gravity of the oil from the deep well was 56° Bé. Some gas accompanies the oil [6, 1932].

Mexico

In the Gulf Coastal Plain of Mexico many oil seepages come to the surface following breaks in the rock caused by igneous intrusions, including igneous plugs, dykes, and sills. As a rule, the igneous rock does not afford storage of the oil in commercial quantities. However, in the Furbero oilfield in Vera Cruz commercial production has been obtained. At this locality a sill of igneous rock, gabbro, has penetrated Tertiary shales and has altered the shale both above and below the sill. Oil is obtained both from the igneous rock and from the metamorphosed shale. The production to the end of 1931 was 1,971,600 bbl., and the field was then producing 183 bbl. per day. With regard to this occurrence, E. De Golyer [5, 1932] says:

> 'The writer sees no particular significance in this exceptional association of oil and igneous rock beyond the fact that the intrusion of the igneous rock from below and its metamorphism of contiguous shales formed a channel for migration from deeply buried oil-bearing beds and a trap for the accumulation of the oil.'

United States

California.

In the State of California oil is found in commercial quantities in igneous rock at one locality, the Conejo Pass oilfield in Ventura County. At this locality the surface rock is igneous, consising of volcanic agglomerate and flows of basalt and andesite. The oil occurs at shallow depths, 60 to 250 ft., being stored in the agglomerate, sheared basalt, or in alluvium overlying igneous rock. Not far north of the field the igneous rock is in fault contact with Tertiary sediments. The oil in this field is heavy, 16° Bé., and contains no gasolene. The production is small, amounting to about ¼ bbl. per well per day.

With regard to the probable source of the oil, Taliaferro [10, 1924] writes as follows:

> 'There are three possible sources for the oil: (1) it may have originated in the Eocene shales below the volcanics; (2) it may have migrated into the fault, and thus into the volcanics, from sands in the Sespe; (3) or it may have come from organic shales interdigitated with the flows and agglomerates. There is no direct evidence as to which of these hypotheses is correct. Small amounts of oil have evidently moved upward along the somewhat porous agglomerates and accumulated in the alluvium which overlies them in the shallow valleys at the edge of the hills.'

Texas.

In the Amarillo region of north-west Texas some oil has been obtained from fissures in granite and from altered and reworked granitic material underlying the oilfields of that region. This oil, obviously, is derived from the adjacent Palaeozoic formations.

In the Coastal Plain region of Texas oil has been found in commercial quantities in igneous rock in four counties, as follows: Bastrop, six fields; Caldwell, four fields; Travis, one field; Williamson, three fields. In all of these fields the igneous rock in which oil is stored lies embedded in Cretaceous formations, the volcanic activity giving rise to the igneous rock having occurred during Cretaceous time. In some instances apparently the lava was erupted in the Cretaceous sea and formed a submarine volcanic cone. Some of the volcanic cones projected above sea-level or were subsequently so elevated as to be exposed and subjected to erosion. Some possibly were entirely submarine. A part of the igneous rock did not reach the surface and is found in the formations in the form of laccoliths, dykes, or sills. Many of the igneous masses in this region, originally embedded in Cretaceous strata, are now exposed. None of the exposed igneous rocks produces oil, and of the embedded igneous masses many are likewise non-productive.

The formations of that part of the coastal region of Texas in which these igneous rocks are found are as follows:

	Uvalde region		Austin region	
	Formation	Thickness ft.	Formation	Thickness ft.
Eocene	Wilcox	350–750	Wilcox	1,000–2,000
	Midway	250	Midway	300–400
Upper Cretaceous	Escondido	500	Navarro	400–600
	Anacacho	300–500	Taylor	600–1,000
	Austin	350–500	Austin	300–400
	Eagle Ford	75–400	Eagle Ford	30–70
Lower Cretaceous	Buda	75–150	Buda	30–60
	Del Rio	75–150	Del Rio	60–90
	Georgetown	30±	Georgetown	70–100
	Edwards	500±	Edwards	300–350
	Comanche Peak	60±	Comanche Peak	40–50
			Walnut	15
	Glen Rose	1,000–3,500	Glen Rose	1,000–2,000
	Travis Peak	100–350	Travis Peak	100–350

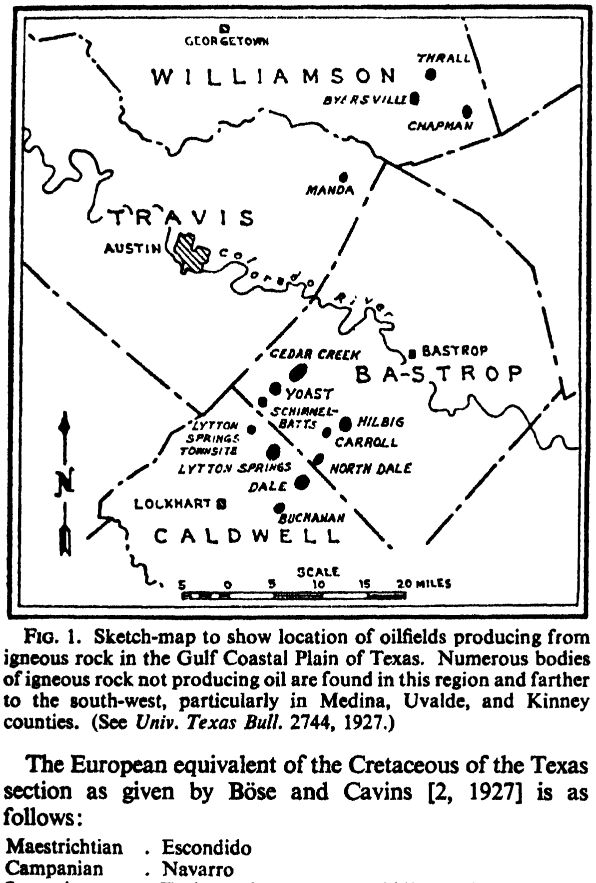

FIG. 1. Sketch-map to show location of oilfields producing from igneous rock in the Gulf Coastal Plain of Texas. Numerous bodies of igneous rock not producing oil are found in this region and farther to the south-west, particularly in Medina, Uvalde, and Kinney counties. (See *Univ. Texas Bull.* 2744, 1927.)

The European equivalent of the Cretaceous of the Texas section as given by Böse and Cavins [2, 1927] is as follows:

Maestrichtian	. Escondido
Campanian	. Navarro
Santonian	. Taylor and Upper and Middle Austin
Coniacian	. Lower Austin
Turonian .	. Upper Eagle Ford
Cenomanian	. Lower Eagle Ford, Buda, Del Rio, and Upper Georgetown
Albian .	. Lower Georgetown, Edwards, Comanche Peak, Walnut, and Glen Rose
Aptian .	. Travis Peak and basal sands

The history of the formation of these storage reservoirs appears to be as follows: Eruption and intrusion of a basaltic igneous rock occurred over an extensive area in Texas in Upper Cretaceous time. Igneous activity occurred intermittently during a long period of time, the igneous material being found in several formations. The eruptions which resulted in the most favourable conditions for storage of oil in commercial quantities were those that occurred during or immediately following deposition of the Austin chalk formation of about mid-Upper Cretaceous time. The igneous rocks became altered and were in part reworked, and, consisting probably of successive flows, they were for the most part highly porous. Subsequently they were engulfed in the next later cycle of Cretaceous sedimentation, the clays and marls of the Taylor formation. The conditions favourable to accumulation of oil in commercial quantities in this region occur chiefly in the Taylor formation, and most of the commercial production in these fields is from igneous rock embedded in this formation.

The depth to these buried igneous masses varies. The Cretaceous and Eocene strata of this part of the State form a south-eastward dipping monocline. The first field discovered, Thrall, produces at a depth of 612 to 950 ft. In other fields farther down the dip the igneous rock lies at a greater depth.

Wells producing from the igneous rock in the Texas Coastal Plain vary greatly, large wells often being adjacent to very small wells. The depth that it is necessary to drill into the igneous rock is likewise variable. The oil is mostly relatively light, gravity 36 to 39° Bé., although oil of much lower gravity is found. The oil is high in paraffin (ozokerite), and in most of the fields is accompanied by relatively little water.

Following eruption the igneous rock underwent alteration and hydration. The unaltered igneous masses consist of basaltic rocks of several varieties including olivine basalt, nephelite basalt, limburgite, gabbro, and phonolite. The altered products of these rocks are commonly referred to as serpentine. Lonsdale [7, 1927], however, has called attention to the fact that the name is not specifically descriptive of the rock. Recently the rock of one of the fields, Hilbig, has been identified by Smiser and Wintermann [9, 1935] as palagonite, a hydrated basic glass. Not only has the original rock altered in place, but at many localities has been more or less reworked and redeposited. The oil is stored in part in the altered igneous rocks and in part in reworked igneous rocks on and around these original cones.

The oil in all of these fields is believed to originate in the Taylor formation, the igneous masses serving only as storage reservoirs. The irregularly distributed, although often high, porosity of these volcanic rocks results from their accumulation as massive flows, the igneous masses being chiefly altered tuffs.

Bastrop County.

The commercial producing fields in Bastrop County are Cedar Creek (including North Cedar Creek), Carroll, Hilbig, North Dale, Schimmel-Batts, and Yost. To the end of 1934 these fields had produced a total of 1,765,001 bbl. of oil, of which the Yost field had produced 819,293 bbl. and the Hilbig field, 510,583 bbl. Each of the fields is a small igneous cone, embedded in Cretaceous strata, chiefly in the Taylor formation. The bases of the cones rest either in or on the Austin formation, although for each igneous mass there is presumably a neck or vent extending downwards. The Austin formation may in some instances slightly overlap the sides of the igneous rock. Such is reported to be the condition in the Hilbig field and, if true, indicates extrusion of the lava of this field somewhat before the close of the deposition of the Austin formation.

Yost was the first of these fields discovered, 1928,

and is now practically exhausted. The Hilbig field, discovered in 1933, which is being developed as a unit, will undoubtedly yield a much larger ultimate production than the Yost field.

Caldwell County.

The commercial producing fields from igneous rock in Caldwell County are Buchanan, Dale, Lytton Springs, and Lytton Springs townsite. The production from these fields to the end of 1934 was 9,129,500 bbl. This total comes chiefly from Lytton Springs field, 7,782,319 bbl., and from Dale field, 1,185,460 bbl.

The character of the igneous rock and its place in the Cretaceous section in these fields is similar to that of the fields in Bastrop County. The Lytton Springs field, the largest and most carefully studied of the fields of this county, has a producing area of about 1,385 acres. The oil, gravity 38° Bé., contains much paraffin. The igneous mass is oval in shape, being slightly elongated north–south, its dimensions being approximately 9,500 by 9,000 ft. The igneous cone is flat topped with steep sides. From the crest the slope, aside from minor irregularities, is gradual in all directions for distances ranging from 2,500 to 4,000 ft., beyond which it is abrupt. The difference in elevation from a high point on the crest to the lowest point that can be measured on the margin is 500 or 600 ft. The igneous rock lies near the base of the Taylor formation. It rests directly on the Austin chalk in part of the field and, in places, takes the place of the chalk. However, Bybee and Short [3, 1925] have shown that in a well near the margin of the field part of the Taylor marl underlies the igneous rock. The known thickness of the igneous rock ranges from more than 500 ft. in the central part of the field to a few feet or almost nothing at the margins. A slight structural dome at the surface overlies the igneous mass. At the crest of the dome, according to Collingwood and Rettger [4, 1926], the Lower Midway formation is exposed surrounded by Middle and Upper Midway.

Considerable faulting occurs near the dome. One fault, seen at the surface south of the field, trends north-east directly towards, and possibly into, the field.

Travis and Williamson Counties.

The one small field discovered in Travis County, the Manda field, has produced only a few hundred barrels of oil. In Williamson County three fields have been developed, Byersville, Chapman, and Thrall. The total production from these fields to the end of 1934 was 6,097,847 bbl.

The Thrall field, discovered in 1915, was the first field to produce from igneous rock. Although nearly depleted, this field is still producing in a small way, its total production to the end of 1934 having been 2,353,962 bbl. The igneous mass is somewhat irregular in outline, being about 4,800 ft. in extent east–west and 5,000 ft. north–south. The slope from the flat-topped crest is at first steep and then more gentle. The steepest slope is about 275 ft. in one-third of a mile. The producing area of the field is 473 acres. The gravity of the oil is 39° Bé.

The igneous rock lies within the Taylor marl, many well logs showing 200–300 ft. of Taylor marl under it. However, in a well assumed to be near the vent through which the igneous rock came, only 10 ft. of Taylor marl intervenes between the igneous rock and the Austin formation.

Immediately overlying the igneous rock is a thin stratum referred to by the driller as 'cap-rock'. In the north-eastern half of the field this rock consists very largely of a porous shell breccia. Towards the south-west the 'cap' consists of clay or marls with some compact limestone. This rock, in the opinion of Udden and Bybee [11, 1916], indicates that the igneous rock was extruded into the Taylor sea; subsequently the shell breccia formed on the flank which was more directly exposed to wave action, and marl and limestone on the side less exposed.

The Chapman field has been more productive, having produced 3,707,385 bbl. from its discovery in January 1930 to the end of 1934. The total producing area is 476 acres. The gravity of the oil is 37 to 38° Bé.

The igneous mass of this field, as shown by the accompanying contour map, is approximately circular or with a slight north–south elongation, being about 4,000 ft. wide and 5,500 ft. long. The maximum difference in elevation from the crest to the margins of the dome is about 400 ft. The steepest slope is towards the north-east. Faulting is not definitely recognized in this field. Only a little water has been found. The initial production of oil varies from a few barrels to more than 5,000 bbl. Large and small wells are irregularly distributed. It is difficult to determine from the logs where productive strata are located in the wells, but they are apparently at varying depths in the igneous rock. Wells drilled through the rock indicate that its thickness varies from 525 ft. in the centre to a few inches at the margins.

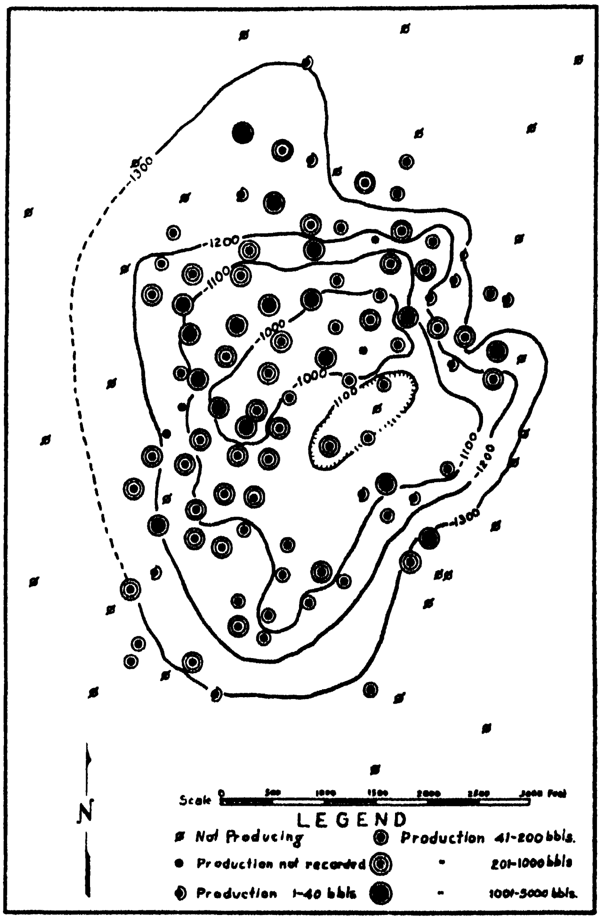

FIG. 2. Contour map of the Chapman oilfield contoured on top of the igneous rock. Contour interval 100 ft. The approximate initial production of wells is indicated by symbols as shown in the legend. This and the following illustration are adapted from illustrations made by the author and used in *Bull. Amer. Assoc. Petrol. Geol.* **16**, 748 and 749 (1932).

The igneous rock lies within but close to the base of the Taylor formation. Most of the wells drilled through the igneous rock in the central part of the field enter the Austin chalk with no intervening marl, but in wells near the margin the drillers usually log gumbo, shale, and marl between the igneous rock and chalk. In the absence of cores it is difficult to check these logs, since, as is well known, the soft igneous rock drills like gumbo and shale. However, a sample was obtained from Westbrook's M. D. Lawrence No. 8 directly under the igneous rock, depth 1,740 to 1,760 ft., which consists of fossiliferous brown shale probably of Taylor age. The records thus indicate that although the igneous rock rests on Austin chalk in the central part of the field, in some places, particularly near the margins, part of the Taylor marl intervenes between the igneous rock and the Austin chalk. The igneous rock is, therefore, a flattened oval mass lying chiefly within the Taylor formation, but with a part of the base resting on the Austin chalk. An east–west section through the dome is shown in the accompanying figure.

Not all of the oil of this field is produced from the igneous rock. A thin stratum of limestone, probably similar to that at the west side of the Thrall oilfield, overlies the igneous rock, and several of the wells are productive from this horizon. A contour map at this horizon indicates doming in this limestone, probably somewhat less in amount than the relief on the top of the igneous rock. The apparent doming of the chalk stratum overlying the igneous rock may be incidental to the presence of the dome at the time the chalk was being formed.

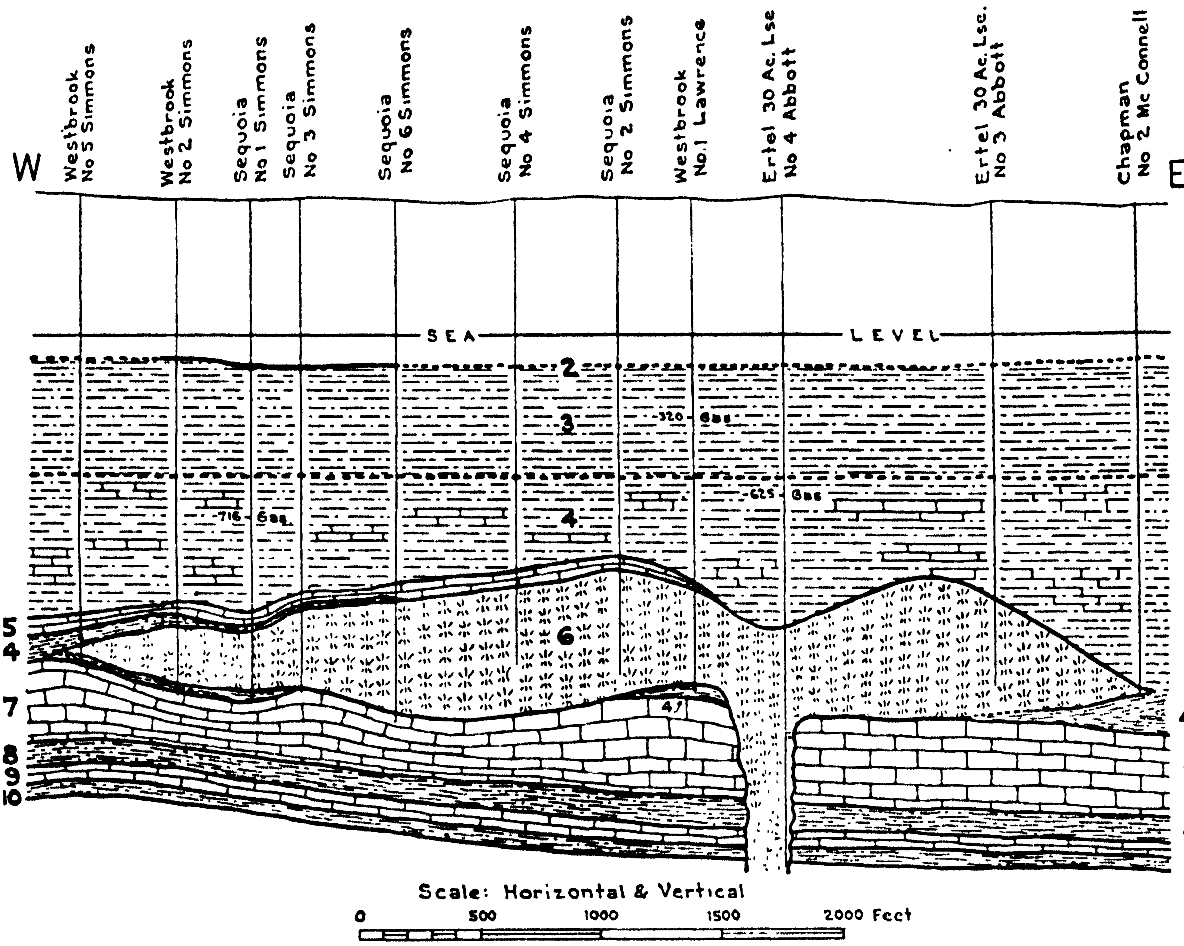

FIG. 3. Section through the Chapman oilfield showing relationship of igneous rock to overlying and underlying formations. 1, Tertiary formations, Wilcox and Midway; 2, Greensand horizon, probably at base of Midway; 3–10, Cretaceous formations as follows: 3, Navarro; 4, Taylor; 5, chalk stratum near base of Taylor; 6, igneous rock from which oil is obtained; 7, Austin; 8, Eagle Ford; 9, Buda; 10, Del Rio. One of the wells, Ertel No. 4 Abbott, penetrated 954 ft. of igneous rock, depth 1,666 to 2,260. This well apparently is located in the opening through which the igneous rock was extruded.

It seems probable that the lava flow forming this cone occurred in early Taylor time and was probably subaqueous, as indicated by the relative flatness of the igneous mass.

In conclusion, there is no evidence that the oil originated in igneous rock. On the contrary, all of the occurrences described in this paper on which there is reliable evidence support the conclusion that the oil without exception has originated in sedimentary rocks and has migrated into the nearby igneous rocks which serve only as a storage reservoir.

SECTION 7

GEOLOGICAL METHODS OF EXPLORATION

HISTORICAL NOTES ON THE DEVELOPMENT OF THE TECHNIQUE OF PROSPECTING FOR PETROLEUM

By E. De Golyer, A.B., Sc.D., F.G.S.

Introduction

The Drake well, completed on 29 August 1859, at Oil Creek, Pennsylvania, is commonly accepted as marking the beginning of the petroleum industry in the United States, if not in the entire world. This well, 69 ft. deep and with an initial production of only some 25 bbl. daily by pumping, is unimpressive enough in itself and important only because of the train of consequences which followed.

The petroleums were no new thing. They have a history of usefulness to man running back into the mists of antiquity and long antedating the establishment of the modern industry. Asphalt and bitumens were used as a cement in building the walls of Babylon, and were an article of commerce among the ancient Mexicans. Liquid petroleum, collected from springs, was used as a medicine both internally and externally by many primitive peoples, and was used as a lamp oil in Italy and China before the beginning of the Christian era. Flares from burning gas and oil springs were strange and impressive phenomena having a place in the religious rites of the ancient Iranians, Israelites, Egyptians, and Greeks, and formed the central mystery around which grew up that strange sect, the fire-worshippers of Baku.

Successful wells, purposely drilled for natural gas, had been completed near Fredonia, New York, as early as 1821. Petroleum in quantities great enough to defeat the purpose for which they had been drilled was commonly encountered in brine-wells for half a century before the Drake well. Many of these wells produced petroleum and gas in considerable quantities, a notable example being the famous 'American Well', drilled for brine in 1829 to a depth of 180 ft. on Rennix Creek, Cumberland County, Kentucky. This well flowed by heads, at intervals of 2 to 5 minutes, for 3 or 4 weeks, and then flowed steadily 'many thousands of gallons per day'.

Time was ripe for the establishment of a petroleum industry in the 1850's. The sperm-whale fisheries had passed their zenith in the late 1840's and were on a decline. Sperm oil, the prime illuminant, in the face of this decline in production and constantly increasing consumption, was becoming more expensive. Substitutes were being sought. By 1859 some considerable success was being had in the production of 'coal-oil', oil distilled from coal or shale, and already the suitability for lamp oil of the products derived by the distillation of crude petroleum had been demonstrated.

The only question with regard to petroleum as a suitable raw material from which to manufacture lamp oil and lubricants was the all-important one of quantity. This question was answered with an emphatic affirmative by the developments which followed upon the completion of the Drake well.

For almost half a century the petroleum industry continued chiefly as a supplier of lamp and lubricating oils. During the first decade of the present century, fuel oil became an important product. For almost all the last quarter-century, and at present, gasoline has been, and is, its most important product.

The Problem of Prospecting

The two essential preliminary steps involved in the discovery of a pool of petroleum or natural gas—in successful exploration or wild-catting—are, first, the selection of a suitable site for the prospect well and, second, the proper drilling of such well.

The selection of a suitable site for the well may be accomplished by casual and random location, by accident, and on the basis of incorrect conclusions and misunderstanding. Indeed, it is remarkable how many great pools have been discovered in such manner. The prospect wells themselves have at times been worried to successful completion by entirely inadequate and badly handled equipment. These are lucky accidents, however—the romantic discoveries which have their parallel in almost every mineral industry. We are concerned with the best practice rather than some spectacularly happy result which may attend the worst practice.

The science of prospecting has been more highly developed in the petroleum industry than in any other mineral industry. This condition is the result of the necessity imposed by the exceedingly high rate of consumption of petroleum and its products. The entire production of the States of Pennsylvania and New York since the beginning of the industry is hardly more than enough to satisfy the current requirements of the United States for a single year. All the oil yet produced in the eastern fields of the United States would hardly suffice for three years. We consume at the rate of six to eight Humbles or Spindletops, two to three Salt Creeks, Cushings, Coalingas, or Santa Fe Springs per year. No single pool has yet produced a total of oil sufficient to satisfy our current consumption requirements for one year, and only one field—East Texas—gives evidence of being able to break this record. Obviously, an industry subject to such tremendous demands must develop every possible skill in prospecting for new deposits.

The Drake well was drilled because of nearby oil-springs, by men whose entire knowledge of the occurrence of petroleum could have been only that it could sometimes be skimmed from the flow of springs, that the exceedingly low rate of production from springs could often be increased by digging pits or trenches, that petroleum could sometimes be found impregnating rock outcrops, that it was often found—at times in quantities great enough to make it a nuisance—in wells drilled for brine, and that it might be associated with natural gas-springs. The successful completion of this well after months of wearisome effort, at the shallow depth of 69 ft., marks the beginning of successful prospecting for petroleum. The successful completion at a depth of 9,572 ft., in 1935, of the discovery well of the Lafitte pool, Louisiana, at a site in the flat swampy delta of the Mississippi River, selected as a result of the mapping of a suitable structure by the reflection method of seismic survey, is an outstanding example of the best modern practice in prospecting.

The modern science of oil prospecting has developed within the three-quarters of a century which have passed since the completion of the Drake well; for the most part

it has developed during the past quarter-century—the period when the demand for gasoline has put such pressure on the industry.

The selection of a proper site for a test well, in best modern practice, has become the business of the geologist. He early recognized the fact that most oil-pools occur in sedimentary rocks lying in folds of anticlinal type. With the study of hundreds of oil-pools, he recognized variations and modified his simple anticlinal theory, first into the more inclusive structural theory, and later, with some understanding of the fewer cases in which stratigraphic variation alone or principally may achieve a similar effect, into the trap theory.

The technique of geological work has improved substantially, particularly within the last decade. Starting with surface structural work, mapped with clinometer or by the distribution of formation outcrops, achieving further structure-finding ability through subsurface studies, and particularly after the introduction of micro-palaeontology as an aid and a control, it progressed to core drilling for structure and finally, with notable success, to the use of geophysical methods for structure finding.

The drilling of the test well has been, and is, the business of the driller and of the engineer. Constantly improving ability to drill quickly and cheaply to ever greater depths has been one of the most notable advances in drilling technique, culminating, for the moment, in the notable Gulf McElroy well No. 103, drilled to the record-breaking depth of 12,786 ft. Oklahoma City and Kettleman Hills are outstanding examples of major pools which had been recognized as favourable prospects and drilled, but which had to await this extension of ability to drill to deeper horizons before they could be successfully explored. An improvement in ability to test and secure pertinent information from the formations penetrated, as a result of improvements in coring practice, drill-stem testing, and electrical logging, has been hardly less important, as an aid to prospecting, than the increasing ability to drill deeper.

Location of Site for Test Well

The first commonly accepted guide to the location of test wells was the occurrence of direct indications—oil-springs, gas seeps, asphalt, oil-impregnated rocks, or oil-shows in wells drilled for other purposes. Most of the important oil regions and many of the great oil-pools of the world were prospected first of all because of the common occurrence of direct indications. Even a cursory review shows that this was true for Canada, Pennsylvania, West Virginia, Kentucky, Ohio, Indiana, Texas, Louisiana, Oklahoma, Kansas, Wyoming, California, Mexico, Trinidad, Peru, Columbia, Venezuela, Russia, Roumania, Poland, Persia, Borneo, Sumatra, and Java. Several great oil enterprises owe their initiation to the faith inspired by the occurrence of marked or abundant direct indications, notable examples being the Doheney and Pearson operations in Mexico and the Anglo-Iranian operations in Iran.

There is a notable tendency among modern geologists to neglect and undervalue such direct indications. It may be admitted that the direct indications are chiefly of value as positive evidence of the petroliferous character of the rock section of a particular region, and that, once such condition is definitely established by the development of oil-pools, the existence of direct indications on any specific prospect is of much less importance than in an altogether untested region.

As more pools were outlined, a crude technique of prospecting began to develop empirically. At its best, prospecting of this period was guided by vague and ill-defined geological considerations, not recognized as such by the prospector. Trend lines—lines established for any particular region by the strike of the major axes of pools already developed or by lines connecting developed pools and, when real, generally coincident with the geologic grain of the region—had great vogue in Pennsylvania and were useful as late as the early development of Oklahoma. Topographic resemblance, when effective generally a reflection of structure, had great vogue among unsophisticated prospectors. This clue was sound and was extremely useful for the earlier developers of the Texas and Louisiana coast.

These early gropings of untrained prospectors towards some understanding of the habits of occurrence of the mineral which they were seeking suggest that if the science of geology, then in its infancy and just emerging from the broad fields of natural philosophy and mining, had not been ready at hand for use when the time came, the industry would have developed a geological science, particularly the branches of stratigraphy and structure, for itself.

The first and by far the most important step towards the development of a rational technique of prospecting was the acceptance of geology as a guide by the industry. The production of oil had hardly started before the habits of its occurrence began to be studied by geologists.

Within nine months after the completion of the Drake well, Henry D. Rogers, then Regius Professor of Natural History at the University of Glasgow, State Geologist of New Jersey 1835–40 and of Pennsylvania 1846–58, and the leading structural geologist of his time, noted that the newly discovered oilfields were located on anticlines.

The first clear statement of the anticlinal theory, however, was made in 1861, in a public address at Montreal by T. Sterry Hunt, a brilliant but erratic chemist and geologist, then chemist in the Canadian Geological Survey and afterwards assistant on the Second Pennsylvania Survey. In 1865 Hunt elaborated his beliefs to the effect that oil was formed chiefly in limestones and black shales, that it was liberated by folding and fracturing which occurred chiefly along the axes of anticlines, and that it rose and accumulated along the crowns of anticlines as a result of being lighter than the water with which it was associated.

It is remarkable how clear, comprehensive, and workable a theory of petroleum origin, accumulation, and occurrence was thought out and published by T. Sterry Hunt at this early date, and how little advance in theory, except for elaborations and amendments growing out of almost three-quarters of a century of experience, has been made since his time. A modern reasonably competent geologist, with no special training in petroleum geology beyond the writings of Dr. Hunt as a text, would not be altogether inadequately trained for prospecting even to-day.

Within 8 months after the initial announcement of the anticlinal theory by Hunt, E. B. Andrews, then Professor of Geology at Marietta College, Ohio, and afterwards Assistant Geologist to the Ohio State Survey under Newberry, noted the occurrence of oil along the Volcano anticline—the 'Oil Break'—in West Virginia and Ohio, and published his conclusions describing the anticlinal occurrence of the oil and oil-springs, but apparently regarding fissures as the factor controlling accumulation and the anticline of importance only because its axis might be a likely locus for fissures.

Andrews belonged to that important and extensive school of the early days of the industry which regarded fissures in the containing rock as essential to account for the

occurrence of important accumulations of petroleum, and which failed to recognize the quantitative sufficiency for such purpose of the pore space in ordinary sandstones.

The common belief in the importance of crevices and fissures was so great that a 'crevice finder' was invented and wells were explored with it for several years to the profit of its operators.

The 'fissurites' died but slowly, though Alexander Winchell, sometime Professor of Civil Engineering and later of Geology, Zoology, and Botany in the University of Michigan, State Geologist of Michigan 1859–61 and again in 1869–71, and one of the most popular writers and lecturers on geology of his day, had suggested as early as 1860 that sandstones themselves were sufficiently porous to contain oil, even without fracturing, and John F. Carll, oil expert to the Second Pennsylvania Survey, showed that the normal porosity of sandstone was great enough to account for the most productive wells yet discovered.

Henry D. Rogers, in 1863, in a paper notable chiefly for its clear statement at so early a date of the fundamental principles of the carbon ratio theory, afterwards rediscovered and applied by David White, notes additional evidence favouring the anticlinal theory.

Hunt, in his early writing, showed a remarkable understanding, for so early a time, of the function of gas in the production of oil, and a Mr. Briggs, in 1865, suggested that oil-wells flow because 'Petroleum is an intimate mechanical mixture of the gases into which petroleum decomposes, with the petroleum fluid, like that which exists between the carbonic acid and the water in a soda fountain.'

Various other geologists during this early period of speculation published theories and comments essentially in the nature of those by the authors mentioned, but geology was little used, if at all, in the actual business of prospecting. The validity of the anticlinal theory was not accepted unanimously even by geologists themselves. The emotional, energetic, sometimes pessimistic, and always caustic J. Peter Lesley, topographer on the First Pennsylvania Survey, one time Congregational minister, Professor of Geology in the University of Pennsylvania, and head of the Second Geological Survey of Pennsylvania (1874–88), attacked it often and with vigour. His opposition, as the head of the official survey of the then most important oil-producing State in the world, must have done much to delay the acceptance of the theory by the industry.

The Canadian, West Virginia, Ohio, and Indiana surveys stood definitely for the theory of anticlinal accumulation; the Pennsylvania survey, under Lesley's direction, stood definitely and bitterly against it. This is the more surprising, since the anticlinal occurrence of oil had already been noted by Lesley's eminent predecessor, H. D. Rogers, and the roster of assistants on his own survey included the names of T. Sterry Hunt, discoverer of the theory, and I. C. White, who by his application and championship of the theory has indelibly associated his name with it.

Hans Höfer, the eminent Austrian geologist whose name is often linked with those of Hunt and Andrews as discoverers of the anticlinal theory, in 1876 published the conclusions resulting from a visit to America in which he called attention to the fact that in Canada, Ohio, and West Virginia the greater quantity of the oil occurs on the anticlines.

I. C. White, the father of the anticlinal theory, was an assistant on the Second Geological Survey of Pennsylvania under Lesley from 1875 to 1884, engaged chiefly in palaeontological and stratigraphical investigations. Early in 1883 he was approached by William A. Earseman, a veteran oil operator then in the employ of the Anchor Oil Company, who had noted the occurrence of many of the great gas-wells of Pennsylvania along anticlinal axes as shown on maps of the State Geological Survey of Pennsylvania, and who had enlisted the financial support of J. J. Vandergrift, President of the Forest Oil Company, for a geological investigation of the occurrence of natural gas. White spent the month of June 1883 in visiting and studying the geological surroundings of all the great gas-wells that had been struck in the Appalachian district. In this work he was often accompanied by Earseman, and the conclusion which was expressed in his report to Vandergrift, at the close of his examination, was that 'the rock disturbance caused by anticlinal waves was the main and important factor in the occurrence of both petroleum and natural gas'. The hypothesis was verified during the next 2 years by the successful location of the Grapeville, Washington, and Belleveron fields, and in 1885 the theory was published.

The importance of White's work is that it was apparently the first field investigation on a broad enough scale to justify generalization, that he made practical proof of the resulting theory, and that, with the aid of other geologists, among the foremost being Edward Orton of Ohio, he successfully defended it against the renewed attack of Lesley and the opposition of Carll, Ashburner, and Chance, all of the Second Pennsylvania Survey.

White's own modest statement and probably his last statement of his position as a discoverer and applier of the theory is as follows:

> 'As you are aware, I was the first petroleum geologist, although Hunt, Andrews, and Höfer had preceded me, in suggesting the anticlinal theory for the accumulation of oil and gas. Their publications, however, were unknown to me, and the discovery was original so far as I was concerned. However, none of the three did anything to put their discoveries into practical operation. I was the first one to do that and demonstrate the truth of the structural theory for the accumulation of oil and gas by going into the field and actually making successful locations on structure.' (I. C. White to E. De Golyer, 4 February 1925.)

Notwithstanding White's brilliant demonstration of the value of the structural theory, the oil industry ran on for another 30 years without much more than sporadic attempts to utilize it. For the United States, this is not surprising. The petroleum resources of the nation were enormous and almost untouched. Drilling was to shallow depths and comparatively cheap. Enough oil was found by ordinary hit-or-miss wild-catting to result in temporary but frequently recurring periods of over-production and consequent market demoralization. There was no economic necessity for improved methods of prospecting, and the industry was not concerned about them.

Among the earliest sustained efforts to organize geological work as an aid to prospecting were probably those in foreign fields, notably the Dutch in the East Indies and the English in Mexico. The late Edwin T. Dumble joined the Southern Pacific Companies as a geologist in 1897, and W. W. Orcutt the Union Oil Company of California in 1898. The organizations founded by these two pioneers are probably the two oldest geological departments having to do with oil which exist in the United States to-day. A. C. Veatch was geologist to the Houston Oil Company for a short period in 1901–2.

The reports and publications of the United States Geological Survey since an early date have contained occasional important papers dealing with the geology of oilfields, but from about 1907 to 1915 an exceptionally important series of reports on the geology of oil-producing areas scattered from Pennsylvania to California were published. Any unprejudiced consideration of this series of reports revealed such evidence of the structural occurrence of the petroleums as could not fail to convince, and this broad demonstration of the possible value of geology as a guide to prospecting was undoubtedly important in bringing about its use by the oil industry.

These surveys at least convinced the geologists who made them. W. T. Griswold left the Survey for consulting work in oil in 1907. Frederick G. Clapp, Ralph Arnold, and Cassius A. Fisher left for the same purpose in 1908. C. W. Hayes, C. W. Washburne, E. B. Hopkins, and the writer joined the geological staff of the Mexican Eagle Oil Company in 1909.

Among other early American petroleum geologists in commercial work were H. B. Goodrich, who examined the oil possibilities of New Brunswick in 1899–1900, reported on Spindletop and other coastal fields in 1900, on the Ebano field of Mexico in 1902, and located the Wheeler field in southern Oklahoma in 1904, Roswell H. Johnson, who was a consulting geologist in Oklahoma from 1908 to 1912, Charles N. Gould, L. L. Hutchinson, Julius Fohs, W. E. Wrather, James F. Gardner, William Kennedy, Lee Hager, W. F. Cummins, E. W. McCrary, W. S. Vandruff, R. E. Vandruff, and F. J. Carmen. Among foreign geologists early in the petroleum industry were P. C. A. Stewart, T. G. Madgwick, F. W. Moon, Leonard V. Dalton, W. H. Dalton, F. Laurie, G. Jeffreys, Max Muhlberg, and F. Zuber.

The period from 1900 to about 1915 was a period when geology was winning its way into the industry. By 1915 a geological department was the rule rather than the exception in a well-organized oil company. By this time the necessity for increased production and reserves imposed upon the industry by the rapidly increasing use of automobiles and the demands of the Great War had forced it to seek improvement in its prospecting technique.

Improvement in the technique of prospecting, in so far as the selection of a proper site for the test well is concerned, has, since the general acceptance of geology as a guide, become entirely a matter of improvement in geological method and in the geologist's ability to interpret his results.

Development of Geological Technique

The geologist, as a prospector, has always been chiefly a structure hunter. Three methods of finding structure have been developed: by surface mapping, by subsurface studies, and by geophysical methods.

The earliest successful surface mapping for oil prospecting was probably that done by I. C. White, who determined the relative elevations of the outcrop of his key-bed by running a line of spirit-levels. Most of the early work was done by mapping the dip and strike of occasional outcrops with a hand clinometer. Another early method was the simple mapping of the distribution of outcropping formations.

The plane table, which had long been in use by topographers and engineers, was probably first used in the Cadiz, Ohio, quadrangle in 1901 by W. T. Griswold, who as a topographer had been mapping the quadrangle. It was being used by geologists of the U.S. Geological Survey in mapping the public lands of the Western States for coal classification as early as 1906, also it was used by geologists working in Mexico as early as 1909, and was commonly used in Oklahoma in 1913.

The next and latest refinement in surface mapping was the introduction of aeroplane photography about 1920, after the close of the Great War. Aerial photographs record 'all and more than the eye can see'. To the geologist they are important as providing, rapidly and economically, accurate base maps containing a wealth of detail not obtainable by any other method. The camera, as a primary geological instrument, records with such precise fidelity and in such detail physiographical features such as hills, drainage sources, &c., that even stream patterns give clues to the existence of faults and structures—clues that often can be verified by field examinations. It also discriminates between colour values beyond the power of the eye, and often records them clearly enough to indicate the distribution of formations, and so structure. Unfortunately, for many of the oil regions which have already been studied in great detail, much of the geological value of aerial photographs is no longer important, since the structures having surface expression have already been found by less detailed and cruder but effective methods of mapping. The Rancherias gasfield in northern Mexico was first found by aerial reconnaissance, and the Cuevitas field in Starr County, and the O'Conner field, Texas, were indicated for further examination by aerial photographs.

Crude subsurface studies are almost as old as the oil industry, but their first systematic and comprehensive use in petroleum geology probably began with the organization of a subsurface branch of the geological department of the Empire Companies about 1917 by A. W. McCoy. Subsurface studies not only afford clues as to structure, but give information as to stratigraphical variation, the nature, extent, and distribution of sands and formations, the existence and extent of unconformities, information as to convergence, and generally are of essential importance to a proper interpretation of surface studies as well as in their own field.

The basis for most subsurface work is correlation, and the earlier work was crude indeed since it rested on no sounder basis than the driller's log. This was soon corrected to some degree by the collection and examination of samples. Real progress came with the introduction, about 1920 by the late Edwin T. Dumble, of micro-palaeontology as a guide to the determination of the age and stratigraphical position of well cuttings. Coincidentally with the development of micro-palaeontological determination came the introduction of the double-core barrel, improved coring practice, the use of heavy minerals as indices for correlation, and improved correlation as a result of detailed examination, on the basis of lithology alone.

The latest and one of the most important aids to correlation has been the increasing use within the last few years of electric logs.

Belonging properly to subsurface studies, but occupying a place between the study of well logs and surface mapping, are pit-digging for geological information and core-drilling for structure.

The digging of a test pit for purposes of geological examination is essentially an attempt to create artificially a geological exposure. It is a special form of trenching, one of the favourite methods of the mining prospector and engineer, and older than the petroleum industry. The

method was used extensively and successfully in the Dutch East Indies by geologists of the Royal Dutch-Shell group. The ratio of successful prospect wells to dry holes as a result of this work was very great and justified the cost of actually digging the geology out of the ground, but it may well be that the high ratio of success was in large part due to the exactness with which a structure could be mapped. The method was used extensively in the Isthmus of Tehuantepec for several years from 1916. Otherwise it has been but seldom used in North America. It is suitable for extensive use in areas of few rock exposures, soft rocks, and low labour costs. It can be used under other conditions only at critical points and where the information desired is important enough to justify the cost. It is important historically because it is the first method used by the petroleum geologist to secure reliable geological information at points important to his work rather than where it might be naturally available.

Core-drilling for structure was recommended as early as 1917 by George E. Burton, who pointed out that the possibility of finding additional structures by surface work in Oklahoma was pretty well exhausted.

Dr. W. A. J. M. van der Gracht, who used the diamond drill with great success as an exploratory tool in Holland, 1905–15, and who had directed its use in a search for structure in Roumania before 1914, introduced its use into the United States in 1919. During the same year M. M. Travis, formerly of the Mid-Continent Petroleum Company, introduced it independently to check supposed anticlines on the Chilocco Indian Reservation, Oklahoma.

The first notable success for core-drilling was the discovery of the north extension and most prolific part of the Tonkawa Pool, Oklahoma, in mid-1922. Early discoveries by the method include the Thomas, Hunniwell, North Braman, Hubbard, and Deep Rock pools of Oklahoma, the Padgett gas-pool and Graham oil-pool of Kansas. The use of core drills increased until 1925, when as many as 50 separate machines were drilling for structure in the Mid-Continent region alone.

The third and most recently accepted group of methods for mapping geological structure are the geophysical methods, of which four, the magnetic, gravimetric, electrical, and seismic, have been used with some degree of success for oil prospecting.

The first of the methods to be used in the oil industry was that of gravity surveys by the use of the Eötvös torsion balance. The possibility of making gravity observations with a torsion balance was outlined as early as 1888 by the late Baron Roland von Eötvös, Professor of Physics in the University of Budapest. The first instrument was completed in 1890. A period of testing in the field and modification of the original design of instrument ensued. Field investigations on a substantial scale began in 1901 on the ice of Lake Balaton, and were soon extended into the Great Hungarian plain.

Eötvös realized and demonstrated the possibility of interpreting buried regional geological structure from a consideration of gravity anomalies, but his interests were entirely in the fields of geodesy and physics. The more definite understanding of the usefulness of the instrument as a geological tool was the realization of Hugo V. Boeckh, late director of the Hungarian Geological Survey, who in 1917 first called attention to the fact that anticlines and domes with light or heavy cores could be located by means of torsion-balance surveys, citing surveys and the existence of such anticlines at Gbely (Egbell). In 1918 Schweydar, with the advice of Boeckh, used the balance to delineate the boundaries of an explored salt deposit in Germany.

The torsion balance was taken up for use in petroleum geology about 1920, the pioneers being the Royal Dutch-Shell and Anglo-Iranian groups. The first survey known to the writer is that of the Hurghada field in Egypt, made in late 1921 or early 1922.

The first torsion-balance survey made in the United States is believed to have been a survey of the Spindletop, Texas, salt-dome in early December 1922. The first salt-dome or field to be found by the method was the Nash, Texas, dome, proved as a salt-dome in November 1924, and as oil-bearing in early January 1926. This was the first discovery by geophysical methods in the United States and probably the first in the world.

The seismograph, which Dr. L. Mintrop of Germany and Karcher, Haseman, Eckhart, and McCollom had been using since 1919 in an attempt to delineate subsurface structure, was used in Mexico and in the Mexia fault-line region of Texas in 1923, but without success. It was brought into the Gulf Coast region of Texas early in 1924 by the Marland Oil Company, locally under the direction of Alexander Deussen, and was soon taken up by the Gulf Production Company at the instance of L. P. Garret.

It proved successful in the location of hitherto undiscovered salt-domes, by use of the refraction method.

J. C. Karcher, who directed the Geophysical Research Corporation, improved the refraction technique considerably. He introduced the radio time-break, sound surveying, and electrical recording. He also developed the reflection method, successfully mapped structure in 1927, and the work had been checked conclusively and with fortunate practical results in 1930. About 1929 the dip method of reflection surveying was developed and is now in general use on the Gulf Coast.

While the magnetic is the oldest of geophysical methods, having an ancient and honourable history in the discovery of iron ore, its value in the petroleum field is not great, and its use which at one time, about 1924, reached considerable proportions is now somewhat limited.

The electrical methods which were introduced into the petroleum industry about 1924 had but a short and experimental vogue. They were successful to a degree, but could not compete with the other methods as prospecting tools.

Such, in brief, is a bare outline of the most important improvements in the technique of geological work in oil prospecting. Improvement in ability to interpret geological data for the purpose of prospecting is a more intangible and less definite matter. The record of the geologist in pioneering new types of structure or in opening up new petroliferous provinces is not good. In both of these highly speculative and hazardous types of enterprise he has usually followed the more daring and adventurous 'wild-catter'. His greatest success as a prospector has been in hunting for new and similar structures, once a new type had been proved. His greatest service to his client, to within recent years, has probably been to point out the likely direction and extent for a newly discovered pool.

The science of petroleum geology, which serves as a base for our prospecting technique, covers a broad field of speculation regarding the origin and migration of the petroleums. While the solution of these vexing problems would be interesting and would advance in some degree our ability to find oil-pools, they are by no means essential to successful prospecting, as is proved by present practices and the present state of the industry. We have a working

theory of the origin of petroleum, accepted generally enough perhaps to be regarded as orthodox, but, on the other hand, certain able, scientific, and skilful geologists hold views divergent enough to be regarded as heretical if they were fully and publicly stated. Even our foremost students of the subject of origin regard none of the hypotheses as absolutely demonstrated, and if the whole field of this subject were to be subjected to the same type of searching scepticism with which, for example, the anthropologist and palaeontologist test a new discovery of fossil man, we would have to admit that our actual knowledge is meagre. So it is with the question of migration. Leaders in the profession of petroleum geology hold for short migration. Equally competent men hold, with equal tenacity, for long migration. Specialists on origin say: 'Once the problem of migration is solved, we can solve that of origin.' Students of migration can solve their problem easily if that of origin is settled.

The firm rock upon which the whole structure of scientific prospecting is based, however, is that of our knowledge of the habits of occurrence of petroleum accumulations. We know from experience that oil-pools occur in rock traps, generally of structural origin, and we are engaged as prospectors in trying to find and explore traps similar to those already known or, more rarely, traps which should perform the same function. Ours is an empirical science.

Drilling of the Test Well

The problem of drilling the exploratory well differs from problems of ordinary development drilling only in the greater necessity for being able to test every oil- and gas-show in what is essentially untried ground and in the greater importance of securing all geological information which might be pertinent to a solution of the particular problem of exploration. Once a pool has been discovered, the objectives of subsequent wells—depths, casing programmes, producing sands, &c.—are fairly well known or can be estimated closely. The exploratory or wild-cat well, however, must be drilled more slowly, with greater care, and is generally more expensive than the development well. Every device or improvement which will aid in securing more exact or a greater amount of information is correspondingly important.

The nascent petroleum industry received its drilling equipment ready made. The standard, cable, rope, or churn-drill system, as the percussion system has been variously called, had been used for drilling brine-wells during the half-century preceding the drilling of the Drake well. It was used for drilling practically all the oil-wells in the United States during the first 40 years of the industry, and, to within the last 15 years, was regarded as the best, if not the only, system for drilling hard rocks and as the only satisfactory system for prospect or test drilling where it could be used.

The percussion systems, standard-cable, or variants such as Canadian pole tool, Galician, or Russian free fall are of very ancient origin. The Chinese were drilling brine-wells to depths of 1,500–1,800 ft. more than a century ago by methods which are essentially the same. Modern plants are of greater strength and size, of improved design, have various refinements to facilitate handling, and greater and better power application, but are fundamentally the same. Rock is drilled by the percussion of the falling bit. Cuttings are removed by the use of sand-pump or bailer, and the hole is cased as required. Generally the hole is kept dry except for a small amount of water put into it in order to facilitate drilling and the removal of cuttings, though it may also be drilled loaded with mud or water. Manifestly, a well drilled by such system is constantly in an almost ideal condition for testing. Any oil- or gas-show encountered is likely to demonstrate its calibre at once. The source of cuttings can be determined easily to within a few feet. The disadvantages are relative slowness of drilling, necessity for using large amounts of casing either to shut off water-sands or prevent caving, and, with such use of numerous strings of casing, limitation as to depth.

In the soft and unconsolidated rocks of the Gulf Coast of Texas and Louisiana, where cable tools were not successful because of the constant caving and flowing of the formations, a new system was introduced: the rotary, hydraulic, or water-flush system. This system, whether invented by the Baker brothers from South Dakota or developed from some older type of diamond drill, is based, as are all other water-flush systems, on a method invented by Beart, an Englishman, designed by a French engineer, and known, after him, as the Fauville system. It was first used in 1846 in the drilling of a well at Perpignan, France. In this system the rocks are cut by a bit on the end of a turning, hollow, drill stem through which water or mud is forced. The water or mud carries the cuttings outside the drill stem up to the surface.

The advantages of the rotary system are speed in drilling and economy of casing and consequent ability to drill to increasingly greater depths. The disadvantages, in its earlier state, were difficulty in drilling hard rock, difficulty in recognizing and testing oil-, gas-, or water-bearing formations, and difficulty in securing exact geologic information. These defects have been remedied, and the modern rotary system has largely displaced all other systems as a prospecting tool except in regions of hard rock and for very rare and very especial cases. As early as 1925, an engineer with world-wide experience in drilling and acquainted with all drilling systems in actual use, summarizes a discussion of drilling methods with: 'The modern rotary is, however, revolutionizing drilling practice, and except in hard compact sandstones or limestones, it is replacing all percussion systems.' (Thompson, A. Beeby, *Oil-field Exploration and Development*, &c., p. 617 (London, 1925).)

The technical history of recent improvement in prospect drilling is essentially a history of the development of the rotary system.

The greatest and possibly most important improvement in drilling technique from the viewpoint of the prospector has been the constantly improving ability to achieve increasingly greater depths. We are finding important oil-pools to-day at depths of 7,000–10,000 ft. which could not have been reached by the drill under the best practice of 10 years ago. Oklahoma City and Kettleman Hills have already been cited as examples of pools, previously drilled, which remained undiscovered until we had achieved ability to drill to necessary depths. A consideration of the accompanying chart of well-depth and some acquaintanceship with the technique of drilling suggests that increasing depth has come about as a result of better material, equipment, and greater power rather than from any fundamental change in design. In the opinion of the writer, the standardization of drilling equipment programme of the American Petroleum Institute has been one of the greatest single factors in contributing to this condition.

The rotary system of drilling, which is the actual, if not the intentional, descendant of some early form of diamond

drill, was first used by the oil industry at Corsicanna, Texas, in the 1890's. The system had previously been used for drilling water-wells, a well having been drilled to a depth of 3,070 ft. at Galveston. The great impetus to its widespread use, however, came with experience gained in the development of the fields of coastal Texas and Louisiana, following the completion of the Lucas gusher at Spindletop, Texas, in January 1901. It was used exclusively in the exploration and development of the fields of coastal Texas and Louisiana.

As early as 1906 the rotary was used to penetrate the soft sands and shales near the surface in the Santa Maria field of California, and it was used in late 1910 to drill 10 wells to depths of 1,700 to 2,000 ft. for one company in that State. The design of drilling machinery was greatly strengthened and improved to meet the more severe requirements of California conditions, and by 1914 the California equipment was regarded as the best obtainable. About 1910–12 the rotary was being widely used in Mexico, and somewhat later it was introduced into the Roumanian and Russian fields. It was first widely used in Oklahoma in the development of the Tonkawa field in the early 1920's.

In all fields, particularly before the perfection of the rock bit, it was necessary to change over to the standard system when hard rock was encountered in a well being drilled by rotary, and, as late as 1916, it was the custom in California to finish all rotary-drilled wells with standard tools, a custom which was followed in Mexico and which was regarded as best practice in Oklahoma until quite recently. Indeed, this practice was so common that the Californians designed a combination rig which could be changed easily from one system to the other, and this type of rig from about 1912 to 1918 was regarded as the finest type of drilling equipment.

In the earliest rotary practice the circulating medium was water, and its function was apparently regarded as simply that of removing cuttings. Attempts were made to follow down the hole with casing as drilling progressed, much in the fashion of standard-cable practice. It was soon obvious, however, and was noted by Ben Andrews, sen., of New Orleans, that the use of heavier mud for circulation served to wall up the hole and reduced the casing problem to a minimum.

The problem of drilling hard rock was solved by the invention of the rock bit in 1908 and its subsequent perfection and adoption by the industry. Further advances in this direction were made through the adoption some 10 years later of various hard-surfacing alloys, the first of which was stellite, for facing the cutting-edge of ordinary bits such as the fish-tail type.

Up to this point in the development of the rotary system, which was about 1920, the rotary as a tool for making holes had been fairly well perfected, but there had been no notable correction of its deficiencies as a tool for testing. It was no unusual thing for important oil-bearing formations to be passed through without recognition, and it was seldom indeed that water-bearing sands were noted. As late as 1922, the writer protests vigorously against the selection of the rotary by clients for drilling a wild-cat well.

The first real forward step in the improvement of the rotary as a testing tool came with the introduction of the improved core barrel and improved coring practice about 1921. Some coring had been a part of good rotary practice since a very early date, but the core tool was a rather crude affair, the old basket type of barrel consisting generally of a section of casing in the lower end of which teeth or notches had been cut, and core recovery was neither exact nor satisfactory. The earliest of the new double-core barrels with a special cutting head was introduced in California in late 1921 by J. E. Elliot, who had redesigned a tool built by Jan Koster for the Geological Survey of Holland and which had been introduced into the United States by the Survey's late director, Dr. Van der Gracht, then head of the Roxana Petroleum Corporation, for use in core-drilling for geologic structure. With several improvements in design and constant improvement in practice, recovery of cores had been perfected to such an extent that the use of the core barrel is now common rotary practice, and cores secured yield the highest type of geological and practical data which can be secured from a prospect well. The Robischeaux core barrel which, while it secures a smaller core, can be run and withdrawn after taking core without the necessity for pulling the drill stem, supplements the more elaborate type of coring to a degree which allows a geological log of the drilling well to be made which is in no way inferior, and in some ways superior, to those which can be made for holes drilled by any other system.

One of the most notable improvements in the rotary system as a testing device was the introduction of drill-stem testing. The drill stem, closed by a valve at the lower end, is seated with a packer, generally on a shoulder left just above the formation to be tested. The valve is opened and closed by manipulation of the drill stem, and, upon withdrawal, one may judge from the amount and nature of the fluid which the drill stem contains, and the amount of time it has been open, something of the probable value of the formation tested. One of the earliest forms of drill-stem testing consisted of a stem closed with a plate of glass at the lower end instead of a valve. It was used in southwest Texas as early as 1926. The glass was broken by dropping a go-devil, and there was no method of closing it, the drill stem remaining open and seated long enough to allow the fluid from the formation being tested to reach the surface. Drill-stem testing is a common and widely accepted element of rotary practice at the present time.

Of as great or greater importance in improving the testing abilities of the rotary was the introduction of electrical coring. This method, developed as early as 1928 by C. and M. Schlumberger of Paris, consists essentially in measuring the resistivity and electro-filtration of the walls of a drill-hole by the introduction of a series of electrodes. The resistivity log gives information as to oil, gas, and water content. The electro-filtration is studied by the measurement of potential differences and is regarded as an index to porosity. The advantages of electrical coring, which has been widely adopted within the past few years, are to reduce to a minimum the hazard of failing to recognize important oil-, gas-, or water-bearing formations passed through and of furnishing a log which, for correlation purposes, is often superior to any other type of log and which, in specific cases, may even be of greater utility than a complete core section.

A further improvement in rotary-testing practice has come about within the past few years through the introduction of the shot-gun perforator. This is a device which is used for perforating the casing and some inches of the bounding formation, at desired points, by the firing of small steel projectiles. This advance in technique permits a formation to be tested after it has been cased off. In actual practice entire formations, including a number of oil-

and gas-shows, may be penetrated, a single string of casing set and cemented throughout the important section of the hole, and tests may be made at each and every point desired.

Various additional improvements of less importance have been made which have bearing on the perfection of the rotary as a testing tool. Hole surveying serves both to furnish more precise information as to the exact course followed by the drill and as a basis for keeping it straight, if so desired, or as a guide and check for directional drilling. Directional drilling, itself, has been improved within the past few years to a point which greatly increases the possible testing value of a single hole. The improvement of drilling muds serves both to keep the walls of the hole in proper condition and to prevent blow-outs, and so admits of economy in the use of casing, the attainment of greater depth, and prevents the loss of holes. In actual testing, the widespread use of 'chokes' or 'beans', both in drill-stem testing or in actual completion and flowing through tubing and at both the top and bottom of the well, provides a less violent and sounder method of testing oil- and gas-shows of certain types than is afforded by any other method, even the open hole of the standard-cable system.

Many of the improvements in rotary testing should be usable with the diamond drill, which has also been used by the industry, but on theoretical grounds there is no particular difference between the two systems, and modern rotary design already has taken advantage of such improvements as may, at one time, have been peculiar to the diamond drill.

A prospect well, with rare exceptions, in the writer's opinion, can be drilled more quickly, more cheaply, and to greater depth with the rotary than by any other method. Surveyed, cored at important points, logged electrically, drill-stem tested where desired, cased and cemented, and finally perforated for testing by stages, the rotary-drilled prospect hole should be as thoroughly tested as is possible by current methods and equipment for any system.

TABLE I

Chronological List of Deep Wells

Year	*Well*	*Ft.*
1897	Bedell well, Pennsylvania . . . . . . For many years, probably until Geary well, was deepest well in the United States and probably the deepest well drilled for oil in the world.	5,582
1909	Czucho well, near Breslau, Silesia . . . . Coal prospect hole, and deepest well in the world.	7,348
1917	Geary well No. 770, Pennsylvania . . . . Cable tools, deepest well in United States and second only to Czucho well.	7,248
1918	Goff well, West Virginia . . . . . . Cable tools, world's deepest well.	7,386
1919	Lake well, West Virginia. . . . . . Cable tools, world's deepest well.	7,579
1925	Ligonier well, Pennsylvania . . . . . Cable tools, world's deepest well.	7,756
1927	Olinda well No. 96, California . . . . Rotary tools, world's deepest well.	8,201
1928	University 1-B, Big Lake, Texas . . . World's deepest well.	8,523
1929	Nesa well No. 11, Long Beach, California . . Rotary tools, world's deepest well.	9,280
	Hathaway well No. 7, Santa Fe Springs, California . Rotary tools, world's deepest well.	9,356
1930	Mascot well No. 1, Midway, California . . . Rotary tools, world's deepest well.	9,629
1931	Williams well No. 1, Semi Tropic, California . . Rotary tools, world's deepest well.	9,702
	Hobson well No. 2-A, California . . . Rotary tools, world's deepest well.	10,030
	Jardin well No. 35, Alamo, Mexico . . . Cable and rotary tools, world's deepest well.	10,528
1933	Lillis-Welch well No. 1, Kettleman, California . Rotary tools, world's deepest well.	10,924
1934	Berry well No. 1, Belridge, California . . . Rotary tools, world's deepest well.	11,377
1935	McElroy well No. 103, Upton Co., Texas . . Rotary tools, world's deepest well.	12,786

MAPS

By FREDERIC H. LAHEE, A.B., Ph.D.
Chief Geologist, Sun Oil Company

In the oil industry a great many different kinds of maps are used. Some are prepared to facilitate the marketing of refined products. Others show the distribution of pipelines and the various channels for transportation of crude oil. And still others are made to indicate where oil may possibly be discovered underground by drilling, or where oil has already been found and is being brought to the surface for exploitation. In the following pages this discussion will be confined solely to maps of the last kind—maps used in the search for oil and in its production.

Maps may be described both as to the methods by which they are constructed and as to their uses and interpretation. Every map should be provided with a scale, an arrow, or other means of indicating compass directions, and a legend to explain the meaning of symbols, colours, or other special signs and patterns employed on it.

Surface maps are those which portray features of the earth's surface. They include aeroplane photographs, outcrop maps, areal geological maps, topographical maps, well-location maps, structure contour maps, &c. Subsurface maps show underground geological conditions which may be interpreted from well data or from geophysical data.

Surface Maps

The most detailed and accurate maps of the ground surface, if properly made, are photographic views taken from an aeroplane. A high degree of precision has been attained in preparing these photographs, mounting them, and reproducing them to true scale. In some regions where geological structure is revealed by differences in soil and vegetation, or in continuous ledges or larger topographic forms, these aerial maps cannot be surpassed. They are excellent as base maps on which to plot the distribution of rock outcrops, and as base maps for locating stations for geophysical work. Figs. 1 and 2 illustrate two of these maps.

Topographical maps show the surface forms of the earth, such as hills, valleys, &c., usually by contours, a contour being a line having everywhere the same elevation above mean sea-level. On any given map these contours are drawn to represent elevations at regular intervals, as, for instance, every 10 ft. above sea-level, or every 20 ft. above sea-level, and so on (see Fig. 3). Maps of this kind are also of value as base maps on which to plot geological information.

Where less detail is necessary for such base maps only a few features may be accurately surveyed and plotted, such as roads, streams, and property lines when needed; and on such a skeleton map geological data may be sketched.

Outcrop maps indicate the positions of actual exposures of rock, and, if the formations are inclined strata, these maps should show the dip and strike of the bedding at each of the outcrops (see Fig. 4). From a careful study of outcrops, and of soils between these outcrops, it is generally possible to trace the contacts between formations. These contact lines can then be charted and the formations between them can be coloured or otherwise distinguished on the map, thus producing an areal geological map (Fig. 5). On these maps thin soils are usually disregarded, so that the picture is essentially one of the underlying rock formations as these would appear if the soil were removed.

In regions where the rocks beneath the soil consist of low-dipping strata, the geologist may make a structure contour map (Fig. 6). To do this he chooses an easily recognizable bed on which, at various points, he determines the elevation. This is his 'key bed'. Elevations on it may be referred to sea-level by using bench marks already established by precise levelling, or they may be referred to some other assumed datum plane. These elevations are surveyed by plane table, transit, hand-level, or barometer, depending upon the nature of the country, the degree of accuracy required, the time and money available for the work, and a number of other factors. If the selected key bed dips underground, another higher bed is mapped and the interval (thickness of strata) between it and the lower key bed is subtracted to reduce all elevations to this lower horizon (see Fig. 6). Similarly, if the dip of the formations carries the key bed up above the present land surface, where this bed has been eroded away, a lower recognizable bed is mapped and the interval between it and the key bed is added to give elevations on the latter (see Fig. 6).

Subsurface Maps

Subsurface maps are constructed from underground data. For example, where an area is so covered with soil that outcrops of the bedrock are few or absent, holes may be drilled at selected points to determine the attitude of some key bed which may lie a few hundred feet deep (Fig. 7). In unexplored country search has to be made for such a key bed. Sometimes no bed is discovered, within drillable depths, sufficiently distinctive to be recognized in scattered core-holes. Generally, by the study of a considerable section penetrated in the drilling a key horizon can be found. The depth to this key is carefully measured at each hole and is subtracted from the ground elevation of the hole, in order to adjust all elevations to the same horizontal datum (sea-level or assumed). Contours are then drawn in reference to these scattered points—one point at each hole.

In the case of deep drilling the process is similar. Some recognizable key horizon is chosen and its sub-sea depth is calculated in each well, after which the structure on this key is represented by contours.

Obviously contour maps of the kind just described, even if absolutely correct as to elevations on the key bed in the drilled holes, are subject to increasing error in their construction in proportion to increased distance between the holes. Subsurface contour maps based on widely scattered data are merely suggestive, and should be viewed as such. As more holes are drilled, the new information may require extensive modification of earlier interpretation (Fig. 8). Because of this fact, that some degree of inaccuracy is unavoidable in constructing these maps, they have sometimes been ridiculed by people who do not fully understand how they are made. On the contrary, others have placed too much reliance on them and have used them as infallible

FIG. 1. Aeroplane map of parts of township 2 south, range 14 east, Atoka County, Oklahoma. The ridges are due to differences in the resistance of the rock formation to erosion, the harder layers standing out as ridges. Published by permission of Edgar Tobin Aerial Surveys.

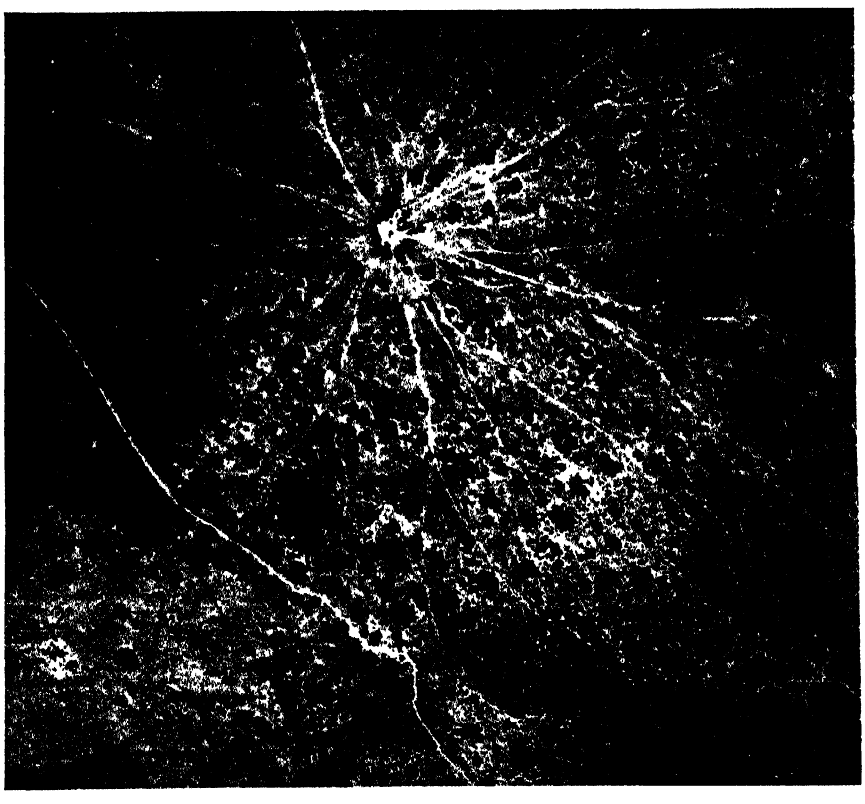

FIG. 2. Aeroplane map of part of Brooks County, south Texas, where there are large ranches, few roads, and practically no rock outcrops. Cattle trails are seen radiating from a water well, the dark patches being low brush. Published through the courtesy of Edgar Tobin Aerial Surveys of San Antonio, Texas

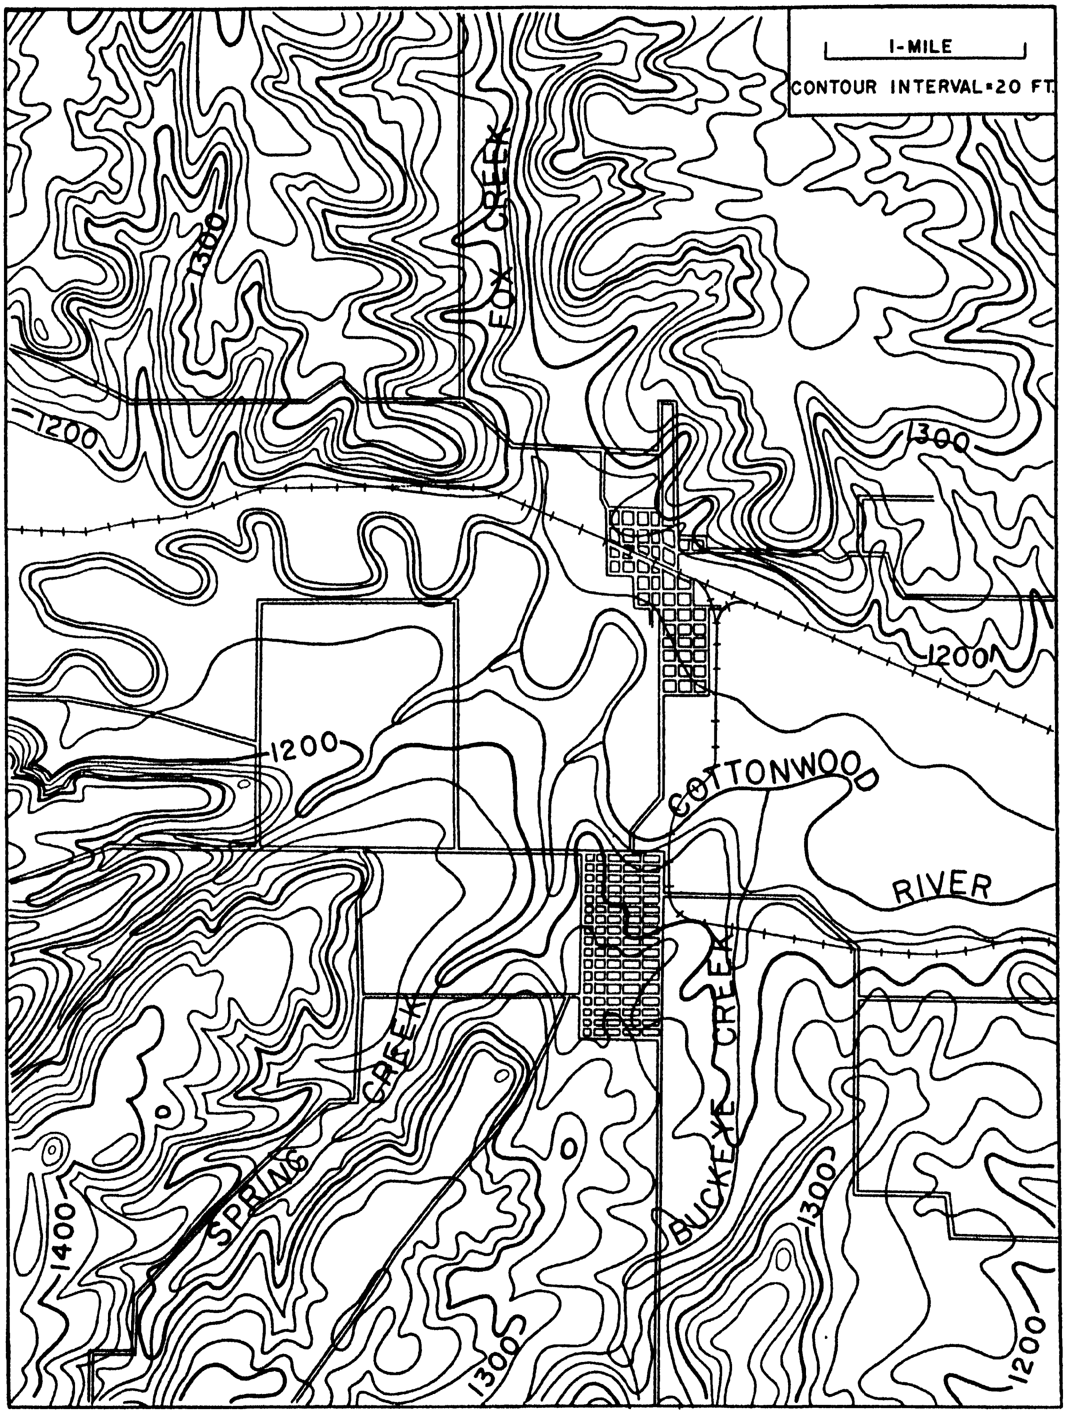

FIG. 3. Part of the U.S.G.S. Cottonwood Falls Quadrangle, Kansas, with some names and other features omitted. This is a topographical contour map, with a 20-ft. contour interval, showing elevations of below 1,180 ft. to more than 1,460 ft. above sea-level. Obviously slopes are *down* towards the streams. Roads and streets are shown by double parallel lines.

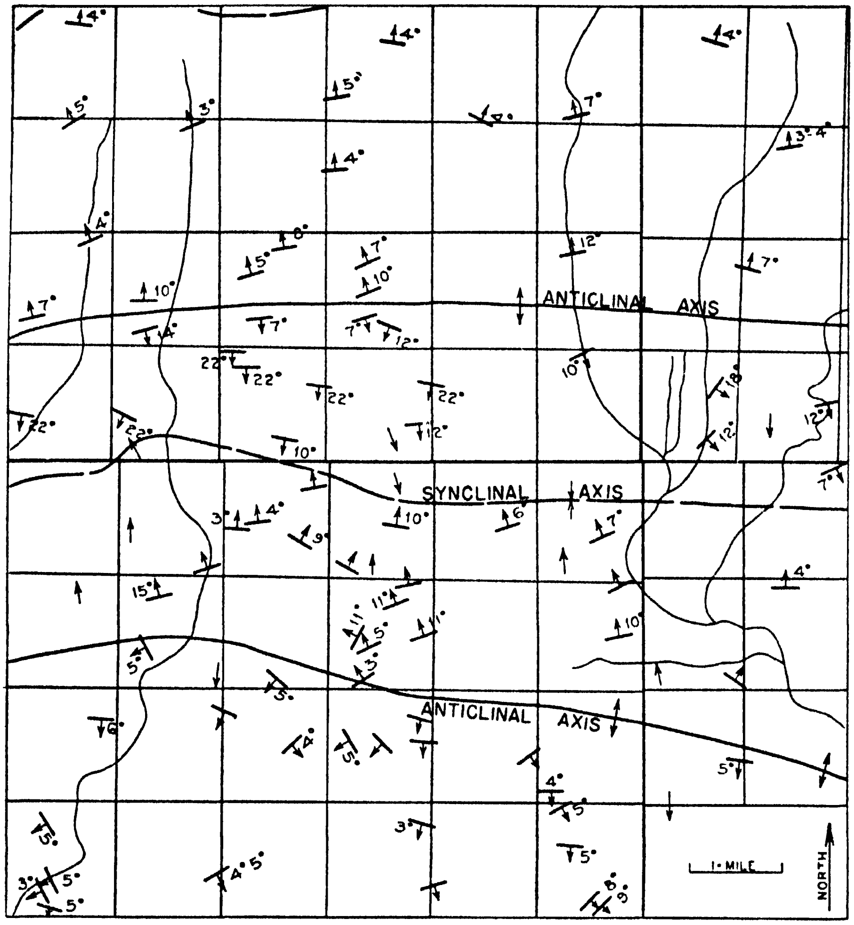

FIG. 4. Outcrop map, showing an area in Arkansas. Details omitted. Arrows point down dip. Cross-lines on arrows indicate direction of strike. Amount of dip of bedding, as measured at each outcrop, shown in degrees. The squares are sections (1 mile on each side).

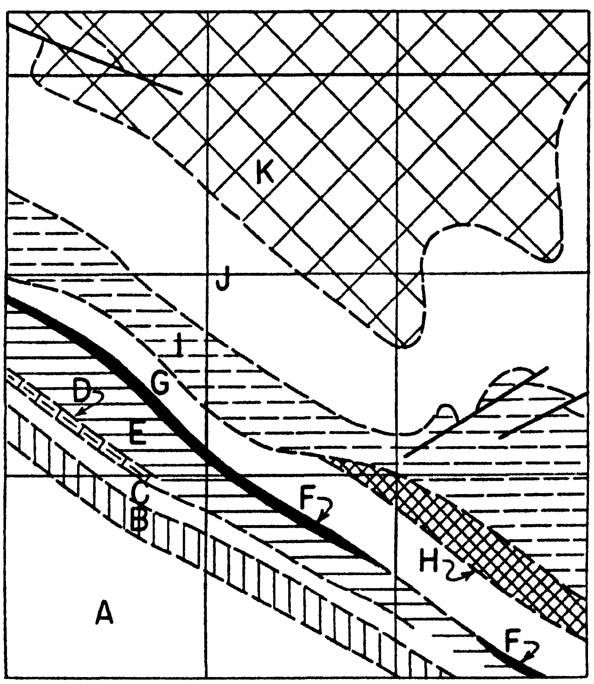

FIG. 5. An aerial geological map, the several formations (*A* to *K*) being indicated by various patterns. The contacts between these formations were first mapped as explained in the text.

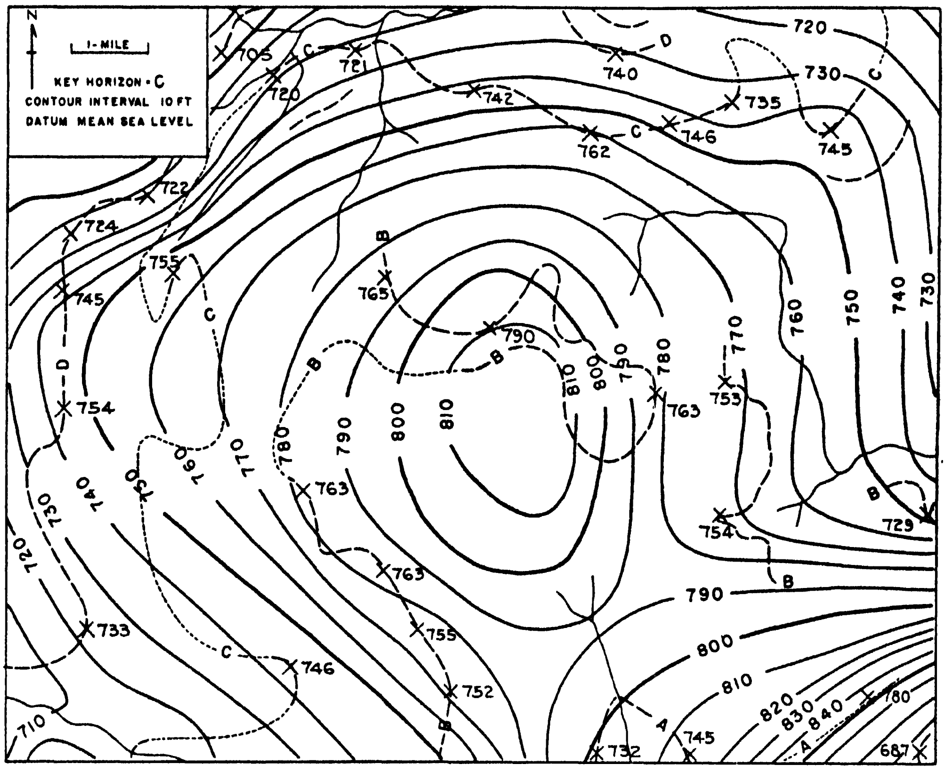

FIG. 6. Structure contour map of a key horizon (C) which has been traced and mapped on the ground and on which the elevation of several points above sea-level has been charted. *A*, *B*, and *D* are other beds, *A* and *B* being respectively 70 ft. and 20 ft. stratigraphically lower than *C*; and *D* being stratigraphically 10 ft. higher than *C*. Consequently, in making this map, where all contours are reduced to *C*, 70 ft. had to be added to all elevations recorded on *A*; 20 ft. had to be added to readings on *B*; and 10 ft. had to be subtracted from elevations recorded on *D*.

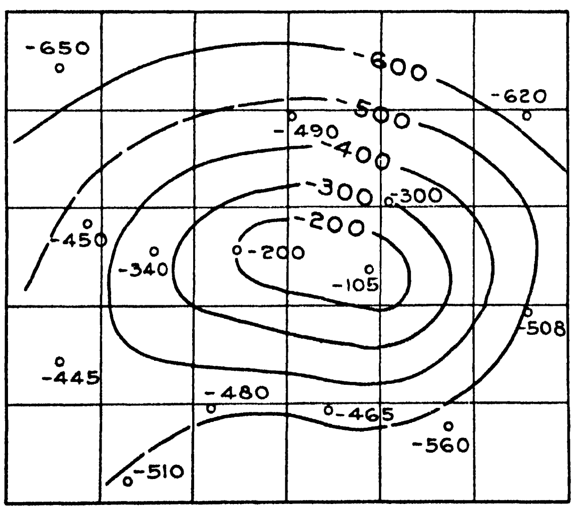

FIG. 7. Structure contour map of a dome which was found by drilling several hundred feet below the soil-covered surface of the ground. The contours are drawn on a fossiliferous key horizon discovered in the drilling. Elevations are below sea-level. The squares are a mile on each side.

pictures of the real underground geological structure. It is important that these maps be given their proper weight. They are valuable as guides to an understanding of subsurface conditions, but they are not precise representations.

The foregoing remarks refer to data obtained from holes drilled vertically. If for any reason the holes deviate from the vertical, an error is introduced into the actual elevation recorded on the key horizon. This is a much more serious defect than the inaccuracies caused merely by generalizing between the points of measurement. Every effort should be made to secure correct basic data. To this end holes are surveyed at intervals during their drilling, and if they are found to be running off plumb, they are brought back into line, or they may be redrilled. If in spite of every precaution they cannot be kept vertical, or if they are intentionally whip-stocked into an inclined position, they must be surveyed for the true location of the point where the key bed was penetrated before the recorded depths to this key can be used in the construction of a contour map. In such cases of deviation from plumb, the point on the key may be considerably displaced both vertically (depth) and horizontally (mapped position of hole). This should be borne in mind not only for subsurface contouring, but also for any map which is intended to give correct relations of land lines and well locations on the ground to the points where these wells reach the oil or gas pay bed. Certainly a map showing regularly spaced wells on a lease is of no value as a guide for development if the wells do not bear the same horizontal spatial relations on the producing formation (Fig. 9).

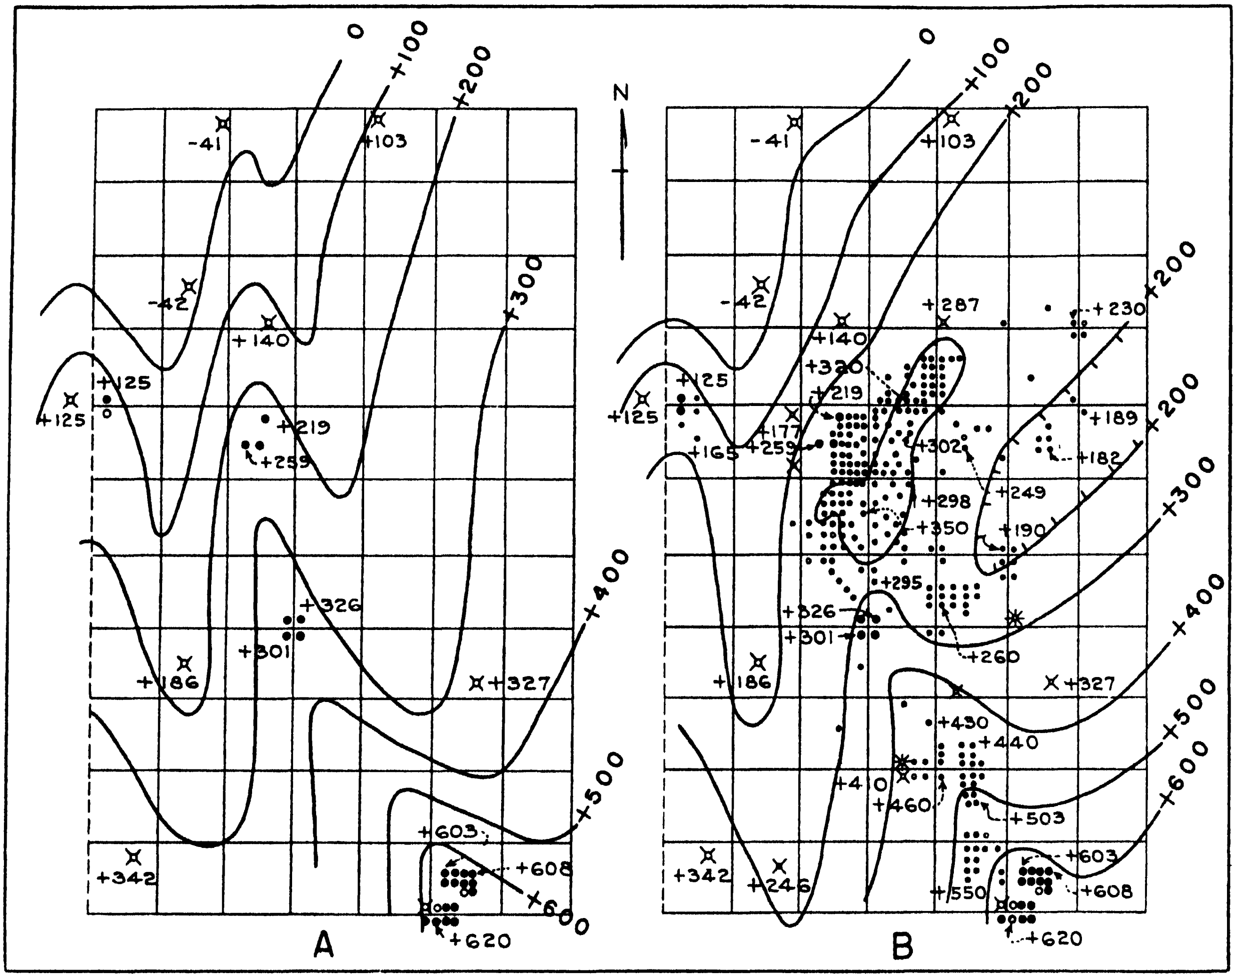

FIG. 8. Subsurface structure contour maps of the same area (*A*) when data were available from only a few deep holes, and (*B*) after many more wells had been drilled and had furnished additional information. Note that the main feature, the anticlinal nosing in *A*, still persists in *B*, though a closure has been proved to exist on it. The low dip in the north-west quarter of *A* by later drilling is shown to consist of a low structural ridge and a structural depression (*B*). The squares are 1 mile on a side.

Isopach maps are used to show, by lines of equal thickness, the variations in vertical interval between any two geological horizons. Since these maps represent thinning of this interval in certain directions, they are also called 'convergence maps' (see Figs. 10, 11). Such maps are of particular value in projecting reasonably certain structure on one key bed downwards to a lower stratum between which and the upper horizon the interval is known at relatively few points.

Maps somewhat similar to contour maps are constructed to show the variations in total solid content, or in total chloride content, of underground waters over considerable areas; or to show variations in recorded pressures in producing oil-pools. Fig. 12 is an example of an isochloride map where the lines are drawn between scattered wells from which water samples were secured and analysed for their chloride content. All the samples came from the same sand body (Woodbine sand).

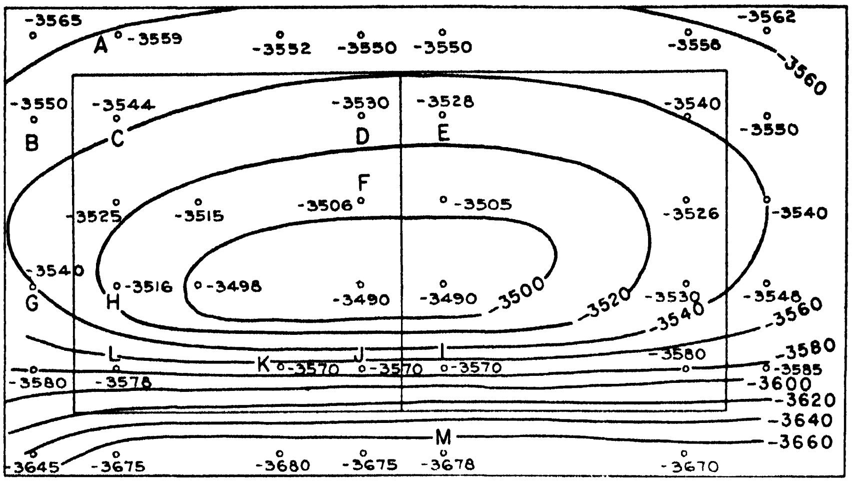

FIG. 9 *A*.

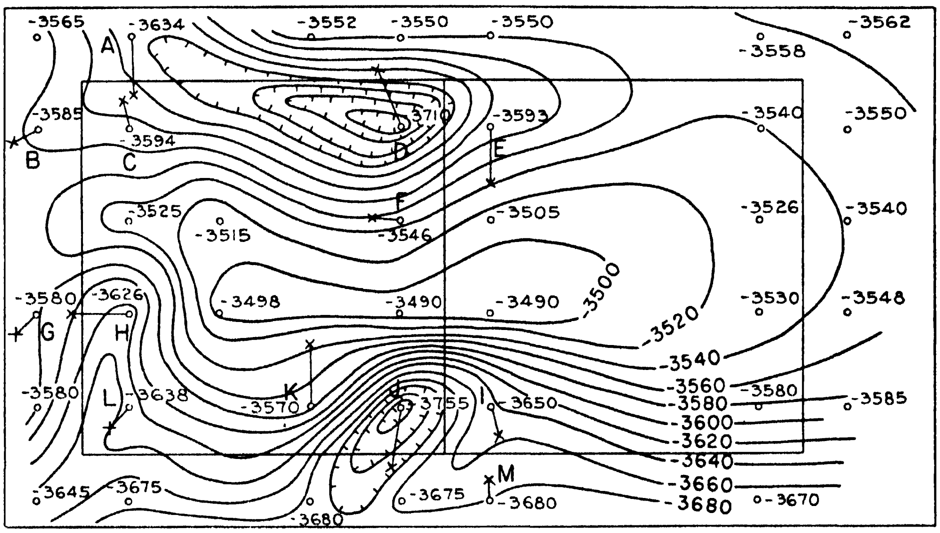

FIG. 9 *B*.

FIG. 9. In Fig. 9 *A* is shown an elongate dome with elevations on the pay sand ranging from 3,490 to 3,680 ft. *below sea-level.* Here all holes are assumed to be vertical. Depth to the pay is assumed to be 5,000 ft., more or less.

In *B* the lettered wells are assumed to be inclined at a uniform angle from the surface to the bottom of the hole, as listed below. The cross marks the actual point vertically below ground where the hole reaches the pay sand, and the recorded elevation was obtained from the measured depth of the inclined hole. We are assuming that the inclined holes are *thought* to be vertical, so that the incorrect depths are recorded as if they were correct below the position of the mouth of the hole.

From incorrect data of this kind, map *B* is constructed, giving an entirely erroneous idea of structure. Furthermore, note the spatial relations of the crooked wells (crosses) as contrasted with their intended positions (circles). Holes *A*, *D*, *H*, and *J* have actually crossed the property boundary on to adjoining land.

The squares are 1 mile on a side.

The following are the data for the inclined holes:

	Inclination from vertical	*Direction of deviation*	*Approx. dip*
A . .	10°	Up dip	100 ft. per mile
B .	5°	Along strike	. .
C . .	5°	Down dip	100 ft. per mile
D .	10°	,,	,, ,,
E . .	10°	Up dip	,, ,,
F .	5°	Along strike	. .
G . .	5°	Down dip	100 ft. per mile
H .	10°	,,	,, ,,
I . .	5°	,,	500 ft. ,,
J . .	10°	,,	,, ,,
K . .	10°	Up dip	,, ,,
L . .	5°	Oblique	,, ,,
M . .	5°	Up dip	,, ,,

Fig. 13 shows the distribution of pressures measured at the bottoms of a selected, well-distributed number of wells in the East Texas field. The chart on the left indicates the bottom-hole or reservoir pressures in early 1933, and that on the right the bottom-hole pressures in the spring of 1935. In the 26 months between the two groups of observations there was an average drop in reservoir pressure, as measured at the bottoms of the holes, amounting to an average of 190 lb. per sq. in., while during the same period over 441,000,000 bbl. of oil were produced. Maps of this kind are used to show progressive change in pressure in pools which are in process of drilling and producing, for these data are of value in assisting engineers to formulate and maintain a programme of rational development.

Geophysical Maps

The following description of geophysical maps was kindly prepared by H. W. Rose at the author's request.

Geophysical maps are maps which represent measurements of some physical quantity or quantities, the variations of which from place to place are directly or indirectly connected with the composition, mode of origin, and/or the structural attitude of the rocks of the subsurface. Most geophysical measurements are made with instruments set at selected points on or near the earth's surface, but valuable information can be and often is obtained by placing certain types of instruments below the surface in deep wells or in mine workings.

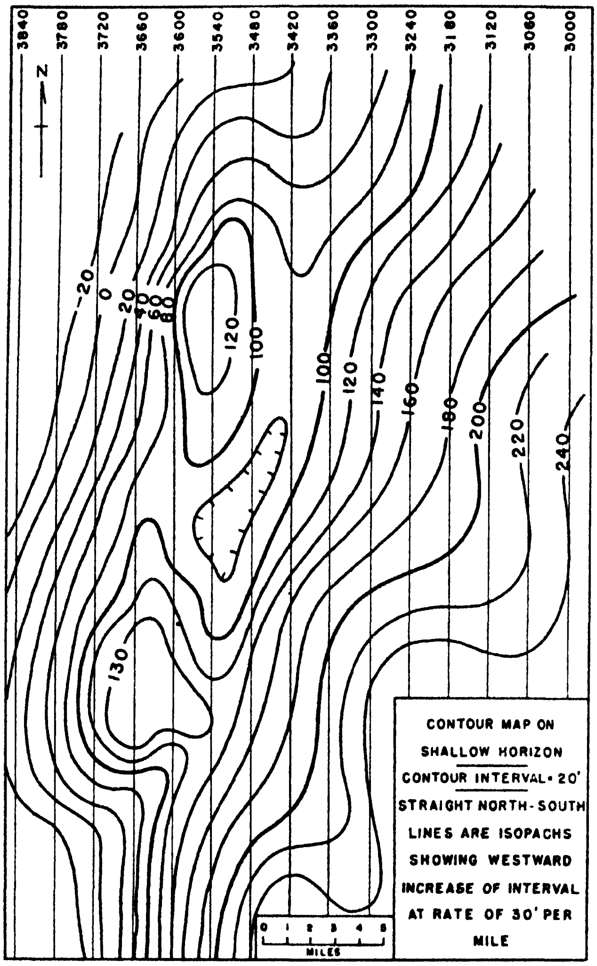

Fig. 10.

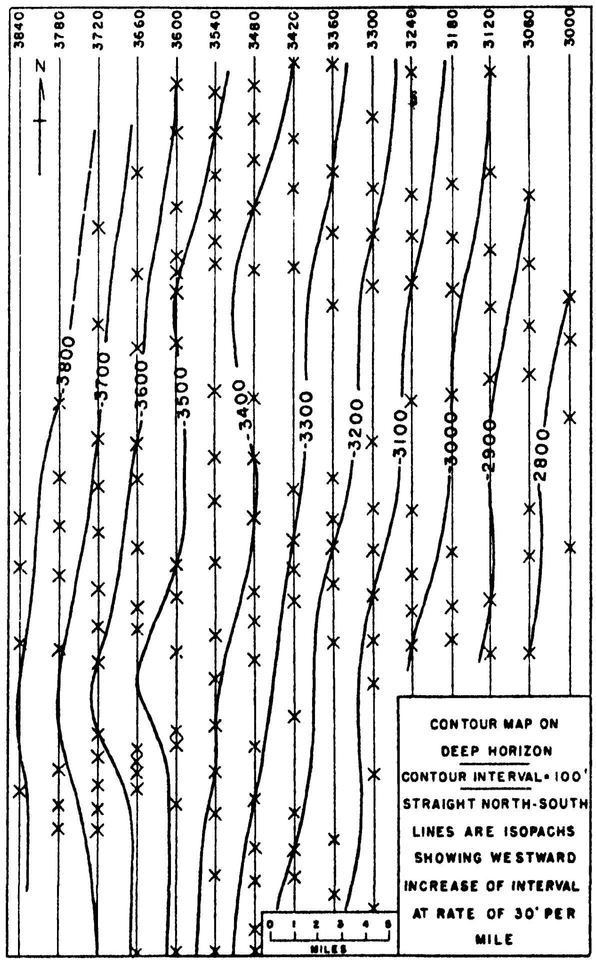

Fig. 11.

Fig. 10. Map of shallow subsurface structure as determined by core-drilling. The zero contour is at sea-level. On this map is superposed a 'convergence map', here assumed as very regular, the convergence being at the rate of about 37 ft. per mile due east; i.e. westward *increase* in interval of 37 ft. per mile between the shallow horizon, here contoured, and a deep horizon some 3,000 ft. below. The isopachs, or lines of equal interval, are shown as straight north-and-south lines. Under natural conditions thinning and thickening would not be regular, and isopachs would therefore bend more like ordinary contours.

Fig. 11. Same area as shown in Fig. 10. The convergence map (isopachs) of Fig. 10 has been repeated here. On the isopachs are crosses which mark the points where contours of Fig. 10 cross isopachs of Fig. 10, and where the interval between the shallow horizon and the deep horizon was calculated by subtracting the shallow contour value from the isopach value. For instance, where the plus 200-ft. contour crosses the 3,000-ft. isopach the deep horizon is 2,800 ft. below sea-level. With these calculations made at each such point, contours were drawn on the deep horizon, producing the structure shown in Fig. 11. Observe that the westward increase in interval between the shallow and deep horizons has completely eliminated the two anticlinal closures and the associated shallow basin (Fig. 10) in the deep horizon. Only a slight flattening of the dip appears here in this deep horizon.

This illustrates what *may* happen to small surface structures with increasing depth. It also demonstrates what important structural effects may result with increasing depth as a result of convergence between formations.

The value of geophysical maps is derived chiefly from the fact that an experienced interpreter can use them to draw certain conclusions about local or regional geological conditions in the area covered. Skilfully used, therefore, geophysical information as represented on geophysical maps becomes an almost indispensable tool of the modern geologist in the exploration of petroleum and other minerals. This is especially true in areas where the surface geology affords little or no clue to possible geological structures at depth, or where scanty subsurface information must be supplemented by information derived from sources more economical than the haphazard drilling of very expensive deep test wells

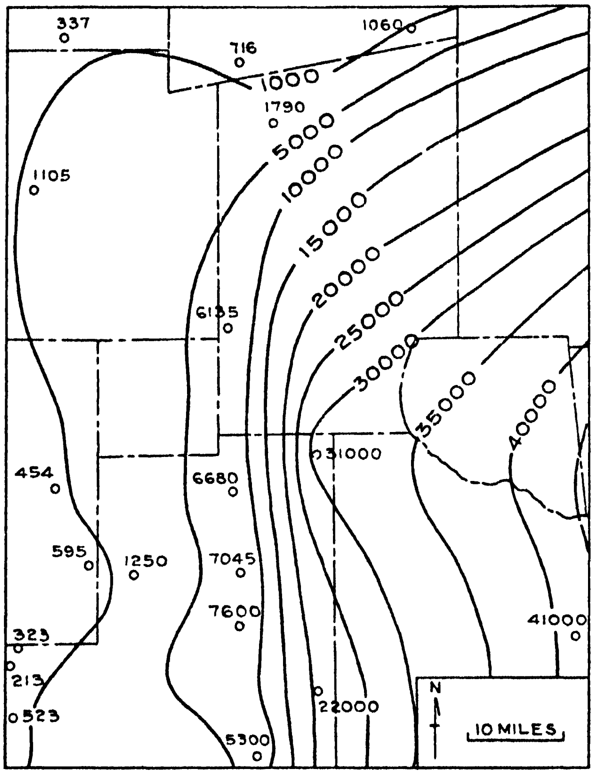

Fig. 12.

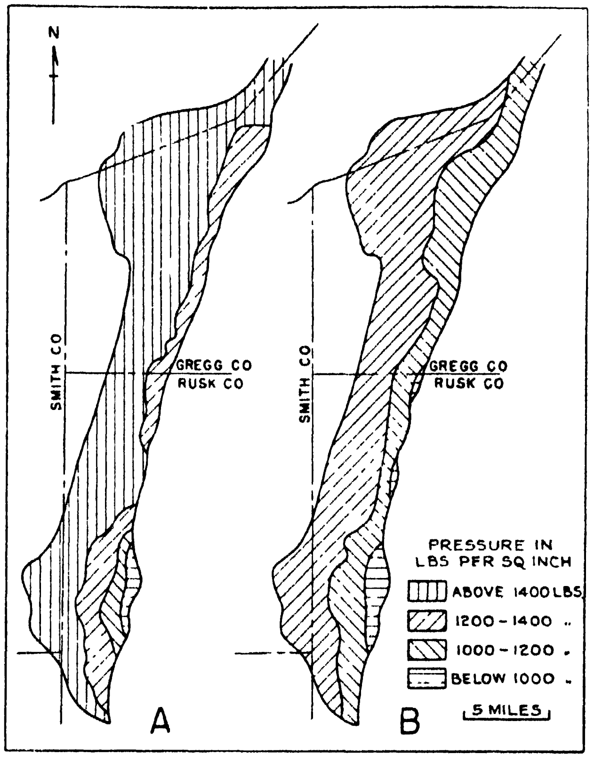

Fig. 13.

Fig. 12. An isochloride map showing, by lines of equal chloride content (isochlorides), the eastward increase in the amount of chlorides in water from the Woodbine sand in several counties in East Texas. The Woodbine formation outcrops not many miles north and west of the area mapped, and it dips eastward and south-eastward, reaching a depth of nearly 5,000 ft. in the south-eastern corner of the mapped area.

Fig. 13. Two maps showing average distribution of reservoir pressures in the East Texas field in early 1933 (*A*) and in the spring of 1935 (*B*). The pressures are highest on the west, or lower edge of the field, where the oil is backed, down dip (on the west), by water. They are lowest on the east where the pay sand wedges out up dip (eastward) beneath unconformably overlying strata. The lowering of pressure in the field as a whole has been caused by the production of some 441 million barrels of oil between the dates of maps *A* and *B*.

The accuracy of geological conclusions drawn from geophysical maps may have a wide range, depending upon surface and geological conditions and on the choice of the geophysical method. In some areas geophysical maps may give only the faintest of indirect clues to structure, but in other areas the proper choice of a geophysical method may yield information which indicates the almost certain presence of structure.

Three different geophysical methods have been used rather extensively in connexion with geological exploration for petroleum. They are (1) the gravimetric method, (2) the magnetic method, and (3) the seismic methods, which are dealt with fully elsewhere in this section.

AERIAL RECONNAISSANCE

By Bt.-Major M. HOTINE, R.E.
Ordnance Survey Office, Southampton

RECONNAISSANCE from aircraft for the location and development of oilfields may broadly be divided into visual and photographic methods, whose relative advantages and limitations should both be clearly understood.

Visual Reconnaissance

Visual observation from the air, being far cheaper than systematic photography and subsequent detailed examination of the photographs, is mainly of value in providing negative information: it may be possible as a result of a few flights to exclude certain areas from further consideration, leaving the more likely areas for detailed photographic investigation later. At the same time it should be realized that systematic photography of small isolated blocks cannot efficiently be undertaken, and that it must be possible to indicate the boundaries of areas to be photographed to the photographic crew. The aim of a preliminary visual reconnaissance should therefore be the selection of interesting blocks, not less than about 100 square miles in extent, whose limits may clearly be defined. The advantage of doing so from the air, as opposed to selection on the ground, lies in the comprehensive yet detailed view obtainable in a short space of time from aircraft.

If the visual reconnaissance is carried out from a high altitude, then obviously a greater area of country can be seen at once and will remain longer under observation, so that the broader surface features are more readily apparent. At the same time, so far as the binocular sense of the observer is concerned, the ground will be so far away as to appear flat. In cases where the geological structure is related to topographic relief, there is accordingly an advantage in flying lower at an altitude of a thousand feet or so. Impressions of relief obtained from such low-altitude flights can be correlated with indications derived from shadows and drainage and carried through to a return flight at a higher altitude of, say, 10,000 ft., during which the broader extensions of such features may be observed. From high altitudes the landscape may also appear monochromatic, owing to reflection of mainly blue light from intervening layers of haze; yet here again an appreciation of colour, to be derived from flights at a lower altitude may be necessary to distinguish changes in soil or vegetational types correlated with changes in the geological structure. The best system is therefore to combine systematic observation from high altitudes with close-up 'samples' from low altitudes. Since no great ceiling is required in any case, light two-seater aircraft with a low cruising speed and low operating costs may be preferred, although the risk of forced landing in broken country from the low-altitude flights may favour a three-engined machine.

The amount of information which may usefully be derived from visual reconnaissance depends to a large extent on available maps on which to record observations. If detailed, fully contoured topographic maps are available, such as would serve for the geological interpretation of topographic land forms, then the only further information obtainable from the air would relate to surface indications which might well be observed and recorded on the available maps during the course of visual reconnaissance flights alone, without the necessity for photography at all. But such cases will obviously be rare in the type of undeveloped country usually associated with oil prospecting. At the other end of the scale, if no topographic maps are available, then it will usually be possible to do no more by visual reconnaissance than select promising areas for photography, as previously recommended. It is perhaps unnecessary to emphasize that an oil geologist charged with this work should acquire air experience, preferably by flights over country with whose surface geology he is acquainted, and which is reasonably well mapped. Otherwise he would be likely to acquire no more information than an ordinary air observer with no experience of geological prospecting, and might thereby infer that air reconnaissance is of no value—a verdict which is certainly not in accordance with the growing weight of informed experience.

Types of Air Photographs

Air photographs exposed for reconnaissance, or other purposes, are usually classified as 'verticals', for which the camera is pointed as nearly as possible vertically downwards; and 'obliques', for which the camera is intentionally tilted, usually to the extent necessary to include an image of the horizon. Oblique photographs, being more closely allied to the normal type of view obtainable on the ground, are the easier to read, and will include a larger area of ground in a single exposure. Against that, they do not show the ground features in as great detail, and for this reason are not as extensively used for this particular purpose as vertical photographs. Even a major fault, or other extensive geological feature, in the background of an oblique photograph may be hidden by trees or by a slight rise of ground towards the camera, although it could be seen even in heavily afforested country if it happened to run towards the camera, and might in any case appear on succeeding exposures. Such wide features as eroded domes show up very well on oblique photographs, usually by a water pattern, whereas they might be missed in the limited area of a single vertical photograph (failing the systematic compilation of vertical photographs into a mosaic), and would almost certainly be missed, without a complete topographic and geological survey, by even the most exhaustive examination on the ground. Nevertheless, for the present purpose, the balance of advantage lies with the vertical photograph, and much the same conclusion applies to photographs exposed obliquely in multi-lens cameras and subsequently 'rectified' to provide a composite vertical photograph covering a wide field. Such photographs may be cheap, and may serve the purpose of a preliminary reconnaissance better than purely visual observation (especially where the latter is hampered by absence of maps), yet, nevertheless, the oblique view towards the edges tends to obscure detail—particularly in enclosed or broken country—which detail may be vital to a proper interpretation of minor geological features.

Arrangement of Photography

Air photography for systematic geological examination will usually be carried out by a specialized operating company, but the geologist should nevertheless understand broadly how it is done. To facilitate covering the area economically without gaps or excessive overlaps, as well as to simplify indexing and reference, the aircraft flies straight and level parallel courses at such an interval as will ensure that the 'strips' of photographs exposed on each flight completely cover the ground. A side wind will cause the machine to 'drift' off the 'course-steered' (that is, the direction in which the fore-and-aft axis of the machine is pointed) along a different ground track or

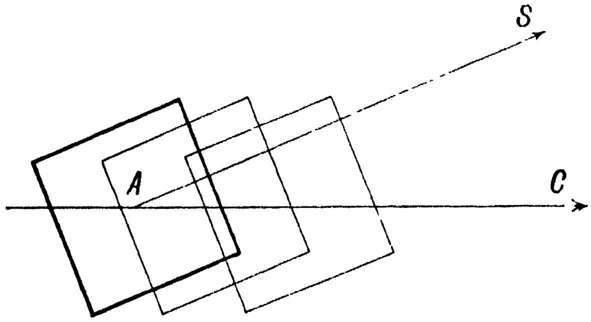

FIG. 1.

'course-made-good'. The angle between the two courses, or the 'angle of drift', must be determined by means of a suitable drift sight, after which the required steady compass course may be set to cover the general direction of the photographic strips. The actual photographs must be symmetrical about the course-made-good, so that provision is required for rotation of the camera in its mounting: if the camera remained fixed in its mounting with the sides of the photographs parallel to the fore-and-aft axis of the machine, then the effect of drift will be to stagger (or 'crab') successive exposures as shown in Fig. 1, where AS represents the course-steered and AC the track or course-made-good. This fault is likely to occasion gaps between strips and will reduce the area of the 'overlap' between successive exposures which is required for stereoscopic examination. Correct rotation of the camera for drift results in successive exposures appearing as in Fig. 2, in which the stereoscopic overlap is shaded.

The navigation of photographic strip flights is a skilled operation, on which depend economy and convenience in subsequent handling, if not the entire success of the operation. If no maps of a large area exist, it may be necessary to photograph strips around the boundaries of the area and to compile these into a rough map or mosaic, on which the starting and terminal points and tracks of the parallel strips may be plotted for use in the air. Such boundary strips may well be photographed with a multi-lens camera.

A common arrangement of oblique photographs consists of one photograph exposed forward along the track, followed quickly by successive exposures to left and right. Suppose, for example, that the camera is equipped with a lens of 7-in. focal length covering a 7-in. square photograph. A suitable altitude is 5,000 ft. With these data it may be calculated that the swing of the side obliques should be about 45°. The next set of three photographs would be exposed after an interval of about 2 miles, and a suitable interval between strips in order that the ground may be covered in reasonable detail would be 6 miles. Such photographs, although cheap, have the disadvantage that they cannot be examined in a simple stereoscope. They are, however, used to a large extent in Canada over flat country for the location of broad geological structures mainly associated with surface markings. If it is desired to examine oblique photographs stereoscopically, they should be exposed laterally by pointing the camera in a direction at right angles to the track.

Although a vertical photograph looks very much like a map or plan, it has, strictly speaking, no uniform scale, since the scale at a particular point will depend on the (small) tilt of the photograph and on variations in the relief of the ground. Nevertheless, it is convenient to speak of the rough scale of a vertical photograph, although it should be understood that this can only be exact in the case of an untilted photograph of flat country. Such a rough scale may be determined by dividing the focal length of the camera by the mean altitude of flight above the ground photographed. A 7-in. lens flown from 12,000 ft. will, for instance, yield contact prints on a scale of about 1/20,000 or nearly 3 in. to the mile. Vertical photographs for geological examination may conveniently be on a scale between 1/10,000 and 1/20,000.

To ensure that the whole ground is covered by stereoscopic overlaps, the interval between successive vertical photographs in a strip should be such as to allow a 'fore-and-aft overlap' of 50% of the fore-and-aft dimension of the photograph, and it is usual to allow 60% to avoid a break in stereoscopic overlaps through an accidental tilt, or sudden rise in altitude (of the ground or of the aircraft),

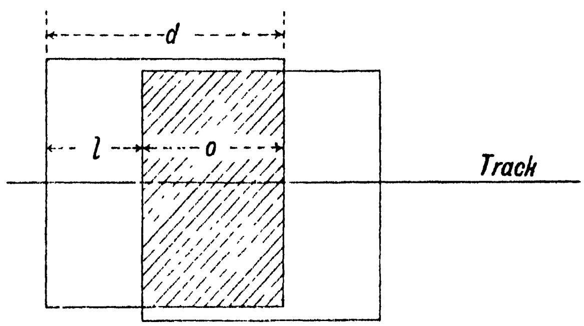

FIG. 2.

or increase in air speed. Thus in Fig. 2, o/d will usually be 60%. Successive exposures are made automatically on a time interval derived by calculation, or by observation in a suitable overlap sight. The 'lateral overlap' between strips is usually fixed at 25% to avoid a gap between strips occasioned by small lateral tilts or departures from a straight course. The amount of lateral overlap, in conjunction with the scale of the photographs, settles the distance between strips. Given the scale and the overlaps, it is also a simple matter to calculate the number of photographs required to cover a given area of ground.

Air photographs are usually examined or utilized in whole strips. There is accordingly some advantage in arranging the strips to run parallel to the broad topographic features of the country, if such there be. A better view of the steep slopes of mountain ranges, or a more continuous record of the structure of valleys, might, for instance, be obtained by doing so. A photographic pilot should not, however, be asked to fly accurate compass courses within, say, 10° of magnetic north. If he attempts to do so, a slight accidental banked turn out of a straight

and level course will cause the vertical component of the earth's magnetic field to act on his compass so as to indicate a turn in the opposite direction. Instead of correcting the initial turn, he is therefore likely to make it worse. This 'northerly turning error', as it is called, does not apply on southerly courses, on which the compass indications would be *more* stable. In the case of oblique photography, a further disadvantage of northerly (or in this case southerly) courses is that there may be a tendency for the midday sun to shine into the lens of the camera and fog the photograph.

Modern air cameras utilize roll film contained in magazines of 100 exposures, although it is usually possible to carry sufficient spare magazines for a photographic flight of any reasonable duration.

Stereoscopic Examination of Air Photographs

Any two successive vertical (or lateral oblique) photographs in a strip may be examined in a simple stereoscope to provide an impression of relief, provided that they have a sufficient overlap. The examination is very simply carried out if only such local impressions as a tree standing up out of its surroundings is required, or the detection of such structures as are associated with similar *sudden* changes of height or stereoscopic depth, but rather more care must be exercised if impressions of the relief of topographic features over large areas are required. Such wide impressions usually are required, at least in the early stages of geological examination. Methods will accordingly be discussed first for examining the entire overlap in correct stereoscopic relief: to relax the conditions for the less exacting conditions of local relief will then be a simple matter. It will be assumed that the photographs are vertical, although much the same conclusions would apply to lateral oblique photographs.

Air photographs used for surveying purposes have marks (known as 'collimating marks') along the edges or at the corners which may be joined to indicate a point near the centre of the photograph known as the 'principal point'. If no such marks occur on the particular photographs under examination, the geometrical centre of the photograph should first be marked as the intersection of small central portions of the diagonals, and taken to represent the principal point. The exact location of the principal point is not of very great importance, provided that it is marked consistently throughout a series of strip photographs. For this purpose it will be convenient to make up a celluloid template, which can be fitted over the collimating marks or corners of the photograph, and containing a central cross whose position can be pricked through to the photograph.

Ground detail around the principal point will also be photographed near the edge of the next photograph of the strip. Consequently the position of the principal point of each photograph of the stereoscopic pair can be transferred through such detail to the other photograph of the pair. If, for instance, the principal point falls on a bush, the same bush may be identified near the edge of the other photograph of the pair and suitably pricked or marked. The line joining a principal point to the transferred image of the next principal point is known as the 'principal point base line' and should be marked up right across the overlap on both photographs of the pair.

Place one photograph over the other so that the area of common ground in the overlap more or less coincides, and so that the shadows in the photographs run towards the observer; if necessary, turning both photographs round together to fulfil the latter condition. The photograph which is now mainly to the left will be called the left-hand photograph of the pair and will be examined with the left eye in the stereoscope. If the photographs are not placed thus correctly left to right, an inverted impression of relief might be obtained; hills appearing as depressions and valleys as spurs. But such an inverted impression would appear unnatural: the so-called common sense of the observer might outweigh his binocular sense and give him a weak impression, or illusion, of relief. Usually, if the photographs are inverted left to right, the result would be a drawn battle between common sense and binocular sense, and the landscape would appear quite flat. It is for much the same reason that the photographs should be so placed as to make the shadows run towards the observer, that is, away from the normal source of illumination *during examination*. In this way the impression of relief derived from shadows will *supplement* that derived from binocular sense, whereas if this recommendation is not followed the resulting unnatural run of shadows during examination might again result in a flat, or weak, stereoscopic impression.

Now lay a straight-edge on a wooden table roughly parallel to the edge of the table and consequently roughly parallel to the line joining the two eyes of the observer. Place the two photographs of the stereoscopic pair under the straight-edge in their correct relative positions, as obtained above, but separated so that the entire overlap can be seen on both photographs. Bring the two principal point base lines against the straight-edge and pin the photographs in this position to the table. Remove the straight-edge and examine the pair with a simple stereoscope, which for the present purpose may be of the ordinary hand prismatic type. A suitable cheap achromatic prism stereoscope for use with air photographs about 7 in. square can be obtained from such optical firms as Messrs. Adam Hilger. It is a mistake to attempt a saving of a few shillings by acquiring an inferior article made from non-achromatic combinations and possibly not even of optical glass. Neither can a stereoscope made of half-lenses be recommended for the present purpose of stereoscopic examination of the entire overlap, since the field of the cheap lenses mostly used in such articles is strongly curved and may give a totally erroneous impression of relief, in addition to causing severe eye-strain.

Choose a prominent point of detail in the photographic overlap, such as a distinctive white field, and concentrate the attention on it through the stereoscope. Usually two images of the object will be seen. If one of these images is apparently higher than the other, turn the head, and the stereoscope, until they appear at the same level, that is, on a line parallel to the principal point bases. Now attempt to 'fuse' the two images into one by endeavouring to look *through* the table. If this cannot be done, or the two objects can only be fused and kept fused by excessive eye-strain, unpin one photograph and move it parallel to itself (replacing the straight-edge as a guide) until the apparent separation of the images is sufficiently reduced to allow easy fusion. Fusion will often be secured straight away without any later movements of the photographs, particularly after a little practice. When the two images have been fused, allow the eyes to wander gradually over the entire overlap and at the same time keep an open mind as to the relief of the landscape. Such local differences of relief as are occasioned by houses and trees will be readily

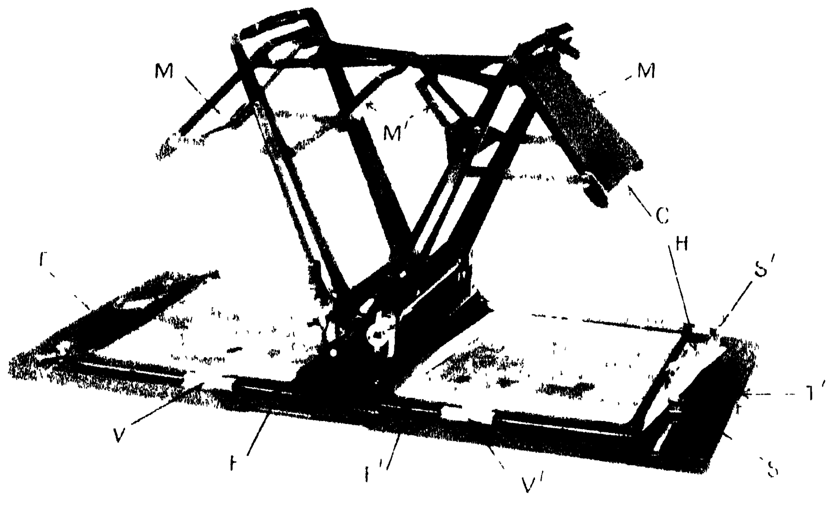

Fig. 3

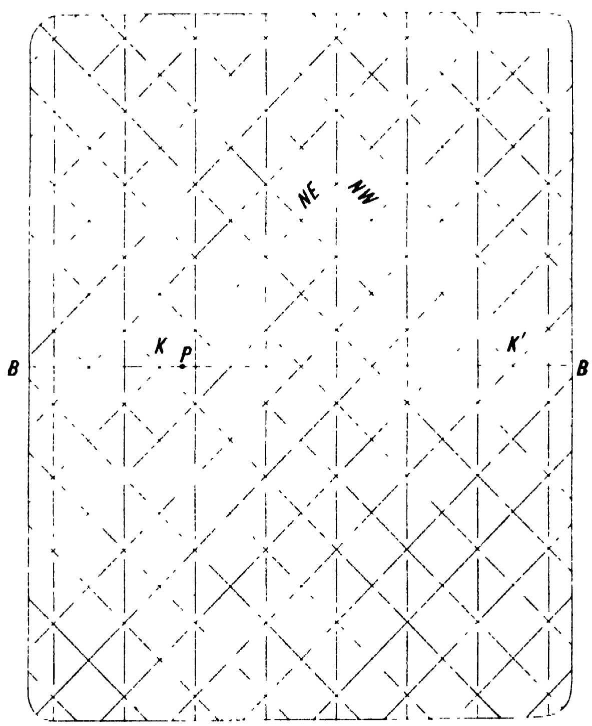

Fig. 4

apparent, but to appreciate the broader topographic features may need practice and the cultivation of a habit of unbiased and systematic examination of the whole area. Once the broad impression of relief is obtained there is no mistaking it.

The distance between corresponding points of detail on the pair of photographs as set for stereoscopic observation (known as their 'separation' and measured parallel to the principal point base) will be found to vary for different points. The separation of corresponding points on the top of a hill is, for instance, less than the separation of corresponding points in a valley. This variation in separation of corresponding points, or parallax, is introduced by exposing the photographs from different camera stations, and gives rise to the impression of relief during the later examination.

To assist in the stereoscopic examination of broad topographic features a special Topographic Stereoscope (Fig. 3) is made by Messrs. Barr & Stroud. The visual system of the stereoscope consists of parallel pairs of inclined mirrors M and M', which form virtual images of the photographs immediately under the eyes and, by thus reducing the separation of the photographic images, makes them easier to fuse. The use of plane mirrors also eliminates the effect of aberrations, which are never entirely absent in even the best prism or lens stereoscopes. Two entirely similar glass plates (illustrated in Fig. 4) carrying a network of lines engraved on the underside are fixed in the frames F and F', and are thus hinged to lie flat over the photographs. These engraved plates are known as parallactic grids, and their purpose is to provide the impression of a reference plane in the stereoscopic field, against which reference plane wider variations in the relief of the landscape will be more readily apparent than they are with no such aid. Being entirely similar (and thus not containing any internal differences of separation or parallax between corresponding lines), the two images of the grids fuse to form an apparently flat plane, whose height or stereoscopic depth above the landscape may be varied by altering the separation of the grids, leaving the two photographs fixed. The entire phenomenon is purely relative. If the grids were viewed stereoscopically with blank sheets of paper under them, then any alteration in their separation would occasion no apparent rise or fall of the fused image, which can only be appreciated when the attention is held by the fusion of the underlying photographs. Although the similarity of the grids should, as stated above, imply their fusion into a flat plane—and usually does so—the same relative interaction of the photographs may result in the grid image being broken up in depth, when the photographic detail introduces disturbing influences. Suppose, for instance, that a grid cross K is placed exactly over a point of photographic detail on one photograph, while the corresponding point of detail on the other photograph lies above the corresponding cross. The separation of the diagonal line NE. is thus greater than the separation of the photographic detail, and its fused image will apparently lie below the fused detail. In the same way the separation of the other diagonal lines of the cross (parallel to the NW. direction) is less than that of the photographic detail, and the fused image of this arm of the cross will therefore appear above the fused detail. In the result, the two arms of the cross are split in depth by the detail.

This property of the grids affords a means of accurately setting the photographs. The principal points P are set under the base lines BB of the grids and the photographs are rotated about them until the corresponding detail on the other photograph of the pair also lies roughly under the base line. A grid cross K near the left principal point is now examined stereoscopically. The right-hand photograph is then finally rotated, and the separation of the grids varied, until *both* arms of the cross appear to touch the ground. The same procedure is adopted in relation to a cross K' near the right-hand principal point for the final orientation of the left photograph. It is important that the cross as a whole should be brought continuously down to the ground as the adjustment proceeds by varying the grid separation, since otherwise the effect is usually lost. When set, the photographs are clamped by means of the screw-clamps S, S' (Fig. 3). The grid plates may be raised off the photographs by hooking the spring clip H to the underside of the mirror at C. A straight-edge may then be placed against the stops T, T' in order to rule up the principal point bases on the photographs to facilitate resetting on any future occasion. A change in separation of the grids can be read off the vernier scales V, V' for the rough measurement of heights as described below. The instrument is collapsible and can easily be shut up into a small case for carriage.

If the (vertical) photographs are tilted or are exposed from slightly different altitudes, corresponding points of detail will not lie at quite the same distances from their respective principal point bases. Consequently, the effect described above of a grid cross appearing split in depth may still be apparent even after the photographs have been correctly set, particularly towards the corners of the overlap. For certain purposes, connected mainly with rapid mapping from the photographs, a quantitative use is made of this property, but for purely qualitative examination it is merely confusing. Once the photographs have been correctly set in the Topographic Stereoscope, the fused grid should therefore be raised above the landscape until the effect disappears. The subsequent examination is much the same as looking at a landscape through a fine-latticed window. If the photographs were untilted and exposed from the same altitude—as is nearly the case—the plane of the grid would be a horizontal plane. The indications of a fixed horizontal thus carried over the overlap offer a ready means of appreciating the general rise and fall of the landscape. It is unnecessary to pay any particular attention to the fused grid for this purpose; it will obtrude itself on the attention of the observer without any special effort on his part, and he may therefore concentrate on the ground features. If the examination is carried out in such a grid stereoscope, it will be unnecessary to rely on such adventitious aids to securing an impression of relief as, for instance, obtaining the correct run of shadows in relation to the lighting during examination. If the photographs are inverted left for right, the resulting inverted or pseudoscopic relief may also be clearly seen in such a stereoscope.

A rough measurement of the difference in height of ground features may on occasion assist a detailed geological examination. This may be calculated from the following simple formula:

$$Hp/l,$$

where H is the mean altitude of flight above the ground, obtainable from altimeter measurements or photographic records during the strip flight;

l is the distance on the photograph in the direction of the principal point base which is *not* overlapped by the next photograph in the strip (see Fig. 2). To reduce the effects of accidental tilts,

it is advisable to obtain a mean value of this measurement from a whole strip of photographs exposed on the same flight at a constant time interval;

and p is the difference in separation of the two points considered. This may be measured most accurately with the parallactic grids of a Topographical Stereoscope. A fused vertical line of the grids is brought alongside one of the objects and the separation of the grids altered until the fused line appears to lie at the same height as the object. Both grid scales are then read and the process is repeated for the second object. Addition and subtraction of the scale readings, in a manner which needs no detailed explanation, will then give the required difference in separation. In place of using vertical lines of the grid, either a NE. line may be used for the whole operation, or a NW. line, or a mean reading may be derived from both. But the use of a NE. line for one point and a NW. line for the other would involve serious error on slightly tilted photographs.

Messrs. Barr & Stroud manufacture precision models of the Topographical Stereoscope which are designed to facilitate such measurements and which are also equipped with such refinements as turn-tables for more rapid setting of the photographs. They are mainly used for mapping purposes, but might nevertheless repay the higher cost on other work if they are required for extensive use.

The simple method of calculating differences of height given above assumes that the photographs are untilted and exposed from equal altitudes, and in practice can therefore only be applied with assurance when the two points whose heights are required are situated close together. The difference in height of two points at opposite extremities of the overlap would usually be in error by about 1 ft. for every minute of tilt, for instance, so that no very useful measurement can be made by these means when there are random tilts up to 2°, as is usually the case, unless the effect of tilt is counteracted by restricting measurement to points appearing fairly close to one another in the overlap. Accurate stereoscopic measurements, moreover, require practice, and should not properly be carried out on the ordinary photographic printing-paper of commerce which is liable to considerable distortion. If much quantitative information is sought, it would therefore be advisable to have detailed topographic maps prepared at this stage from the photographs, and for this purpose it would be as well to enlist the services of a specialized cartographic establishment. The methods employed to produce such maps are outside the scope of the present article.

For the examination of local surface markings occasioned, for instance, by faulting or rock outcrops, a magnified stereoscopic impression, which in this case may be distorted without disadvantage, is usually of value. A very suitable stereoscope for this purpose may be improvised from two similar high-powered magnifying glasses held in retort stands. The eyes should be placed over the inner halves of the magnifying glasses. No very accurate setting of the photographs is required for such local examination, although the usual precautions should be taken to choose the correct left and right photographs to obtain the natural run of shadows, and to ensure a very rough orientation. It may be found necessary to place the two photographs so close together that there is a risk of obscuring one photograph by the other. In that case the unwanted inner portions of the photographs may be passed down through a slit in the table, or in a box on which the photographs are placed.

Mosaics

A single overlap of air photographs on the scales commonly used for geological examination covers only a square mile or so of country. It is with a view to extending the area of ground which may be examined simultaneously that various attempts are usually made to compile the photographs together into a 'mosaic', by joining them together so that the detail is more or less continuous over the join, and pasting down photographs so joined on a large sheet of material such as Bristol board. To obtain the best continuity of detail across the joins, it is usual to cut adjacent photographs across the area of their overlap. Consequently, it is not possible, as is sometimes suggested, to obtain stereoscopic impressions by examining portions of the mosaic in conjunction with a loose photograph. Nevertheless, a mosaic may serve a valuable purpose as a comprehensive index, showing in approximately relative position the information gleaned from stereoscopic examination of a duplicate set of photographs. It may also indicate, for more detailed study on the separate overlaps, certain geological structures which cover too wide an area to be picked up in the first place on separate overlaps.

It will be realized that a perfect join between two adjacent photographs can only be obtained when the photographs have the same uniform scale, and it has already been pointed out that this is only the case when the photographs are untilted, are exposed from equal altitudes, and are photographs of flat country. Variations in scale introduced by tilts and unequal altitudes are not likely to be very significant for the present purpose if the flying and photography are carried out by a properly trained and practised photographic crew. It would be unusual, for instance, to encounter tilts exceeding 2°, with a corresponding non-uniform scale variation between one side of the photograph and the centre of the order of 2%; while an accidental increase or decrease of 100 ft. in a flying altitude of 10,000 ft. would only occasion a departure of 1% from a mean uniform scale. By arranging to utilize only the central portions of the photographs for the mosaic, the effects of such scale variations may easily be reduced to within tolerable practical limits. But it is otherwise if the country is not fairly flat. A variation in relief of the ground of only 200 ft. or so, in the case of photographs exposed from 10,000 ft., would superimpose an error equal to the probable effect of tilt and variation in flying altitude combined. This source of variation in scale is also counteracted to some extent by utilizing only the central portions of the photographs, but if the variations in relief are at all considerable, it may well be impossible to compile a mosaic to serve any useful purpose at all. Accuracy in the measurement of distances on the completed mosaic has nothing to do with this question. If the scale variations are excessive, prominent detail may either appear twice on the compilation or not at all, and there is a limit to the extent to which this failing may be cloaked by judicious cutting of the photographs so as to throw such omissions and duplications into unimportant areas. An accurate plan of the area may not be required, but a reasonably complete and unique representation of the ground certainly is required for any purpose.

In such cases, the only solution of the difficulty is to give

up the production of a mosaic altogether in favour of the compilation of a drawn map. Methods exist whereby this may be done rapidly—although it would be advisable to seek the co-operation of a competent cartographic establishment to do it—and the result will have the advantage that distances may be scaled off it with some assurance. Even the largest scale conventionally drawn maps cannot show as much detail as appears on the original photographs, but this disadvantage—if disadvantage it is to non-specialized map-users—can easily be offset for systematic geological examination by using the map in conjunction with stereoscopic examination of the original photographs.

The compilation of a large mosaic, even of flat country, is a skilled operation which would usually best be undertaken by the company or organization employed for aerial photography. The principles are simple enough, but their application needs practice. The desirability of choosing the central parts of the photographs for final display in the compilation, and trimming off the overlaps accordingly, has already been mentioned. Another property of air photographs of which use is made is that directions from the principal point are to a large extent unaffected by scale variation—whether due to tilt or unequal altitude or relief—so that a join of two photographs by making the two principal point bases coincide will be mainly correct and will facilitate the addition of further photographs to the compilation. A last principle is that no photograph or portion of a photograph should be finally stuck down until there is no possibility of having to move it to secure a better fit of other photographs. It is impossible to obtain perfect joins everywhere, and if any attempt is made to do so, the trouble will merely be pushed ahead and made worse at a subsequent join: the aim should be to distribute imperfections throughout the compilation.

Interpretation of Air Photographs

The vertical air photograph records an unfamiliar view of the ground which requires some little practice and experience for its interpretation. Such practice, which may best be obtained by studying air photographs of familiar ground, is indispensable. A few general principles may be conveyed in print as a basis for practical study, but no amount of printed description alone will enable very much information—particularly such specialized information as is required for oil geology—to be obtained from the photographs. Generally speaking, the more practised the geologist at reading photographs of different types of country, the less will he need to supplement his observations by field work, although a certain amount of field work will always be necessary, if only to seek confirmation.

Stereoscopic examination should be considered a *sine qua non*. Air photographs suffer from quite enough limitations, which cannot be overcome, without the gratuitous sacrifice of the third dimension in reading them. It is true, but quite beside the point, that various 'lucky strikes' have been made by observing surface markings on an odd single photograph and subsequently prospecting this area on the ground. One hears most of these cases when they are successful, and nothing of the occasions when the markings are due to a peculiar system of native agriculture or grazing, or even to scratches on the film emulsion. The trained geologist will not, of course, neglect to note such features for his subsequent field examination, and will be guided to them by the photographs, but he will no more dispense with the stereoscope in his preliminary field examination than he would willingly use an uncontoured map for the geological interpretation of land forms. The use of a stereoscope, moreover, solves such minor difficulties of interpretation as confusing an object with its shadow, and will dissociate film scratches from the landscape altogether.

An air photograph must always be read in relation to its scale. Unless this is done totally erroneous conclusions may be drawn. Faulting, for instance, will usually appear as a straight and more or less continuous line. On very small-scale photographs the same sort of image would result from a road or straight track, partially obscured by trees, or even a railway. A little calculation and reflection will, however, show that the road or railway on photographs of known scale would have a certain width, and either may be ruled out if that width does not actually appear on the photograph. No ordinarily intelligent person would attempt to read a map of unknown country without first getting some idea of its scale. To dispense with any idea of scale in reading an air photograph is far worse, because the photograph is a much more detailed and faithful representation of the ground than any map. It would be useless attempting to measure the width of a road, for example, on any but the largest scale map, because the width will have been exaggerated or 'generalized' in the interests of clarity, yet on the photograph it is shown in its correct natural proportions.

The smallest size of object which will show up on a photograph depends on the nature of the object and on the quality of the photograph. A small brilliant object reflecting light straight into the camera will often show up when a larger dull one will not. But as general rule it may be assumed that an object will not be distinguishable from its surroundings if any dimension of the photographic image is less than about 0·002 in. An image much smaller than this would be confused with the grain size of the photographic emulsion or would not be resolved by the lens. This implies, of course, that it is little use looking for objects less than 2 ft. wide on 1/10,000 photographs, although smaller objects may sometimes be identified by larger features which are always associated with them. The same reason applies to the appreciation of stereoscopic depth. If, in the formula given above, we substitute 0·002 in. for p, and for the sake of example assume that l is 3 in. while H is 6,000 ft., we find that an object must stand out more than 4 ft. above its surroundings if the fact that it does so is to be appreciated by stereoscopic observation. To examine objects as small—or as low—as this, magnification would be necessary, but no amount of magnification would render smaller—or lower—objects visible. Moreover, the definition of the photographs would need to be good for these limits.

It has already been mentioned that an observer at high altitudes is usually bereft of colour sense, and the same applies to the camera, which as a further means of falsifying colour values is supplied with panchromatic film and a yellow filter, the object of which is to cut out actinic light directly reflected from the intervening haze. Colour, in fact, has very little effect in fixing the 'tone' or shade of white, grey, or black in which an object will appear in the photograph. The deciding factor is the amount of light, of whatever colour, which the object reflects into the camera, and the characteristic which most affects this is the *texture* of the object. Smooth surfaces will usually be dark in tone for the reason that they do not scatter light and—barring an accidental direct reflection into the

camera—which sometimes happens—will therefore most often reflect all the light away from the camera. Rough surfaces will have an intermediate tone depending on the amount of light scattered by them, a more or less fixed proportion of which will reach the camera irrespective of the direction of the incident light. Nevertheless, colour is not altogether non-effective. Chalk, snow, and sand will almost always show up white, whatever the direction of the reflected light. An air camera is very sensitive to differences in reflecting power, and this is perhaps one of its most valuable characteristics. Minor differences in the reflecting power of soils, whether due to change in the underlying geological structure or to the hand of man—in recent or remote ages—show up with amazing clarity. All that can be definitely established from the photograph is that there is a change in reflecting power, which may or may not have a special significance for the purpose in view; more definite conclusions must await examination on the ground, which is narrowed down, but not replaced, by the use of air photographs. The latter, in conjunction with later field work, has, however, often led to the discovery of structures or structural changes which had been missed altogether by ground work alone.

The correlation of vegetational changes with changes of geological structure is also a fruitful field, and the former are clearly visible within definite boundaries on air photographs, but would otherwise be difficult to obtain. Here again a change in vegetational type or density does not necessarily imply a change in geological structure—much less the existence of oil—but it does indicate an exact locality for further investigation. This further investigation may indeed show that the change is due to nothing more significant than climatic exposure, or to partial clearing or burning in conjunction with native agriculture—or it may lead to far-reaching discoveries.

Structures such as synclines, anticlines, and salt-domes which are associated with definite topographic features are, of course, very easy to pick up by simple stereoscopic examination. The air photograph will not, of course, prove or disprove their association with oil, which must be established by geophysical methods or by boring. But, once again, the field for the latter methods will have been narrowed down by the preliminary photographic reconnaissance.

Other Uses of Air Photographs

After the preliminary photographic reconnaissance, the air photographs, together with any maps or mosaics made from them, should be taken into the field to confirm the conclusions drawn and to clear up any doubtful points. Examination of the photographs will enable each day's journey to be planned in advance so as to secure the maximum amount of information in the shortest time. The photographs, or better a mosaic or map compiled from them, will also serve to record the locality of field observations. Later they will facilitate the location and recording of geophysical work.

The wealth of surface topographic data contained in air photographs and in maps compiled from them has obvious uses in the development of oilfields. The general lay-out of existing communications is given at once. The photographic material in the hands of the civil engineer very materially assists his reconnaissance for the improvement of communications, whether road, rail, or pipeline. The efficiency of engineering reconnaissance carried out by these methods is generally far in advance of the older ground methods, owing mainly to the fact that alternative schemes covering a wide area can all be compiled and reviewed at the same time, in as great or in as little detail as may be required, with the certain assurance that no more profitable alternative can have been missed. This increased certainty and efficiency of reconnaissance leads, as a rule, to lower operating and maintenance costs. The general administration of the fields is also simplified by the provision of adequate topographic information on which an efficient lay-out may be based.

SURFACE INDICATIONS OF OIL

By S. E. COOMBER, A.R.S.M., B.Sc., D.I.C.
Imperial College of Science and Technology

Indications of Oil.

SURFACE indications of oil include all those substances commonly associated with petroliferous deposits. The gaseous, liquid, and solid hydrocarbons have the most obvious connexion with such deposits and may be termed direct indications. There are other materials, however, such as salt-water, sulphur and various sulphur compounds, gypsum, and certain types of strata often identified with the source rocks of petroleum, which are not necessarily associated with oil, but one or more of which are so commonly found in oilfields that their occurrence in virgin territory merits examination and close study. These may be termed indirect indications.

In the following description of the various types of oil indications the greatest space is devoted to the direct types. The indirect indications are dealt with more fully in the article by Professor Illing on their significance.

Gas Shows.

The gas from petroleum deposits is, with some exceptions, composed principally of methane. Small quantities of the higher members of the paraffin series—ethane, butane, &c. —are usually present and, in certain cases, sulphur compounds. The occurrence of large quantities of carbon dioxide in association with petroleum is rarer. Seepages of these gases unaccompanied by liquid or solid bitumens are not uncommon.

Recognition of a true gas seepage from petroliferous beds may be difficult, due to the fact that methane in considerable quantities is evolved by decaying vegetation in swampy areas and occurs also in coal and lignite seams. Also, sulphurous gases and carbon dioxide are a feature of some volcanic activities. Such possible sources must therefore be considered and careful examination made to exclude errors in diagnosis on that account.

Gas escaping under water is readily seen. In clear, shallow water with a rocky or sandy bottom it may be possible to see the places from which the gas issues, and there is then little doubt that it has a subsurface origin. In the case of deep or muddy water where the escape is not violent, every effort should be made to trace the seepage to bedrock.

Cases are recorded where the escape of gas is sufficiently strong to agitate large bodies of water to a considerable degree. Thompson [7, 1925], for instance, mentions that boats have been capsized in the Caspian from such a cause.

In arid regions gas seepages, if not violent, are much more difficult to find. Their presence is sometimes indicated by bubbles arising in small puddles. In other cases gas may be revealed by a characteristic odour in sheltered depressions. The presence of sulphur compounds in the gas makes its odour much more apparent. The concentration of gas in depressions may be so great that animals straying into them become asphyxiated. Instances of this are to be found in Central America and elsewhere, the poisonous zone being marked by accumulations of bones.

The escape of gas is often intermittent, due to blocking of the channels along which it passes and the consequent need for its accumulation behind the obstruction until the pressure becomes sufficient for it to break through. Such phenomena are described by Thompson [7, 1925] from the Baku district where violent eruptions of gas commonly take place after several years of quiescence. Earthquakes may also cause the escape of gas in areas where it is not generally found.

In rare cases gas seepages are continuous and of such volume that the gas will burn uninterruptedly for very long periods. The eternal fires at Surakhany are a case in point.

Probably the most spectacular examples of the escape of gas are provided by mud volcanoes. These are due to the escape of gas and water through argillaceous strata, and take the form of conical mounds or of basins full of soft mud in a state of constant agitation. The basin type, of which Lagoon Bouff in Trinadad is an excellent example, is formed where water is abundant and the disruptive and puddling action of the gas gradually erodes the soft strata. The result is a basin which is filled with mud soft enough to flow away when it reaches the general level of the surrounding country. When the mud is so viscous that it does not flow readily, the tendency is to form a cone around the gas vent. In dry regions where heavy rains are uncommon these cones may attain gigantic dimensions. The Boz Dagh mud volcano in the Baku district is 1,000 ft. in height. In other instances a large number of comparatively small cones may form.

The emission from a mud volcano is intermittent. Very high pressures may be built up before an eruption takes place, then, when it does occur, it is very violent. In certain areas in Trinidad the mud resembles a great lava flow and covers large areas. Submarine eruptions have been recorded, in Trinidad and Burma for instance, and the volume of mud ejected has at times been so great that new islands have been formed. Kugler [4, 1933] remarks also on the effect of mud-flows on topography and drainage, saying that in one area in the Cedros Peninsula, Trinidad, there is hardly a normal valley to be seen.

Fossil mud volcanoes, evidence of former activity, are not unknown. They take the form of mud and sand dykes, buried mud-flows, and erratic blocks. They are characterized by very poor grading of the material and the presence of fragments of all the geological horizons down to considerable depths.

Liquid Shows.

The oil in liquid shows varies from a light, colourless oil to black, very heavy and viscous material. The dark, thick oils are the most common type found in seepages and, by their nature, are the most easily recognized. Seepages of very light oil are rare. Some occur in Persia at the White Oil Springs, 38 miles north-east of Ahwaz, where there are two seepages on the crest of a fold and from these about 20 gal. of colourless oil resembling kerosine are obtained per day. The oil was collected by the natives and sold for domestic purposes. Comparatively large seepages of light oil are also found at Lizard Spring in Trinidad, the

oil collecting in the dry bed of a stream during the dry season. Other light oil seepages are found in Venezuela, Colombia, Russia, and a few localities in Europe.

Dark, heavy oils are more easily seen than light oils and they resist dispersion better. Generally there is a tendency towards oxidation and polymerization so that the oil hardens into solid matter. In forest areas it frequently mixes with leaves and fallen twigs, making a dense, black, asphaltic carpet. Seepages of this type occur in the Magdalena Valley in Colombia, and Stutzer [6, 1931] describes one area there as resembling a moor in which asphalt-cemented leaves replace the usual water-saturated peat. The bed of one stream is covered with asphalt, and the twigs and grasses on the banks are smeared with heavy oil to a height of 6 ft.

The seepages at Qaiyarah on the River Tigris, some 35 miles south of Mosul, are very impressive. Large areas are covered with material which shows all gradations from thick, tarry oil to solid asphalt. The heavy oil wells up from numerous small vents in these patches and is accompanied by inflammable gases containing hydrogen sulphide.

Where oil escapes under water its presence is indicated on the surface by an iridescent film. This must not be confused with the film of hydrated iron oxide which is often seen on stagnant water. The iron oxide film is readily broken with a stick, whereas an oil film immediately re-forms after being disturbed. If a seepage is of any size, it will tend to form a thick oily scum on stagnant water. Oil has been recovered from such seepages by skimming or by dragging cloths along the surface of the water and then squeezing the oil from the cloth. It was obtained from the River Ohio in this manner and sold as 'Seneca Oil'. In the case of rivers carrying much silt and clay the oil does not usually remain for long at the surface, but is carried down by the mineral matter. The seepage therefore tends to be localized in those cases. Thompson [7, 1925] records a number of interesting examples of submarine seepages. Such an occurrence off Yucatan in Mexico produced an oily scum on the sea and resulted in the death of so many fishes that troops had to be engaged to destroy them when they were washed up on the shores. Oil 'ponds' off the coast of Texas are mentioned by Fenneman [3, 1906], who states that they are used by coasting vessels seeking quiet water during storms.

In dry, sandy areas the seepages produce impregnated sands from which oil may sometimes be obtained by digging pits. This is more the case with the non-asphaltic types of oils, for with the asphaltic types inspissation produces a hard asphaltic mass as already described.

The surface extent of oil seepages varies between very wide limits. Most of those already described are large, but very many are quite small. The Khaur dome in the Punjab is an interesting example of a producing field associated with a very small seepage. Seepages derived from outcropping sands in Burma are also frequently very small, Craig [2, 1912] stating that even from thick oil sands pools of only a foot or so in diameter are obtained. The small and less obvious shows are usually associated with paraffinous oil which is comparatively easily dispersed by surface waters.

Solid Shows.

Solid shows are very numerous and many are derived from the liquid shows, a fact already noted, and are the result of inspissation of the oil. In general we may consider the following types of solid shows: (1) impregnations, (2) solid asphalt accumulated at the surface, (3) bitumens of deep-seated origin, and (4) wax.

Impregnations are the commonest form of show and are found in clays, limestones, argillaceous limestones, sandstones, conglomerates, &c., with the oil or bitumen in the pores of these rocks. A rock with a considerable oil content may show a tendency to flow under pressure. This is the case with the Athabaska tar sands which, incidentally, are undoubtedly the greatest oil show in the world. The tar sand, which is of Lower Cretaceous age, outcrops for a distance of 120 miles along the Athabaska River in Alberta. In the richer part of the rock the oil is the sole cementing material. Excellent examples of impregnated limestones are to be found in Europe—Val de Travers, Garde, Limmer, &c. They have a bitumen content up to 10% and are used to a large extent for road-making purposes.

Impregnated clays are tough and resist weathering. The adsorptive properties of clays are such that small quantities of bitumen are unnoticed, but as the amount increases the characteristic odour becomes apparent and finally the clay sweats oil. The colour also darkens, and this tends to be more pronounced with asphaltic oils than with paraffinous oils. In addition, well-impregnated sands are tough, and in describing the Athabaska tar sands Clark and Blair [1, 1927] remark that a heavy blow with a hammer makes little impression, although the surface can be picked easily with a sharp tool. Such sandstones tend to weather with rounded instead of sharp corners and edges. Fluctuations of the water-table may flush impregnated sediments completely if the oil is comparatively light, so that the examination should, if possible, be extended to rocks below the permanent water-table. On the other hand, impregnations of heavy asphaltic oils leave black coatings on the rocks even after thorough flushing.

A very simple test may be applied to identify impregnated rocks. A sample of the rock is powdered and warmed with a solvent such as benzene or chloroform, which is afterwards poured on to a piece of blotting-paper and allowed to evaporate. If oil is present in the rock, it will leave a stain on the paper. In some carbonaceous shales resins are present which may give a false show with this test. They may be distinguished, however, by their high degree of solubility in alcohol in contrast to the low solubility of bitumen.

Solid asphalts accumulating at the surface are found wherever inspissation of seepages of asphaltic oils takes place. They have already been described to a large extent in the section dealing with liquid shows. Frequently these asphalts contain considerable amounts of mineral matter picked up before the mass had hardened and they tend to spread out concentrically from the seepage. The 'chapapote' of Mexico is a thin bituminous veneer formed in this manner. The Bermudez pitch lake in Venezuela, on the other hand, is a comparatively pure bitumen contaminated with only a little vegetable matter. Other noteworthy occurrences of such asphalt deposits are to be found in Iraq, Colombia, California, Russia, Mexico, and Trinidad. Very interesting collections of skeletons of extinct animals have been obtained from some of these deposits, the animals having strayed into the sticky mass and been engulfed.

The famous Trinidad pitch lake is of a different type from those just mentioned. It is not an ordinary bitumen, but an emulsion of about 40% bitumen, 30% silty clay, and 30% water. The pitch occupies a depression of some 127 acres in extent and in the centre it is soft, and sulphurous gases escape from numerous small vents. Removal of the pitch has caused lateral flow and subsidence near the edge. On one side of the basin there is a depression which was

originally an overflow channel, and much pitch has been extracted from this. The level of the lake is now slowly falling due to continued excavation.

The deep-seated bitumens are of various types, often very pure, and fill fissures, joints, and fault planes near to petroliferous strata. Some of the principal types are grahamite, uintaite, gilsonite, manjak, albertite, and wurtzilite. They are best described separately.

The type locality of grahamite is in West Virginia. It occurs also in Oklahoma, where there are exceptionally large veins, in Texas, Cuba, Mexico, and Trinidad. Grahamites have a black streak, a conchoidal to hackly fracture, and a high melting-point. They are heavier than water, very soluble in carbon disulphide and chloroform, partly soluble in petroleum spirit, and insoluble in alcohol. Their mode of occurrence is in veins which vary from a few inches to as much as 25 ft. in width. The material in the thicker veins often contains an appreciable quantity of mineral matter. The so-called manjak of Trinidad is really more of a grahamite than a true manjak. It occurs in a zone of complicated tectonics and is found along fault planes. Its melting-point decreases with depth, and also in the deeper levels there is a variety which approaches more closely to the true manjak in type.

Manjak is usually very pure with a dark-brown streak, conchoidal fracture, and specific gravity of 1·1. The type locality is in Barbados, whilst it also is found in Colombia, Syria, and the Dead Sea. In its solubility in various solvents it is similar to grahamite. Uintaite or gilsonite resembles manjak, but has a slightly lower specific gravity. It is restricted in its occurrence, being found only in Utah and Colorado as vertical veins which may be as much as several feet in thickness.

Albertite, a lustrous, black, bituminous substance with a conchoidal fracture, is characterized by its infusibility, insolubility in carbon disulphide, high percentage of fixed carbon, and low oxygen content. It is found in veins in Lower Carboniferous shales in New Brunswick, there being one principal vein with minor off-shoots. Similar material has also been found in Africa and in Tasmania. Wurtzilite resembles Albertite in its infusibility, but it is slightly soluble in carbon disulphide. It occurs in thin, steep veins in a limited area in Utah.

The typical occurrence of mineral wax or ozokerite is at Boryslaw in Poland, where it is mined and forms a very important product. It is found in fissures and veins in Miocene strata above the great Boryslaw overfold and acts as a cementing material for the breccia filling those veins. It is yellow to dark brown in colour and apparently is derived from the very paraffinous oil contained in the underlying strata. The thickness of the veins is very variable. Other occurrences are known in Russia and the United States. Somewhat similar material is found in association with lignites, and care must be taken not to confuse this with ozokerite.

Indirect Indications.

Sulphur occurs commonly as gaseous compounds associated with the gas from petroliferous deposits and as such has already been mentioned. It is also present as dissolved hydrogen sulphide in oilfield waters in many parts of the earth. Such waters are readily distinguished by their odour and also in many cases by a milky appearance which may be due to precipitated sulphur. Sometimes these waters are quite hot, and brilliantly coloured algae may exist in them. Brines are also commonly associated with oil, and seepages of such brines may leave deposits of salt on evaporation.

Rock-salt in the form of salt-domes is sometimes connected with oil-pools, but such phenomena are rarely observed at the surface. In south Persia and in the Dead Sea, however, cases of the salt penetrating to the surface are known. Saliferous clays are also associated with oil measures, and important examples of these are to be found in Roumania and Poland. Deposits of gypsum occur in petroliferous areas in Persia. This has been described by Lees [5, 1933] as soft, powdery gypsum, white at the surface but brown beneath, and containing crystals of sulphur. In many areas it is accompanied by a development of aragonitic limestone which may be the result of the action of hydrocarbon gases on former gypsum beds.

Amongst the most important indirect indications of petroleum are the various types of strata commonly associated with source rocks. These are dealt with in the article by Professor Illing on the significance of oil indications.

THE SIGNIFICANCE OF SURFACE INDICATIONS OF OIL

By Professor V. C. ILLING, M.A., F.G.S., M.Inst.P.T.

Imperial College of Science and Technology

It is difficult to convey a correct impression of the part played by surface oil indications in the discovery of oil-pools, for conditions vary so widely in different areas that it is impossible to generalize without the danger of being misunderstood. Petroleum occurs far more commonly than is generally realized, although in most cases it is dispersed throughout the rock masses and is of no commercial value. The basis of a commercial field is an accumulation of oil and gas in such form and in such quantities that their extraction becomes profitable. This combination of circumstances is not so common.

It must also be remembered that an active oil or gas seepage is in reality a leakage from a reservoir below, and therefore the latter has been perforated and is being depleted. This seepage may represent the first or last stages of such depletion, and the significance to be attached to it will depend largely on this consideration. Unfortunately it is not usually possible to decide this from the seepage itself, and the problem has to be attacked by other methods.

There are many oilfields which were first discovered as a result of the attention drawn to them by their associated seepages. There are, on the other hand, numerous areas in which the seepages are just as good and yet all efforts to discover oilfields in their vicinity have been fruitless. Finally, there are many areas where there are numerous large oil- and gasfields completely lacking in all the normal surface indications of the presence of oil.

It is, therefore, clear that the discovery of an oil show is but one step in a long investigation which demands careful consideration of all the evidence before its significance can be properly assessed. Its relationships to the commercial pool are by no means as direct as are the relationships of the outcrop of a mineral lode to the lode itself. Oil is mobile and readily dispersed, and there is usually a considerable distance between the seepage and the parent reservoir rock.

As already indicated, there is no necessity for an oil-pool to have any surface indications; indeed, a perfectly enclosed oil reservoir should not have any, although there may be indications from other rocks in the neighbourhood. In the Palaeozoic oilfields of the United States little or no attention is paid to surface indications, firstly because they are uncommon, and secondly because the factors considered in the search for oil-pools are almost entirely structural. Among the oilfields of Tertiary age seepages are far more common, for in most cases the structures involved are more highly deformed, denudation and oil dispersion more active, and the oil-bearing strata more clearly exposed. This leads to a more rapid dispersal of oil and gas, but as the rocks are much younger the time interval has not been sufficient for complete dispersal. The same truth may be expressed in another way by saying that among the Palaeozoic oilfields, the only ones which have been preserved over long geological periods are those which were exceptionally well covered and have no active seepages in their neighbourhood. The oilfields of Pennsylvania, Kansas, North and Central Oklahoma, and the Bend Arch district of Texas are good examples of such fields. There are, of course, some small seepages where the oil-bearing rocks in these areas approach the surface, but they are relatively insignificant and are not usually in the zone of the prolific fields.

Contrast this condition with that of the oilfields of Venezuela, Burma, or Iraq, where there are very few oil-pools which have not seepages at the surface and where the rocks are so folded and faulted that erosion has bitten deeply into the structures and the fluids within the latter have suffered considerable readjustment and loss. The absence of seepages in rocks so well exposed would be highly unfavourable. Should the geological condition, on the other hand, be such that the oil and gas horizons are covered by impervious rocks, then the lack of seepages would not deter the geologist from testing suitable structures.

The following conditions summarize briefly the general relationships between oil shows and oil-pools:

1. Oil and gas are very widespread in nature, but most of the occurrences have little commercial significance.
2. An active seepage indicates loss of oil or gas. Before reaching optimistic conclusions, care must be taken to determine the extent of depletion of the reservoir.
3. Oil shows are more common in the folded rocks of Tertiary age and they can be used more safely under such conditions.
4. Protection from dispersal of the oil is more necessary in the older rocks in order to preserve the field for long geological periods. In such areas oil shows are less obvious and their absence is not a discouraging feature.

Types of Oil Indications

Gas Shows.

Care is necessary first of all to determine that the gas is of the type associated with petroleum (so-called 'natural gas') and not marsh gas or the gas from carbonaceous strata. Chemically these gases may be indistinguishable, although some natural gases contain higher homologues of the paraffin series as well as methane. Normally the pressure and volume of natural gases are much higher than those of gases of other origin, and such phenomena as mud volcanoes are largely restricted to areas where they occur. There seems to be no reason, however, why other gases should not sometimes produce similar phenomena.

Natural gas has low density and great mobility, and when under pressure it is capable of migrating to great distances. Only unbroken and very impervious rocks or, alternatively, water-saturated rocks under pressure are able to prevent this movement. Fractures, such as joints and faults, form avenues of escape for the imprisoned materials. The distances of such migration across the bedding may be very great, in some instances amounting to as much as many thousands of feet. These excessive movements sometimes carry the gases far from the original reservoir, and care is therefore necessary in the location of wells on such evidence. There are also many cases of clays which are very gaseous but contain no reservoir rocks. Such clays are well known in the coastal areas of Colombia and they give spectacular gas shows, but have not led to successful drilling.

Some accumulations of commercial value contain gas alone, so that a gas seepage does not necessarily indicate the presence of oil. This dissociation of gas and oil occurs in all types of strata, but its development is best exemplified in the United States, where many fields are developed solely for their gas.

In spite of these cases many gas seepages, with or without oil, have been the precursors of large oilfields. Such seepages have the important advantage that they normally represent the early stages of fluid dispersion, for the gas occupies the highest position in the reservoir, and though the oil below may have suffered a loss of pressure, it is still largely intact.

Oil Shows.

The possibilities of confusion between oil and other substances of similar physical appearance may not be so common as in the case of gas, but oily materials may be produced by contact metamorphism of coals and allied substances. Such occurrences are common in many of the British coalfields, particularly in South Scotland and Northumberland where there are igneous intrusions. The Karroo beds of South Africa contain examples of gas and oil formed by the dolerite intrusions heating the coals and carbonaceous shales. The residual coal has lost much of its volatile matter and the oil and gas have accumulated in the rocks near by.

Oil shows are usually in one of two forms, an impregnation of a rock or a seepage of free oil. The former may consist of small quantities of oil in a fine-grained rock such as clay, shale, or compact limestone, or it may be oil in the larger pores of a reservoir rock such as sand or limestone. Oil-impregnated strata may indicate a general case of stratigraphical oil impregnation, possibly signifying a source rock. On the other hand, some fine-grained rocks become so fissured by earth movements that they become impregnated throughout a considerable zone although the oil is really in a state of slow movement. Such cases can only be differentiated by careful field study.

Free oil seepages are usually associated with oil movement along fissures or with the escape of oil from a reservoir rock with or without the aid of water. Such free oil tends, therefore, to support the view that there are rocks in the neighbourhood which not only contain oil, but are sufficiently permeable to give it up. This is not always a safe conclusion, for water will wash oil out of exceedingly fine clays in the zone of weathering, though the process is slow and the free oil not very abundant. Most oil seepages are rendered obvious by the fact that the oil is floating on water. The oil from such seepages does not usually travel far, even in streams, it being carried to the bottom by becoming attached to mineral matter.

Some exceedingly light oil seepages may be the result of condensation from wet gases which have travelled considerable distances before reaching the surface. As a general rule an oil loses its lighter constituents near the seepage, so that the oil underground may differ considerably in its properties from that in the associated seepage. The difference is displayed most markedly in some asphaltic oils which change to heavy tars, or even asphalts, in the shallower zones of an oilfield.

Solid Shows.

There is every gradation from the liquid to the solid state in oils and, as indicated above, the oils in many fields are changed gradually to asphalts either by evaporation and oxidation, or by changes produced by bacteria present in the invading waters. Seepages of asphaltic oils which harden at the surface into asphalts have the true significance of liquid shows. Solid veins of asphaltic material or ozokerite sometimes represent channels along which oil has migrated during periods of excessive trans-formational movement. It is probable that in these cases the migrating liquid had a considerable admixture of oil which was absorbed into the walls of the surrounding rock, or, in the case of ozokerite, that the wax was filtered out of a waxy oil during its passage. As a general rule the occurrence of veins of solid hydrocarbons appears to be the least valuable of oil indications, for many of them undoubtedly represent the last traces of former oilfields. Their vein-like form can only have been produced in rocks so disturbed as to be no longer impervious, and in such cases oil preservation over long periods is unlikely. However, there are exceptions which show how difficult it is to generalize in such matters. As examples of these exceptions the ozokerite veins at Boryslaw and the Grahamite vein of Virginia may be cited.

Indirect Indications.

There are a number of other features associated with oilfields which may have considerable significance in the search for oil-pools. One of the most important is the efficiency of the reservoir cover rocks as a protection against dispersion of the fluids contained therein. This is indicated by:

(*a*) A condition of high pressure in the formation.
(*b*) A considerable degree of salinity in the entombed waters.

Both of these conditions are favourable features and it is exceedingly rare to find any important oil-pools in a region in which these are not satisfied. The first can only be discovered by drilling, and even then only by taking adequate precautions. The presence of salt-waters, on the other hand, may often be proved in outcropping formations and in water springs, although it is also best studied in wells. Almost all oil-pools are underlain by water, and in almost all cases this water is saline. In the shallower fields the brines are of a mixed type, but in deeper sands they tend to be more concentrated, the principal salt being sodium chloride. Such deep brines are probably entombed sea-water, or 'connate water', as it is termed. Their presence in marine formations indicates a freedom from water flushing which is a feature favourable to the preservation of oil. Care must be taken, however, to exclude from this consideration brines derived from the leaching of salt masses.

The occurrence of rock-salt itself may be of significance. In the form of salt-domes it is associated with structures favourable to oil concentration and also, when in the form of a sheet of plastic salt, there can be little doubt that it acts as an efficient barrier to upward migration.

The nature of the formations associated with oil is highly significant. The dominant lithological type is clay, or marly clay, although in some cases it is a limestone. The clays are normally dark in colour, whereas the limestones are grey to white. Such rocks, however, cannot provide commercial oil-pools unless they contain porous reservoir rocks of sufficient size, or unless they are themselves rendered porous by jointing and fissuring. Minerals such as pyrite and gypsum tend to occur within them, the former probably indicating the anaerobic conditions.

under which the formations were laid down. As a whole, these features are generally ascribed to the strata which are termed 'source rocks', and their presence in most oilfields supports the conclusion that the oil was formed in them. There are, however, notable exceptions to these generalizations on colour, as, for example, the red Permian oil rocks of Texas and the Devonian of Pennsylvania.

Relationships of Seepages to Structure and Erosion.

It has been emphasized that oil shows are either impregnations or seepages. In any movement of oil or gas to the surface two conditions are clearly necessary, a driving force and a permeable zone through which the fluids can travel. The driving force is supplied by the gas and oil pressure, or by the movement of water currents. The permeable zone is supplied by the porous rocks and by fractures such as joints and faults. Hence, while an impregnation of a compact rock may occur under almost any conditions, the impregnation of a porous rock or a free seepage normally tends to occur under certain structural conditions. Three of these conditions can be treated as typical of most seepages.

1. **An Outcropping Oil Reservoir Rock.** An outcropping oil sand or limestone will show oil impregnation if it be asphaltic, but may lose all of its oil in the parts above the water table if it be paraffinous. The flushing action of meteoric water usually removes the oil from the rock and it collects in hollows along the outcrop. Streams may cut across the oil-bearing strata and wash out some of the oil, but this is rapidly deposited on the stream bed unless the water is free from sediment.

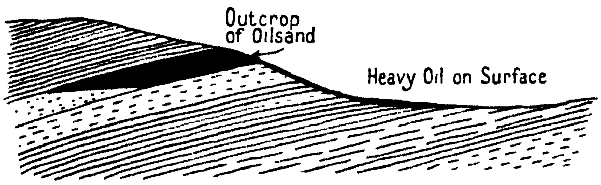

FIG. 1. Seepage from an outcropping oil sand.

Such an outcropping formation cannot be considered as a favourable zone for drilling since it has lost its pressure and much of its oil. At the most only a few pumping wells can be expected, unless there be an impermeable zone down dip, due to faulting, cementation, or lenticularity, which may have protected oil below it from dispersal. Whilst, however, there is little hope of obtaining commercial production from the outcropping sand, it nevertheless indicates that the original structural conditions were favourable to accumulation. Deeper drilling to lower horizons may therefore give good production. The ultimate significance of such a show obviously depends on the nature and thickness of the beds below, and only careful stratigraphical studies and field mapping will give the required data.

2. **Oil Seepages associated with Faults.** Faults may not only provide zones of movement for the oil, but, conversely, they may also limit movement in porous rocks and thereby cause accumulation on one side of the fault-plane. Seepages along the outcrops of faults are common phenomena and are always worthy of close study. The linear relationships of such seepages and their position on the geological map give a clue to conditions underground. On the other hand, structures of this type are usually complicated and variable, so that drilling must be undertaken with circumspection and several initial test wells may be required.

3. **Seepages through the Cover of a Closed Reservoir.** As denudation proceeds the cap-rocks become so thin that they are unable to hold the gas and oil in the reservoir formations. This is usually indicated by an increase in gas and oil shows over the highest portions of the structure. Should it be only the uppermost horizon of an oil-bearing series which is thus being uncovered, great possibilities

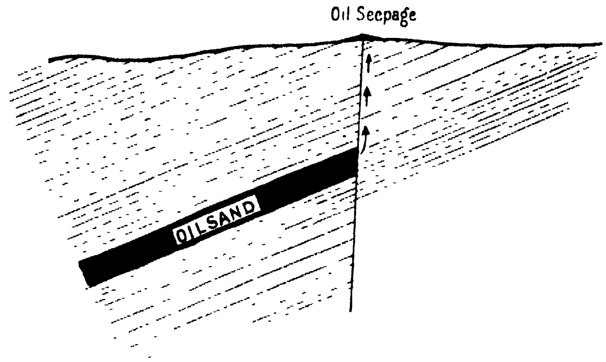

FIG. 2 Seepage along a fault plane

may still remain in the lower strata. The ultimate value of the pool, therefore, must depend on the thickness of the oil-bearing series still uncovered. This illustrates the point, which is true of all the three cases cited, that the evidence of stratigraphy and structure is always required to assess the value of an oil seepage.

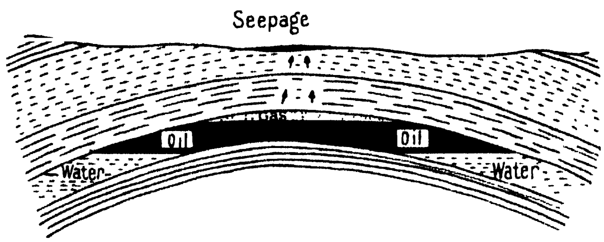

FIG. 3. Seepage through the cover of a closed reservoir.

From the foregoing it may be assumed that the true significance of any specific oil show cannot be obtained by casual inspection. The relationships of the show to the structure must be obtained by careful mapping. The nature and size of the oil reservoir rock should be determined by stratigraphical studies which may require prolonged regional investigation. Then, with those problems solved, the geologist may be in a position to assess the true significance of the surface indication.

In other words, the search for new oil-pools involves careful stratigraphical and structural studies in which the thickness and sequence of the formations and their structural attitudes are the primary consideration. The presence or absence of seepages in such areas must always be related to such studies as part of the complete investigation. If they are present, their significance must be read in terms of the geological conditions in which they occur. If they are absent, their absence must be reviewed in the light of the effectiveness of the cover rocks to prevent oil dispersal. There is no other safe method of assessing the value of a surface oil indication.

NATURE AND SIGNIFICANCE OF SEDIMENTARY VOLCANISM

By H. G. KUGLER, Ph.D., F.G.S., M.Inst.P.T.

Chief Petroleum Geologist, Central Mining and Investment Corporation

IN the following brief account of sedimentary volcanism the writer has endeavoured to convey a clear picture of the subject under review rather than to discuss the literature available on migration of oil and gas.

Source Rocks and Origin of Oil.

Observations and studies in Venezuela and Trinidad have inclined the writer to favour the theory of oil origin advanced by Murray Stuart, Archangelski, Krejci, and others, who consider the source of oil and gas to be black sapropelic mud trapped in depressions and covered by unaerated, stagnant water charged with albumen-reducing, anaerobic bacteria.

Although a small amount of organic substance is found in most recent and fossil marine deposits, such has little practical bearing on the formation of oil, otherwise oil would be found in almost every well-sealed and tilted formation composed of such deposits.

In support of Krejci's theory, one cannot altogether ignore the presence of water derived from planktonic matter during the formation of oil. Such water is rich in halogens and differs from ordinary sea-water. It is unlikely that all oilfield saline waters are such 'by-product water', but one must consider the possibility of a complete absorption of connate water during diagenetic processes. Such 'internal desiccation' is known to be the cause of the dry sands found in oilfields. Their importance during the migration of oil, gas, or even water is obvious.

Migration.

Illing has shown, in a convincing way, that oil migration is at least a twofold process, i.e. primary and secondary migration.

(*a*) **Primary migration** is the movement of fluids from the source rock to the reservoir rock. This movement is mainly completed when compaction ceases, and therefore could be called *Compaction Migration.*

(*b*) **Secondary migration** is responsible for the segregation of gas, oil, and water within the reservoir bed, where the texture of the rock has a decided influence on the distribution of the fluids. As gravity is the dominating factor, it is suggested that this movement be termed *Gravity Migration.*

In order to complete this conception of migration, it is necessary to add a third process to those proposed by Illing, i.e.:

(*c*) **Relief migration** which involves the movement of fluids from reservoir to reservoir. It is obvious that the cause of this movement is pressure relief, the natural tendency of a fluid being to migrate from an area of high pressure to one of low pressure. This migration is not controlled by compaction, neither is gas necessarily the driving force.

This movement, sometimes termed 'Vertical Migration', is started by diastrophism or exogenetic influences. Inasmuch as relief migration follows the line of least resistance in a similar manner to compaction and gravity migration, there is no particular direction along which the movement of the fluids occurs, although the vertical direction is most common. The resultant impregnation generally takes the form of a cone with its apex upwards, and this is typical of relief migration. Excellent examples of such deposits are known in the oilfields of California, Rumania, Russia, Trinidad, Burma, &c. The Rumanian and Baku areas are famous for the occurrence of commercial accumulations of oil in fresh-water and even terrestrial deposits where oil could never have originated.

Where diastrophism causes a revival of the movement of oil from source rocks along newly formed fissures and cracks, relief migration may be mistaken for compaction migration. Such oil is not newly derived from polybitumen but exists in a free state in fine joints and fissures. Replenishment of overlying reservoirs from source rocks may explain some of the occurrences of oil in formations resting unconformably on source rocks, which were compacted and lithified long before the reservoir beds were deposited.

Origin of Sedimentary Volcanism.

In relief migration it is observed that liberation of gas under pressure can cause migration of fluids and even clastic material. Such migration is herein called '*Gas-drive Migration*'.

The lithological, depositional, and orographical features resulting from this activity of gas are comparable with those of pyrogenetic volcanism and are discussed under the heading 'Dykes, breccia, blocks, and mud volcanoes'.

Gas drive becomes identical with relief migration when gas under pressure is liberated by exogenetic influences such as erosion of superincumbent beds, desiccation cracks, or artificial tapping. It is also possible that endogenetic processes are responsible for pressure relief, but, as far as the source of the high gas pressures is concerned, orogenetic forces must be considered primarily responsible. Goubkin, for instance, in a series of illuminating examples, demonstrated the relationship of the mud volcanoes of the Apsheron Peninsula to diapiric folds. In addition to the requisite plastic clay and weak spots in the overlying beds, he considers vertical pressure to be essential to the formation of diapiric folds and plugs. On the other hand, Cizancourt and others concluded that diapiric structures are the result of tangential pressure with plastic clay acting as a lubricant for the laterally gliding masses, resulting in incongruous, and finally, disharmonic folding ('Abscherung' or 'Décollement').

The physical properties of salt are primarily responsible for the facile injection of salt formations, causing salt-domes and plugs. Such tectonic features cannot be formed by ordinary clay which lacks the physical properties of salt. A gas-saturated clay lubricated with oil is, however, much more prone to such injection than is pure clay. If, in addition, the continuous generation of gas is possible through geochemical and perhaps biochemical processes, the expelling force would become an integral part of the movement. Although it is not suggested that such gas pressure is responsible for the formation of uplifts, it is possible that gas-saturated clays and shales, especially

when coated with oil, will behave in a manner similar to a salt mass, should conditions permit.

Whenever incompetent masses of bituminous clays are squeezed up through an overlying series of competent beds, whether by lateral or by vertical pressure, the movement can only occur along a line of weakness, for preference, along an open fault. Although faults have always been considered convenient passages for escaping gas, and thus for the origin of mud volcanoes, it would be interesting to analyse the relationships of mud volcanoes to local underground and regional tectonic conditions. It is, for instance, not quite clear whether or not NNW.-SSE. directed transverse faults (Blattverschiebungen) are the original cause of the obliquely trending folds with diapiric cores known in the Apsheron Peninsula.

Tension cracks formed during orogenetic movements are natural passages for escaping gas. Crestal collapse of anticlines causes revival of such movement along the lines of fracture. Open tension faults and gaping joints undoubtedly play a more important role than is generally admitted in the literature.

A bore-hole which produces sand or heavy mud which has passed from a neighbouring hole can only do so if fine fissures or small cavities are present. Conversely, the heavy drilling mud of a well can only disappear into the formation when cavities are present. The fissures may be as fine as those of the compact Iranian Asmari limestone.

If cracks are formed in competent beds above an oil- and gas-saturated clay or a highly charged reservoir of unconsolidated sand, it is natural that the clay or sand will be forced into these cracks either slowly or in an explosive manner. The texture of the resulting dykes of clay, mudflow, breccia, or sand indicates the velocity of intrusion.

Dykes, Breccia, Blocks, and Mud-volcanoes.

Fissures several miles long and hundreds of feet in depth are known to exist in petroliferous areas. They generally correspond to cross and transverse faults oblique to the main direction of the orogenetic force. Thrust planes with plastering material have a sealing effect, and prevent migration of fluids. Fissures filled with bitumen alone or mixed with country rock are described from various oilfields and even from the oil shales of Scotland.

The occurrences of 'hydrocarbon dyke' fissures filled with materials such as ozokerite or asphaltites received early attention due to their economic value.

Sandstone dykes are probably the best known amongst the fissures containing clastic material. Such sand dykes soaked with inspissated oil occur in Trinidad and attain a thickness of 10 ft. In addition they carry edge-worn pieces of fossiliferous rock derived from beds stratigraphically several hundred feet below. In other parts of Trinidad, *clay* and *silt* dykes are proved by their foraminiferal assemblages to be derived from beds which occur stratigraphically as much as 5,000 ft. deeper.

Considerable interest has been attached to the *pebbly clays* or *breccias* of various oilfields. Many geologists have been inclined to consider these breccias as evidence of extensive thrust movements and as being expelled by orogenetic forces at the outcrop of the thrust plane. Hence some Russian geologists have termed them 'tectonites'. There is, however, no doubt but that they simply represent mudflows composed of angular fragments. Some brecciated clay dykes, and particularly the corresponding mudflows, resemble *tillites* and may be mistaken for such, especially if striated pebbles are present. Krejci notes that such striated pebbles occur in Roumanian mudflows.

In Trinidad, mudflow breccias are known to attain thicknesses of several hundred feet. They may be composed of sub-angular pieces of upper Eocene marl mixed with fragments of younger beds, but actually they are found interbedded in productive Miocene sands and silts several thousand feet above their provenance.

The practical significance of the occurrence of older formations amidst younger ones becomes clear when it is realized that drilling has often been discontinued on the assumption that such rocks have been reached and that they represent the unproductive basement, yet later exploratory drilling has shown the same younger formation, with rich oil deposits, underlying these mudflow intercalations.

In the Guayaguayare field of Trinidad, even Cretaceous foraminifera have been found in injected clay veins amidst Miocene silts and sands.

Once it is admitted that smaller fragments form a part of mudflow, there is every reason to expect larger components, and the writer has demonstrated this to be the case in Trinidad, where blocks weighing 100 tons or more have been transported by mudflow. Moreover, there is every likelihood that the so-called 'erratic blocks' of the Tintea area of Roumania do not belong to fanglomerates as suggested by Krejci, but represent the residue of large masses of mudflow, the fine parts of which have been washed away. Goubkin mentions similar phenomena in the Apsheron Peninsula, where blocks of Mesozoic beds are found in mudflow extruding from Pliocene formation.

The transport of such large blocks is intimately connected with gas-drive migration and occurs as follows:

Liberated gas derived from the oil-mother rock or from a reservoir forces its way into a fissure filled with water, or one which is, at least, in communication with water sands. By the churning action of gas-agitated water, the clay of the walls forms a viscous mud. Through further action of gas and water, large blocks of the wall become engulfed. The movement may temporarily cease due to the weight of mud formed, but will commence again either by further release of pressure or by the pressure of geochemically-produced gas which has continued to accumulate. Finally, the mud carries the blocks to the surface where they may be expelled explosively or simply carried into the mud cone where they remain. Subsequent changes of the vent and denudation of the mud lead to the accumulation of the blocks on the original surface on which the mud cone rested.

The nature and occurrence of *mud volcanoes* has been sufficiently described, so that further comments are unnecessary. It may be mentioned, however, that, under certain circumstances, mud may be accumulated in downward-tapering conical-shaped basins. The mud of such basins can be subjected to the churning action of gas to such an extent that it becomes completely gas-cut and frothy. Through the rotation of every particle of non-collôidal material, a mud of semi-pisolitic structure incorporating hydrocarbons is formed. When hardened, this floats on water and burns like an oilshale. The rim of the Pitch Lake in Trinidad is characterized by this type of pebbly clay.

The *life of mud volcanoes*, hence the duration of gaseous exhalations, may last thousands of years at one particular spot. The term 'eternal fires' given to some of the gas seeps near Baku, and the discovery of Megatherium bones in a mud volcano in Trinidad, are unquestionable proofs

of the great age of such volcanoes. The amount of gas issuing into the air from a single major gas seep must be enormous.

General Conclusions.

Although it is still a moot point as to how much pressure subterranean gas is able to develop, one cannot deny the important role played by gas in the formation of diapiric folds and dykes, the transport of fluids, mud, and blocks, and finally in the formation of mud cones and basins on the surface.

The types of rocks and other features arising from the activity of gas are included under the term 'Sedimentary Volcanism', which is itself intimately connected with the relief migration of fluids.

Finally, it may be remembered that in 1861 Andrews considered that anticlines contained oil because they were full of fissures. This conception is by no means in conflict with the views of adherents of the allothigenic nature of oil accumulations, though it may offend the ardent supporters of the view that oil in commercial quantities is essentially authigenic.

APPLICATION OF PALAEOGEOLOGY TO PETROLEUM GEOLOGY

By A. I. LEVORSEN, G.S.A., A.A.Pet.Geol., A.I.M.M.E.

Consulting Geologist, Tulsa, Oklahoma

PALAEOGEOLOGY is defined as the science which treats of the geology of ancient time. Palaeogeology bears the same relationship to palaeogeography that geology bears to geography. It requires that one place himself—mentally—as if he were at some point in geological time and then consider the geology of the particular area as it existed *at that time* and prior to any later geological history.

There are several methods by which palaeogeological reasoning is applied to the problems of petroleum geology. The basis of all such reasoning, however, is that whatever laws are found to operate to-day in the origin, accumulation, and behaviour of oil and gas must have operated in a similar manner in past geological time. Palaeogeology is the consideration of these phenomena as they occurred under ancient geological conditions in the light of our present knowledge. Some of the methods of palaeogeology follow.

Palaeogeological Maps

Palaeogeological maps show the areal geology of an ancient surface. They are constructed by plotting the formations which are found in contact with the base of the key or datum horizon, and as the control becomes sufficient, the geological contacts and formation boundaries may be drawn. Through interpretation of the relationships of the older to the younger rocks, the structure of the rocks is determined in the same manner as the present structure is interpreted from areal geological maps. The extent of the ancient shorelines, overlaps, erosion, and regional warping and truncation are also readily determined. Each unconformity surface offers an opportunity for making a palaeogeological map. The greater the overlap of the overlying key formation, the more interesting and valuable is the story revealed by the palaeogeological map.

An example of a palaeogeological map is shown in Fig. 1, which shows the areal geology of the Oklahoma City oilfield immediately prior to its being covered by sands and shales of Pennsylvanian age. It is seen from the map that in pre-Pennsylvanian time formations ranging in age from Lower Ordovician to Middle Mississippian cropped out in the form of an inlier as the result of a fault with 2,000 ft. of throw. Any theory of oil and gas origin and accumulation, when applied to this pool, must be considered and timed in the light of the structure, erosion, topography, and other features revealed by the palaeogeological map as they existed at that time in the area.

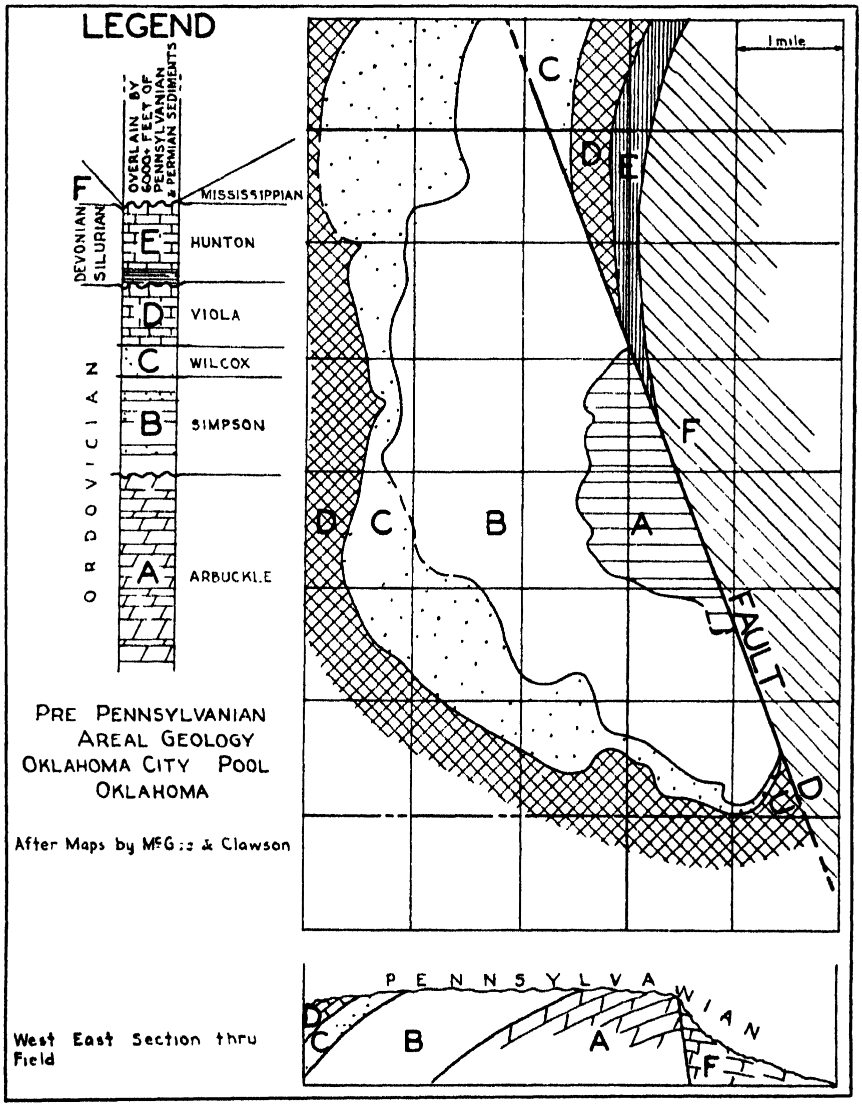

FIG. 1. A palaeogeological map of the Oklahoma City, Oklahoma, oilfield showing the areal geology as it was in pre-Pennsylvanian and post-Mississippian time. Adapted from maps by McGee, Clawson, and others.

Another type of palaeogeological map is that of a large region such as a state or a continent. An example of this sort of map is shown in Fig. 2, which is the pre-Mississippian areal geology of the United States. This map repre-

sents the areal geology of the surface upon which the Mississippian sediments were deposited. It was prepared by plotting with different symbols the age of the different rocks which are found in contact with the base of the Mississippian, and as the data accumulated and the control increased, formation boundaries were drawn with increasing accuracy. Only those points of control were used where the formation in contact with the base of the Mississippian was known, excepting where the Devonian system is now exposed, in which cases it obviously was present and not removed by erosion, prior to the overlap by the Mississippian rocks.

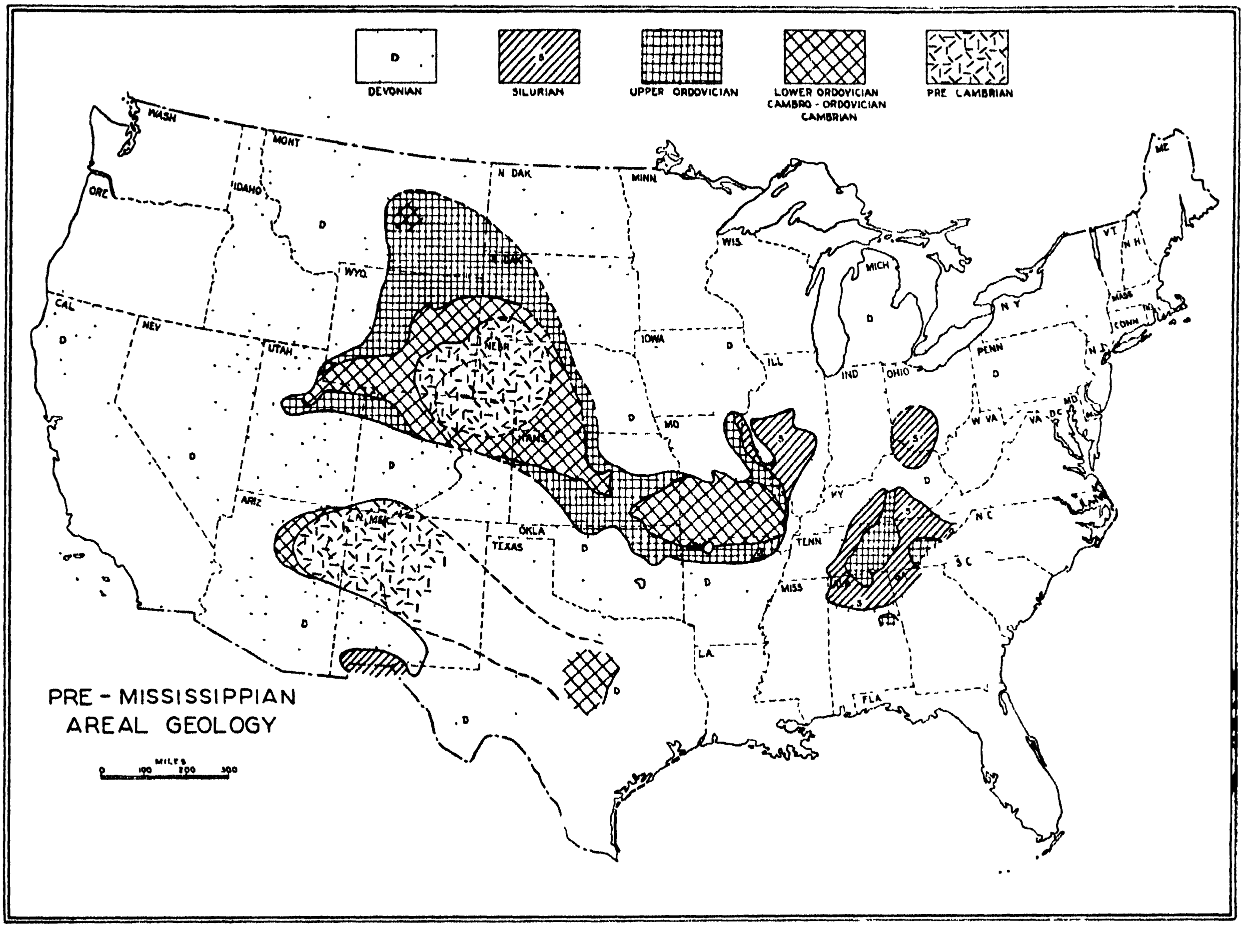

FIG. 2. Example of a regional palaeogeological map. This map shows the areal geology of the United States as it existed in pre-Mississippian and post-Upper Devonian time.

The distribution of the rocks as shown on the pre-Mississippian palaeogeological map furnishes a clue to the regional structure of the area of the United States at that time. Thus a structurally high area is shown extending from Utah and Wyoming south-eastward across the country and through the Central Kansas uplift, the Ozark uplift in Missouri, the Nashville dome in Tennessee, and opening towards the south-east beyond the present Appalachian Mountains in Tennessee. There is some evidence that a parallel high area extended from the Grand Canyon region of Arizona, across New Mexico, and at least as far as the central part of Texas. This early north-west to south-east trend of the folding possibly influenced the direction of some of the later folding such as the Amarillo–Arbuckle trend in Texas and Oklahoma. A study of the map shows the Devonian rocks also overlapping the older formations at many places, thus indicating that folding was present at least prior to Devonian time and that it persisted until overlapped completely by the Chattanooga shale and the Madison limestone of Mississippian age.

Isopachous Maps

Isopachous maps are those maps which show by means of contours the varying thickness of the material intervening between two strata or between two geological horizons. An unconformity surface is often used as one of the horizons in the preparation of an isopachous map. Such a map is of particular value when considered as a palaeogeological map, since it shows the structure of the lower of the two strata or surfaces *at the time* the upper was being formed. When used in this manner in studying an oilfield, isopachous maps furnish a method of dating and measuring the early folding and thereby the time of earliest possible accumulation of oil and gas in the fold.

Application of Palaeogeology to Accumulation of Oil and Gas

Investigations of oil- and gas-pools throughout the world have shown that the oil and water, or the gas and water, contacts tend to approach a level plane. Accumulations of oil and gas, in other words, are found to approach complete gravity adjustment to the present structure and attitude

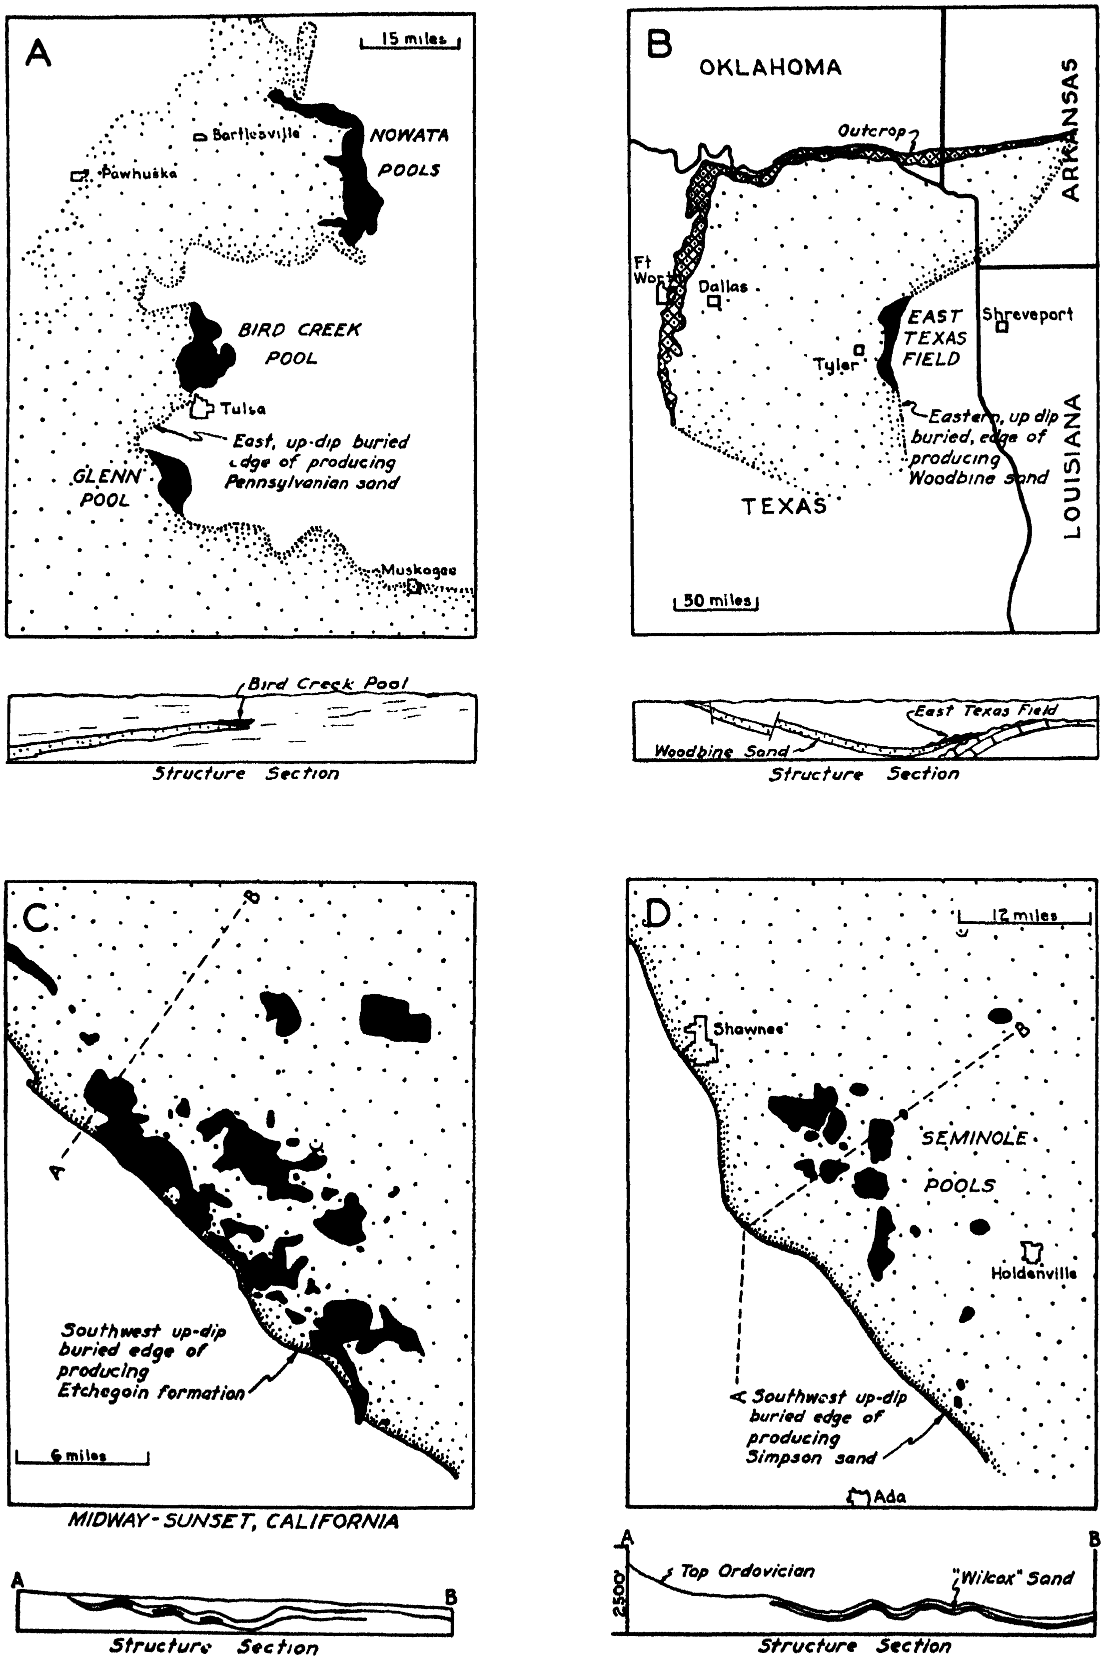

Fig. 3. Four typical examples of oil-producing areas (pools in black) which are located at or in close proximity to the edge of the producing formation. *A*, Lower Pennsylvanian sand pools in Oklahoma. (After maps by Snow.) *B*, East Texas oilfield in Texas. *C*, Midway-Sunset oilfields in California. *D*, Seminole District pools in Oklahoma.

of the reservoir rock regardless of its age or geological history. Furthermore, the oil and gas everywhere are found to occupy the highest possible position within the containing reservoir rock. As these phenomena are true of our present oil- and gas-pools, they must have been true of the oil- and gas-pools of the geological past, and a study of the changing attitude and structure of the reservoir rock, after the oil and gas have entered it, becomes of primary importance.

Furthermore, study of the palaeogeology of many oil- and gas-pools shows that the present attitude of the reservoir rock is not the same as in the past, but that it is the result of many periods of folding, tilting, uplift, erosion, and overlap of both local and regional extent. It may be assumed that the adjustment of the oil and gas to the present structure is likewise the result of a combination of repeated adjustments and migrations, each of which brought the oil and gas into gravity adjustment with the changing attitude and structure of the reservoir rock. This adjusting process commenced as soon as the oil and gas entered the reservoir rock, and must have been in progress continuously to the present time. Furthermore, it must have continued through varying environments of depth, load, pressure, temperature, water concentration, and water movement, all of which probably had a bearing on the speed and ease with which the process advanced. Stated differently, oil- and gas-pools in Ordovician rocks at the end of Ordovician time, for example, were formed and retained under the same principles of up-dip accumulation and gravity adjustment which we believe operate to-day, but the site *of these pools* was controlled by the structural conditions *of that time*. These pools were in a different structural environment during Mississippian time, again during Pennsylvanian time, and again during Mesozoic time, but gravity adjustment must have continued to operate with a consequent shifting and migration of the oil and gas into higher and higher parts of the reservoir rock as the higher areas became accessible.

Another relationship common to the majority of oil- and gas-pools is the proximity of the producing area to the edge of the producing reservoir rock. Four examples showing this relationship in widely different areas are shown in Fig. 3. The Glenn, Nowata, and similar pools in Oklahoma (*A*, Fig. 3) are at the up-dip, wedge edge of the Glenn or Bartlesville sand. The wedge edge in this case is formed by the lateral gradation of a sand into shale. The East Texas field (*B*, Fig. 3), which is the largest accumulation of oil in the world, is found at the eastern up-dip, wedged-out edge of the Woodbine sand. The edge of the sand here, however, is the result of post-Woodbine erosion. The other two examples, the Seminole district (*D*, Fig. 3) in Oklahoma and the Midway-Sunset area in California (*C*, Fig. 3), are both typical of a group of oil-pools in which the oil is found in, and related to, local anticlinal folding, but in which the group of pools as a whole is located near the edge of the producing formation. In the Seminole pools the edge is formed by the grading out into limestone and dolomite towards the south-west of the 'Seminole' or 'First Wilcox' sand, while in the Californian example the Etchegoin producing formation is truncated close to the south-western limits of production. The wedged-out edge of the producing formation is a common factor to each of these accumulations, even though the age of the rocks involved, the age and character of the folding, and the geological history are all quite different. For that reason it follows that the location of the edge of a possible producing formation is an essential element in the problem of searching for new oil- and gas-producing areas. With this relationship as a basis, a logical principle controlling the accumulation of most of our oil and gas may be formulated.

If our reasoning is correct about the repeated migration of oil and gas as they maintain gravitational harmony with the changing structure, then the observed common relationship of the producing fields in proximity with the edge of the reservoir leads to the conclusion that the earliest trap to form is very important. The earliest obstruction to the migration of oil and gas would obviously be a primary change (Fig. 3, *A*) in porosity of the reservoir rock. Regional uplift and erosion of the reservoir rock followed by the overlap of a non-porous cover would also furnish an early obstruction to the movement of oil and gas, and such a sequence has the added advantage that the wedging-out of the reservoir rock is early up the dip (Fig. 3, *B*) and therefore immediately offers a high area towards which any oil and gas in the reservoir rock would tend to move. Subsequently, local folding, tilting, and other changes (Fig. 3, *C* and *D*) may occur in the reservoir rock, with the result that as higher pore space is available to the oil and gas, they will move into it and become adjusted to the local structure by occupying the highest possible space in the reservoir rock.

STRATIGRAPHICAL CONSIDERATIONS

By Professor RAYMOND C. MOORE

Head of Geology Department, University of Kansas

STRATIGRAPHY is the branch of geological science that deals with the characters of rock strata. It includes study of the lithological nature, biological content, thickness, horizontal extent, and to some extent the structural relations of all rock layers. Determination of geological sequence or relative age, recognition of the nature and significance of lateral and vertical changes in the character of stratified sedimentary deposits, differentiation of 'natural' assemblages of rock strata of various magnitudes, and the proper classification of differentiated units are all subjects of stratigraphical inquiry.

Because the occurrence of petroleum and natural gas is associated almost exclusively with stratified rocks of sedimentary origin, the subject-matter of stratigraphy has practical bearing in many ways, directly and indirectly, on exploration for these fuels. Limitations of space prevent exhaustive consideration here of the applications of stratigraphy to scientific search for oil and gas, and accordingly we will confine attention to three aspects of the subject: (1) stratigraphical considerations of source rocks, (2) stratigraphical considerations of reservoir rocks, and (3) stratigraphical considerations bearing on the determination of geological structures.

Stratigraphical Considerations of Source Rocks

Experience has abundantly shown that certain sorts of sedimentary deposits contain no oil or gas, excepting perhaps unimportant local occurrences due to undoubtedly abnormal conditions in which the oil or gas has been derived from another source. These sedimentary deposits initially lacked the organic materials from which petroleum and natural gas might be produced. Emphatically they are not source rocks. Broadly speaking, sedimentary deposits of terrestrial origin, that is, laid down on land by agencies such as streams, winds, glaciers, or even lakes, are likely to contain little or none of the source materials of petroleum. No commercially valuable accumulations of oil or gas are to be expected in such deposits. On the other hand, plant and animal life is extraordinarily abundant in most parts of the shallow seas, and conditions here favour in varying degree the burial and preservation of hydrocarbons derived from this marine life. In view of this fact, and because known oil and gas accumulations appear associated so universally with marine formations, it is reasonable to conclude that important source rocks of oil and gas are marine.

Despite much investigation it is not yet possible to define the environmental conditions most favourable to the making of oil and gas source materials, but evidence points to certain types of marine shales as the most important type of source rocks. Accordingly, stratigraphical consideration of prospective oil and gas development should direct attention to areas that contain marine deposits in which there are appreciable thicknesses of carbonaceous or bituminous shales, and should disregard as potential oil and gas producers formations of continental origin.

Since conditions of sedimentation along the borders of a basin may differ materially from those within the basin, it may happen that absence of source rocks and of subsequent accumulations of oil and gas in one area accompanies their presence in neighbouring territory. This is the case in certain parts of the Mid-Continent and Gulf Coast fields of the United States. Knowledge of the nature and direction of stratigraphical changes guides exploration under these conditions. Lateral changes in the Permian rocks of western Texas, in part associated with the building of thick limestone reefs, exert a very important influence on the location of oil- and gas-fields in that region.

Stratigraphical Considerations of Reservoir Rocks

Reservoir rocks include any type of sediment (and exceptionally igneous rocks associated with sediments) that is moderately porous and permeable. The pore space in the rock must be quantitatively sufficient to provide effective storage for the oil or gas, and the passage-ways must be large enough to permit relatively easy movement of fluids. Loosely cemented gravel and sand deposits contain a large percentage of pore space and are very permeable. They make excellent oil and gas reservoirs. Limestones and dolomites likewise contain a large aggregate porosity if weathering, solution by circulating ground water, or certain other influences have affected them. Large quantities of oil and gas come from such reservoir rocks in some fields.

From the stratigraphical viewpoint, the occurrence of various sorts of reservoir rocks, their kind, position with reference to associated formations, approximate thickness and horizontal extent, can be determined by field investigations or by compilation of data obtained from subsurface studies. This type of stratigraphical information, in connexion with knowledge of geological structure, is most important both in the initial exploration and in the later development of an oil- or gas-containing area. Some of the types of stratigraphical relationships shown by reservoir rocks in different fields may be considered briefly.

Sandstones that in physical characters and stratigraphical relationships offer suitable reservoir sites for oil or gas accumulations include littoral and near-shore deposits of former seas, and also in some cases sand accumulations of sub-aerial origin, where these are associated closely with marine strata. The marine sandstones are likely to be sheet-like bodies of considerable uniformity that extend over large areas, but it is generally found that persistence is greater in a direction parallel to the former shore line than toward the deeper part of geosyncline, interior basin, or large seaway. In an off-shore direction the sand becomes finer and grades into shaly or calcareous deposits that may be good source rocks but lack the properties of an oil or gas reservoir. Stratigraphical studies provide a basis for inferences concerning the distribution and the direction of lateral changes in such sandstone deposits. The lenticular character of many sheet-like sandstone bodies contributes importantly to their effectiveness as oil and gas reservoirs, for the presence of enclosing impervious shale prevents escape of fluids from the sandstone. Sand lenses are formed in several different ways—beach deposits that terminate shoreward, off-shore bars, barrier beaches that lie between lagoonal deposits on one side and deeper water fine sediments on the other, deltaic sands that wedge out both seaward and landward. All of these may be buried by overlapping fine sediments of subsequently transgressing

seas. Sand-filled channels, characterized by convexity of the lower boundary of the sand body, may occur in shale or limestone. Some of the 'shoestring' sands that serve as oil and gas reservoirs in the Mid-Continent field of the United States and elsewhere are of this type. In each case consideration of stratigraphical characters is of primary importance in prospecting these sandstone reservoirs.

The occurrence in many instances of coarse detrital sediments at the base of an overlapping series of rock strata, and likewise under some conditions at the summit of an off-lapping series, provides reservoir sites for oil and gas accumulations. The sandstone and conglomerate of these deposits in different places differ in age and in relationship to associated sediments. Determination of favourable areas for oil and gas exploration must take account of these stratigraphical relationships. Local deposits of sandstone and conglomerate that in many places occur immediately above unconformities are commonly sources of oil and gas production.

The porosity of many limestones and dolomites, which fits them to serve as reservoir rocks, appears to have resulted from their exposure to surface weathering and solution by circulating ground water previous to burial by younger sedimentary deposits. The process of dolomitization may also increase porosity. It is from investigations of a stratigraphical nature that the occurrence of such conditions can be ascertained and applied to exploration of areas in which the formations concerned are buried. This is well illustrated in western Kansas and in Oklahoma, where stratigraphical research that showed the existence of certain unconformities has guided prospecting for the porous, weathered limestones below the unconformities, as well as the sandy accumulations above the unconformities.

A special type of stratigraphical relationships is furnished by deposits in which differences of facies are maintained in adjoining areas during deposition of a thick series of sedimentary deposits. Such conditions are encountered in various geosynclines where sediments of one type accumulate in one place while materials of another sort are contemporaneously laid down near by. The thick limestone reefs in the Permian of Trans-Pecos Texas and southeastern New Mexico appear to be exactly equivalent in age to thin-bedded limestones and shales, dark siliceous shales, sandstones, red beds, and evaporite deposits in closely adjacent areas. Oil and gas in large quantities are found in certain parts of this region, chiefly in massive limestone. The mode of occurrence of the oil and gas, and the apparent structural relationships of the fields are not at all intelligible unless consideration is given to the stratigraphical conditions that have been deciphered.

Exploration for oil and gas, as guided by geological studies, until now has been almost entirely dependent on finding favourable geological structures. First by surface investigations, then, in many regions where surface evidence of structure is lacking, by core-drilling, and finally by application of geophysical methods, the search for structural traps has been extended until in the more intensively studied regions of the globe, such as the possible oil-producing areas of the United States, there is little prospect of finding important new fields as a result of the discovery of untested favourable structures. On the other hand, there are large possibilities of the existence of undiscovered major oil- and gasfields in which accumulation of the oil and gas is due to stratigraphical conditions. The occurrence of a porous reservoir rock overlain by impervious strata and terminated laterally on the up-dip side by overlap, by thinning to disappearance, or by gradation into fine sediments, furnish favourable conditions for commercially valuable accumulation of oil and gas that may be exceedingly important. Such 'stratigraphic traps' are primarily due to the nature and relations of the rock strata and not to anticlinal structure. It is obvious, also, that the location of such oil- and gas-productive traps may not be discoverable by methods of structural geology. The great East Texas oilfield, the Glenn, Burbank, and Seminole fields in Oklahoma, and the Coalinga field in California are examples of accumulation of oil and gas in very large quantities mainly or entirely because of local stratigraphical conditions. It is reasonable to conclude that the chief new developments in oil- and gas-finding, as regards additions of important production, will come through application of stratigraphical studies which have as their object the finding of 'stratigraphic traps'.

Stratigraphical Considerations bearing on Determination of Geological Structure

The cardinal importance of geological structures in connexion with exploration for oil and gas is well recognized. This subject is treated at some length in another section of the present work. It is pertinent here merely to call attention to the place of stratigraphy in the determination of geological structures, both surface and subsurface, by the geologist. Without detailed knowledge of the character and sequence of rock strata in a given region it is impossible to formulate conclusions as to structure that will serve as a useful guide to oil and gas development. In actual practice the structural geologist leans heavily on the stratigrapher, or rather, he himself uses all possible stratigraphical information for determining the character, order, thickness, horizontal persistence, and correlation of the beds whose structure is to be indicated. A key horizon or datum is selected for contouring, and a variety of factors, especially precision of determining the key bed, bear on such selection. Special account must be taken of variations in thickness of certain layers, especially if these variations are abrupt, and consideration must be given to unconformities.

One of the obvious but not immediately recognized relationships of stratigraphy to geological structural work in connexion with oil exploration is that presented by variations in thickness of stratigraphical units. Few formations or groups of formations have uniform thickness within even a few square miles of areal extent. Accordingly, it is necessary in determining the structure of different rock layers to make thickness (isopach) maps which indicate the convergence in certain directions between selected datum surfaces. Studies of this sort may demonstrate that a barely perceptible structural 'nose' or terrace in surface rocks may overlie a well-defined 'closed' anticline a few hundred feet beneath the surface, and this anticline may serve as a place of accumulation for commercially valuable quantities of oil and gas.

Finally, we may note that determination of subsurface structure in most oil- and gasfields or in areas of exploration is primarily based on stratigraphical conclusions as to identity and age of rocks penetrated by the drill. The development of technique using microscopic fossils, petrographic characters, insoluble residues, analyses of waters, and all other possible means of identifying stratigraphical horizons, constitutes the greatest advance made in recent years in the application of geology to the quest for oil and gas. Reliable conclusions as to geological structures rest on these more accurate determinations of stratigraphical conditions and relationships.

PALAEONTOLOGY

By A. MORLEY DAVIES, D.Sc.
Late of the Imperial College of Science and Technology

THE value of fossils to oilfield geologists consists essentially in the fact that they may serve to distinguish horizons in a rock-sequence. Two beds of sand or marl which are indistinguishable lithologically may contain quite different fossils, while the same fossil species may occur in limestone in one place and in shale in another, thus proving (or at least suggesting) that they are of the same geological date. It is to William Smith (1769–1839) that we owe the demonstration of this use of fossils. His pioneer observations were quite empirical: he had no explanation of why the fossils of the successive strata of the Bath district should differ from one another—or why an oyster should be the index fossil of one formation, an ammonite of another, and a sea-urchin of a third. Practical stratigraphical palaeontology still remains in large measure empirical; but there are traps into which empiricists may fall, and more scientific consideration is necessary to avoid them. The fossil fauna (or flora) of any bed is determined by a number of factors:

1. The actual living faunal (or floral) community which existed in the immediate area where the sediment now forming that bed was being deposited. This in turn depends upon—

   (*a*) the stage of evolution of the animal (and vegetable) world at the time;

   (*b*) the particular conditions prevailing in the immediate area of deposition, determining what forms of animal (or plant) life could and could not live there;

   (*c*) the geographical restrictions to dispersal, which isolate provinces, and, when they cease to exist, allow of sudden and rapid migration.

2. The facilities for transport of dead organisms or their skeletons to areas where they were not found living.

3. The local conditions which determine whether any or what organisms or what portions of them shall be preserved after death.

Let us consider these in order.

1. (*a*) That animal and plant fossils, viewed in a broad way, show a general progression from the earliest fossiliferous deposits to the present day, was recognized long before Darwin's theory of evolution was propounded, and by palaeontologists like Agassiz who rejected that theory.

Thanks to this generalization, even a tyro in palaeontology can recognize whether any moderately varied fossil fauna comes from strata of the Older Palaeozoic, Newer Palaeozoic, Mesozoic, or Cainozoic Era: with luck he may even be able to refer them to one of the periods into which each era is subdivided. Even here, however, empiricism creeps in. No one can say why Trilobites are confined to the Palaeozoic: they were not ancestral to any later forms. With Cephalopods the case is better, for Goniatites are obviously less highly evolved than the Ammonites which succeeded them. It is among the Vertebrates (and especially the Mammalia) that the stage of evolution can be most safely recognized and used as a time-indicator.

There are, however, a few cases in which slow- and short-range evolution may be of stratigraphical service. Such are the lineages in Lower Carboniferous corals, the gradual changes in detailed structure of the Micrasters during the deposition of the White Chalk, and probably those in certain long-range Tertiary foraminifera which oilfield palaeontologists are now following up. These are characteristic of periods and areas where external conditions remained fairly constant, or changed fairly steadily in one direction, so that evolution (far slower than the average) took place without the disturbance produced by faunal migrations. In the Roumanian and South Russian oilfields the evolution of the *Adacnidae* may be of service as a guide to age, if the difficulties due to complex branching can be eliminated; and the rapidity of evolution of *Valenciennesia* suggests it as a possible means of subdividing the Maeotian stage.

In general, as we descend from Vertebrates to Invertebrates, and from the eras and periods to the finer time-divisions, the direct applicability of grade of evolution to determination of age becomes less and less, owing to the increasing importance of other factors, namely:

(i) **Persistence of Type.** There are certain forms of life which endure for long periods with little or no change, or at least without any steady change in one continuous direction. The classical example is the brachiopod *Lingula*, ranging from Ordovician to Recent. *Nucula* (or closely allied forms, not readily distinguished by the field-geologist) ranges from Devonian to Recent (Cretaceous to Recent in the narrowest interpretation of the genus). Some Recent lamellibranch genera start in the Carboniferous, and limpets not differing apparently from the Recent *Patella* date from Silurian time. Similarly, *Nautilus* ranges from Triassic to Recent. Even among the rapidly evolving Mammalia we find the opossum (*Didelphys*) already existing in Eocene time. Descending to species, we find that certain oysters, which have been taken as horizon-markers because they 'flare up' in profusion in certain beds, did not become extinct after flaring up, so that solitary specimens are untrustworthy guides to age (e.g. *O. gryphoides* [*crassissima*], accepted as distinctively Miocene, but surviving to-day in the Bay of Bengal).

(ii) **Repetition and Convergence of Types.** Among Mollusca, the possible variety of shell-form (and ornament) is so limited that it is not surprising that the same form should be repeated at different periods. Thus some Tertiary Pectens have been mistaken for Jurassic species, and (when only shell-form is seen) *Inoceramus* may be confused with *Posidonomya*, &c. The Middle Miocene *Carditae* of the *C. jouanneti* series (*Megacardita*) reproduce the more striking features of the Eocene *planicosta* group (*Venericor*). When the shape is an adaptation to some particular environment there may be *convergence* between widely separated groups, as in the various boring bivalves (*Teredo*, *Clavagella*, &c.). In most of these cases a complete study of the shell will reveal some internal distinction between repetitive or convergent forms, but field-geologists commonly have to deal with incomplete or difficult-to-expose material.

(iii) **Deceptive Evolutionary Series.** Among Cephalopods, Hyatt, Buckman, and others have tried to establish certain principles of evolution, but they are so subject to excep-

tions that their application to novel cases is dangerous. For instance, in the Lower Lias there is a very characteristic group of Ammonites of which *Asteroceras* may be taken as the type, which is followed in time by *Oxynoticeras*, differing from it by its stream-lined shape, indicating better adaptation to swimming. In the Middle Lias we find a parallel pair, *Paltopleuroceras* (characteristic of the Cleveland and other iron-ore deposits) which resembles *Asteroceras*, and *Amaltheus* resembling *Oxynoticeras*. But if we jump to the conclusion that *Amaltheus* must follow *Paltopleuroceras* in the rock-sequence we should be quite wrong, for it precedes it.

1. (*b*) *Facies*. This term denotes all the characteristics, physical and palaeontological, which give a rock-formation its individuality, other than those that come under 1 (*a*). Thus there are only a limited number of facies, and they are repeated over and over again with time-variations. The biggest distinction in facies is between marine and terrestrial, the latter being divisible into fresh-water and subaerial. Marine facies are dependent partly on depth, partly on the lithological character of the deposit—muddy, sandy, pebbly, neritic, &c. On the present sea-bottom there live a series of *communities*, each with its own series of *stations*, the totality of the stations forming the *province* of which the totality of communities forms the *fauna*.

1. (*c*) It is a familiar fact that the native animals and plants of one continent, to-day, are very different from those of another; and the same is true of the oceans. This is only partly a matter of climate, since artificially introduced species often thrive as well as the natives. It indicates past isolation of regions or provinces, so that the floras and faunas have evolved independently. That similar provinces have existed in the past, and that at times the barriers between them have broken down and extensive migrations followed, has been amply proved. One result of this is that newly arriving genera serve as excellent dating fossils in their new habitat, but when the geologist seeks to use them in their old home he may fall into serious error. Thus Old-World palaeontologists established a simple sequence in the Orbitoids—*Orbitoides* Cretaceous, *Discocyclina* Eocene, *Lepidocyclina* Oligocene and Miocene; but this was partly an expression of isolation followed by migration, and broke down when tried in the New World. The large *Carditae* of the *planicosta* group also laid traps for geologists, when ideas gained in Europe were too hastily applied to America. These cases illustrate, not the failure of the method, but the need to replace rough generalizations by others more accurate and complex.

2. Fossil faunas rarely correspond to pure living communities: there is more or less mixture after death. The most obvious mixture is that between the swimming or floating population (*nekton* and *plankton*) of the surface waters and the crawling or fixed inhabitants (*benthos*) of the bottom. The dead bodies of the former, if they escape being eaten, or otherwise disintegrated, will sink to the bottom and mix with those of the latter. Besides this, currents will sweep dead shells away from their station and deposit them elsewhere. In dredging, to-day, dead shells are found outside the depth-limits of the living animals. This is particularly the case with easily floated shells, such as those of the chambered cephalopods. The empty shells of the pearly Nautilus are found over a much wider area of the Indo-Pacific than is inhabited by the living animal; and the little *Spirula* has an almost world-wide distribution after death, while its living habitat is only partially known but is certainly very restricted.

This tendency to a mixture of communities to form fossil 'faunules' adds to the difficulties of the palaeo-biologist in interpreting the ecology of ancient oceans, but it is of great advantage to the stratigraphical geologist by enabling him to correlate different facies of the same age by the presence in one faunule of species which, in life, belonged to some other contemporaneous faunule.

Even terrestrial and marine deposits have a better chance of being correlated if land-animals are drowned and drifting out to sea are finally buried in a marine deposit. The only known pre-Pliocene marsupial of Australasia is *Wynyardia bassiana*, an incomplete skeleton from the marine Miocene sandstone of Table Cape, Tasmania. And the first-discovered remains of Mesozoic mammals were those in the 'Stonesfield Slate', a shallow-marine Jurassic sandstone. The discovery of the three-toed horse *Merychippus* in the marine Upper Temblor formation of North Coalinga, California, made possible a correlation between the marine Tertiaries of the Pacific slope and the inland deposits of the Rocky Mountains region.

In the Ordovician and Silurian rocks of Britain and elsewhere we find two sharply contrasted facies—'graptolitic' and 'shelly'. The former consists of shales, usually black, somewhat pyritic, and rarely with other fossils than graptolites and horny brachiopods. The latter are more varied—limestones, shales, or sandstones with calcareous brachiopods, trilobites, corals, &c. So unlike are the faunas that correlation would be almost impossible, were it not for occasional interdigitation of beds of the two facies, and also the occasional drifting of graptolites into the area of the shelly facies in which their tell-tale remains may be found, giving an exact date to the shelly deposit. In the Tertiary beds of some oilfields a somewhat similar problem is presented by the foraminiferal limestone facies and the shelly facies.

3. Every one is justifiably astonished when such soft-bodied animals as jellyfish are recognizable in special deposits such as the Mount Stephen Shale (Middle Cambrian) or the Solnhofen lithographic stone (Upper Jurassic). But most persons take it for granted that marine animals with hard, calcareous or phosphatic shells should be preserved as fossils. Yet there are everywhere destructive agencies at work on the hard shells and skeletons as well as on the soft organic tissues. The ordinary bivalve and univalve mollusca are perhaps the shells which suffer least from destructive agents, since they are found (especially bivalves) in nearly all possible sediments in which any fossils occur at all. Crustacea and Fishes are much more rarely preserved. The trawl brings up from the bottom waters of the English Channel a great abundance of Fishes and many Crustacea, but the dredge brings up the sediment from the sea-floor, and in this one may hunt in vain for any trace of Crustacea or Fishes, except a few otoliths of the latter. So, among the stratified rocks, when Crustacea or Fishes do occur, it is commonly in special beds containing little or nothing else. These seem to denote the sudden destruction of complete shoals of fish, followed by rapid burial which inhibited the chemical action that usually destroys phosphatic skeletons. The famous fish-beds in the *Alveolina* limestones (Middle Eocene) of Monte Bolca are examples.

Star-fish also occur often in special beds in which they abound, just as they do to-day in the 'starfish communities' of the sea-bottom. Such a bed must denote the sudden complete destruction of a community followed by rapid burial. But can we doubt that in the long interval

between such catastrophes starfish communities flourished year after year in the same place but left no trace behind them?

Such fish-beds or starfish-beds may be of great local value in mapping, since they are easily recognized, and if they are not repeated except at long intervals no confusion is likely to arise. But they may be repeated, and a source of confusion may then arise. The graptolite *Dictyonema* occurs in great profusion at the base of the Tremadoc beds of England, Wales, and Scandinavia. It is usual to take it as fixing a definite horizon, but in North Wales (Dolgelley district) Cox and Wells have found that there are two *Dictyonema* beds, separated by about 500 ft. of flags and shales.

MICRO-PALAEONTOLOGY

By W. L. F. NUTTALL, D.F.C., M.A., Ph.D., F.G.S.
N.V. de Bataafsche Petroleum Maatschappij, The Hague

Introduction

THIS article is intended to outline methods that may be advantageously employed in micro-palaeontology as applied to petroleum geology. The principal subject of this paper is the interpretation of palaeontological results that may be of value in stratigraphical correlation. The other aspects of the subject are only briefly touched upon, reference being given to the more important relevant literature.

The great variety of forms among the Foraminifera and the question of their classification attracted the attention of distinguished men of science during the nineteenth century. Pre-eminent among the earlier investigators were Alcide d'Orbigny and H. B. Brady [18, 1917; 1, 1884].

During the last two decades J. A. Cushman and his students have made important contributions to our knowledge of the recent microfaunas and of those from the Tertiary and Cretaceous of America. In Dr. Cushman's Introduction and Dr. Galloway's Manual [8, 1933; 16, 1933] descriptions of the Foraminifera have been outlined and extensive references to the literature given. The economic palaeontologist is deeply indebted to the numerous scientific workers, since without their fundamental morphological studies the recent developments in the practical application of micropalaeontology would not have been possible.

It has long been accepted that the larger Foraminifera (Nummulites, Orbitoidae, &c.) are of value as horizon markers. That the smaller Foraminifera could be enlisted in the service of the stratigraphist was recognized as early as 1898 by F. Chapman in his studies of the Cretaceous of southern England [3]. It was, however, not until about 12 years ago that the practical value of smaller Foraminifera in petroleum geology was first generally accepted in the Tertiary sequence of the Gulf Coast U.S.A. and California. The methods now employed in the study of foraminiferal deposits are based on the investigations of the earlier workers adapted to suit the objectives of the economic palaeontologists.

Technical Preparation of Material

The preparation of foraminiferal argillaceous deposits by washing through sieves or decanting has been described in publications by Chapman [4, 1902], Cushman [8, 1933], Hecht [17, 1933], and others. The residue thereby obtained consists of Foraminifera and sand. The concentration of the Foraminifera from a sandy residue has frequently been successfully accomplished by the use of a separation funnel employing bromoform and other heavy fluids. Also in the case of the Foraminifera being filled with air, it is frequently possible to float them away from the residue employing different suitable liquids. In the case of detailed studies hand-picking is resorted to, while, in each country investigated, slides with several specimens of the different species are prepared. For a description and illustration of convenient forms of slides that may be employed for Foraminifera reference is made to papers by Nuttall [23, 1933] and Plummer [25, 1929]. In economic work it is found that it is convenient to assign each species to its genus and add a number for the species. The numbers are usually assigned consecutively in each genus, and in this form records of the occurrence of each species are kept and frequently tabulated. Later on it is always possible to continue with the study of the scientific literature and identify the known species by their specific name.

In the case of limestones containing larger Foraminifera thin sections are generally prepared in the usual manner. A method which gives details of internal structure has recently been employed by Dr. Van der Vlerk and his students, which is less well known. It consists of the following stages:

(1) Rubbing down the limestone to obtain a satisfactory flat surface, which must be rendered smooth without being actually polished. This can be done by employing the usual abrasives.
(2) Etching this surface with dilute hydrochloric acid and mounting the rock fragment in plasticine so that the surface is uppermost and horizontal.
(3) Covering this surface with amyl acetate. While the surface is still wet it is covered over with a thin layer of 'Rawlplug durofix', which is left for 5 to 6 hours until set hard.
(4) Cutting off the edges and peeling off this layer with a sharp knife. Placing the layer between two sheets of glass (ordinary slides may be employed) and sticking paper around the edge so as to hold the slides together.

The above thin layer when viewed through transmitted light gives similar structural details to those obtained by thin sections.

The Larger Foraminifera

The so-called Larger Foraminifera consist of forms with a fairly complex internal structure which has been subject to evolutionary changes. These developments enable different species to be recognized, a number of which have a restricted vertical range and are therefore valuable as time markers. The more important Larger Foraminifera are as follows:

Palaeozoic: Fusulinidae.
Cretaceous: Orbitoides ss., Orbitolina.
Tertiary: Lepidocyclina, Discocyclina, Borelis (Alveolina), Nummulites, &c.

The Fusulinidae have received the attention of specialists investigating the Palaeozoic formations of the Mid-Continent oilfields of U.S.A. A bibliography on this family has been recently published by Silvestri [27, 1933]. The Middle and Upper Cretaceous contain rich and varied faunas of Larger Foraminifera, a number of forms having a wide lateral distribution [26, 1901–2]. *Omphalocyclus macropora* is, for example, present in the Upper Cretaceous of Cuba, Europe, and India [14, 1932; 32, 1908].

In the Tertiary the Larger Foraminifera play an important role in stratigraphical correlations in oilfield areas, where Tertiary limestones are developed. Such areas are the Netherland East Indies, India, Iran, Iraq, Europe,

Mexico, and the West Indies. A great deal of valuable information on the distribution of the Larger Foraminifera and Mollusca is contained in Dr. Morley Davies' recent book on Tertiary Faunas [12, 1934].

In the East Indies the most important investigations have been made by Martin, Douvillé, and Van der Vlerk [13, 1924–5; 20, 1931]. The difficulty in distinguishing the European stratigraphical divisions has led to the introduction of a system of lettered faunal horizons. In Europe, as in India, the Nummulites in the Eocene are important in stratigraphy and have an extensive literature [see 2, 1911; 22, 1926]. The American Larger Foraminifera have in particular been studied by Vaughan, who recently contributed an interesting paper on factors influencing their distribution [30, 1924; 31, 1933]. As regards the genus Lepidocyclina there are numerous species restricted to the geographical Tertiary regions of America, Europe, and the Far East.

Smaller Foraminifera

For correlation in petroleum geology the study of the Smaller Foraminifera has been mostly confined to Cretaceous and in particular to Tertiary microfaunas. In the Cretaceous there was a marked similarity in the American and European forms, while certain genera such as Globotruncana had world-wide distribution [6, 1926; 28, 1934]. In the early Tertiary tectonic movements caused a change in configuration of the land masses and oceans, producing different areas in which development of the microfaunas proceeded more independently. The resultant present geographical distribution of animal life has been recently summarized by Davies [12, 1934].

In the Tertiary the two principal factors which produce differences in the microfaunas are age and facies. As regards age it can readily be ascertained by a study of the literature that faunal differences exist between beds of different age and of similar facies. Instances of this have been worked out in the Gulf Coast of U.S.A. and Mexico [23, 1933]. For the American faunas typical of the different horizons reference is made to the literature, in which the smaller Foraminifera of the Miocene [10, 1933], Oligocene [5, 1923], Upper Eocene [9, 1926; 15, 1933; 19, 1932], Middle Eocene [11, 1929–30], and Lower Eocene [24, 1926] are described and illustrated. The faunas distinguished from these horizons have a regional distribution, so that where present, in the Gulf Coast of U.S.A. and adjoining areas, the major stratigraphical divisions can readily be recognized by their characteristic foraminiferal species. Difficulties are, however, encountered firstly when areas widely separated from one another are investigated; secondly, where local facies conditions are variable. As a case due to the first cause may be mentioned the Miocene of California, which contains a different fauna from that of the Miocene of the Gulf Coast. This has been explained as due to there being no marine connexion between the two areas during Miocene times. The influence of facies on the microfaunas is another factor, a brief discussion of which follows.

It is generally agreed that living conditions have had as much influence on the smaller Foraminifera as on other marine organisms, such as Mollusca. It is known from studies of living foraminiferal faunas that certain genera are commonly found in brackish water, others in a shallow sea, and others under deeper marine conditions. Furthermore there are several pelagic genera of Foraminifera which may be carried by marine currents, while the greater number of Foraminifera are bottom living. An interesting instance of the influence of depth and temperature on Foraminifera living off the coast of California has formed the subject of a recent paper by Natland [21, 1933].

In view of these facies influences it is necessary for the application of micro-palaeontology to stratigraphical correlation to proceed very cautiously before making detailed long-distance correlations in beds of approximately the same age. As a result of local facies and palaeogeographical influences Tertiary faunas closely resembling one another may occur in different areas at somewhat different stratigraphical horizons within the Tertiary.

For these reasons it is considered necessary to determine the vertical range of the Foraminifera independently in each basin of deposition. After this has been done for a particular part of a certain basin the results are applied over a larger area within the same basin. As the edge of the basin is approached local facies conditions will bring about differences in the microfauna and the vertical range of certain species. In this case it will be necessary to proceed with further detailed studies of stratigraphical sections in the areas of near-shore deposition. After this has been completed the two may be palaeontologically correlated.

It should be borne in mind that locally a change of living conditions influencing the microfaunas may be sharply defined at a given correlative stratigraphical horizon. For example, in a given area at a certain horizon there may be a clear break between marine and non-marine conditions. Similarly in a single basin at a given stratigraphical horizon there may be a sudden incursion or extinction of certain foraminiferal species. A faunal break of this type may be of great practical value for local correlation and may even be found to extend throughout the greater part of a single basin of deposition.

The submarine topography has also frequently had a pronounced influence on the microfaunas. In certain areas it has been found that overlying contemporaneous uplifts reef limestones or shallow water faunas predominate, while in the adjoining depressions marine microfaunas with different assemblages are present.

In general it may be stated that no reliable micro-palaeontological correlation can be expected unless the stratigraphical and palaeontological data are critically compared and as a basis for correlation systematically sampled sections are investigated in detail. These sections should have samples collected from close and regular intervals, so as to give as nearly a continuous stratigraphical sequence as possible. The samples, may be derived from cores in a well or from the surface and in each case should be from an area which is as far as possible not structurally complicated. Only after a basis for correlation for a particular area has been worked out will it be possible for the palaeontologist to determine the stratigraphical horizon of scattered material.

THE CORRELATION OF SEDIMENTS BY MINERAL CRITERIA

By A. BRAMMALL, D.Sc., Ph.D. (Lond.), F.I.C.

Imperial College of Science and Technology

THE value of detrital key-minerals as clues to the source of the sediments containing them was first recognized by Thoulet [16, 1907], who succeeded in tracing to their sources in terrestrial rocks certain detrital species he had observed in oceanic deposits. He thus established a principle which has since been extensively applied to the genetic study of sedimentary rocks [2, 1933; 8, 1921; 12, 1929; 17, 1932]. But the extent to which minerals—in default of fossils or other decisive criteria, may be used to correlate one stratigraphical horizon with another is a question on which opinion is divided.

The value of mineral *assemblages* as clues to both geological age and stratigraphical horizon was first demonstrated by Boswell [1, 1916], working on a restricted area—the London Basin. The application of the method to oilfield stratigraphy, and in particular to the difficult problem of correlating unfossiliferous horizons encountered in borings, dates from 1916, when Illing [9] found that successive groups of Trinidad sediments—particularly the oil-bearing horizons—were characterized by exclusive, and therefore distinctive, mineral assemblages, which could be used as aids to correlation. Thus a principle which, in the first instance, was of purely academic interest, was brought to bear on oilfield economics.

It is therefore not surprising that the most substantial contributions to literature on this subject must be credited to oilfield geologists, whose extensive exploration of its possibilities renders their opinion on its practical value authoritative. Nor is it surprising that this authoritative opinion is divided: the situation is not unfamiliar.

In the following review of the principle and its applications a critical survey of the material evidence usually brought to bear on problems of correlation may serve to suggest possible reasons for its apparent inadequacy in particular cases.

The correlation of strata by either fossils or minerals is, of course, quite compatible with marked contrasts in both facies and mass mineralogy. Fossil and mineral criteria alike usually rest in some small fraction of a rock-mass. The fraction searched for mineralogical evidence is usually the 'sand' grade—particularly the small crop of 'heavy' minerals separable from a much larger amount of associated 'light' minerals (quartz, feldspar, &c.) by mechanical means, mainly sink-and-float technique using heavy liquids such as bromoform. The sand grade itself must first be separated from the silt and clay grades; these being mineralogically 'obscure' and somewhat unmanageable in heavy liquids unless centrifuged are usually discarded after a cursory examination of their characters. A 'limestone' facies is also liable to be discounted as a potential source of material evidence.

The small crop of 'heavy' minerals—commonly representing much less than 1% of a rock mass—is then studied as an 'assemblage': its features are compared, qualitatively and quantitatively, with those of other 'assemblages', the quest being for correspondences distinctive enough to correlate one assemblage with another. The extent to which correlation demands concordance in mineralogical (and other) details must be indefinable; but the 'probabilities in favour' increase with the number of coincidences. That stipulation on this point should possess some degree of elasticity is to be inferred from the fact that 'change'—gradual but incessant—is the feature of

(*a*) The distributive province from which a sediment derives its detrital material.

(*b*) The determinants of facies—climate, physiography, and the conditions of transport and accumulation of detrital material; progressive sorting, and the selective elimination of particular minerals by both mechanical and chemical processes.

(*c*) The post-deposition history of species actually sedimented but thereafter exposed to variable physicochemical conditions.

The various parts of a sediment are as unlikely to be initially isochemical as they are to persist under isophysical conditions.

Correlation is compatible with considerable discrepancy in mineralogical detail—provided the evidence furnished by each sediment concerned in the case reveals *certain qualities* which are both common to and distinctive of them all. This view may appear to need some defence—for which the following considerations may suffice:

(*a*) Incessant change in the determinants of facies, which may vary from one layer to another, is reflected in the variable relative stability of detrital minerals under the physicochemical conditions proper to each facies. A mineral may resist destructive change in one layer, while in another the same mineral may be partly or completely destabilized—to some chloritic, micaceous, or clayey residuum destined for laboratory discard. The resistivity of most rock-forming minerals to hydrolysis and chemical change is in inverse relation to grade size, which is a facies feature [4, 1937; 6, 1937].

(*b*) Clayey residuals are the main loci of base-exchange, which attains a maximum in clays of the bentonitic type [11, 1931, 1935]. Hence geochemical conditions at a clay-rich locus are liable to be alternately favourable and unfavourable to the stability of particular detrital species. Oscillatory conditions of this character could account for some minor discordances between mineral assemblages which, in other respects, may be essentially equivalent.

(*c*) Concretionary growths, notably the flinty and calcareous types, are liable to enclose, and preserve, minerals eliminated from matrix unaffected by these growths.

(*d*) Highly calcareous matrical matter, argillaceous limestones, and common limestones may ensure the persistence of even such reputedly unstable species as biotite, cordierite, amphibole, and feldspars. In limestones, albite may actually grow—as an authigenic species—and is commonly associated with minute well-developed prisms of authigenic quartz. Authigenic potash-feldspar is recorded from sandstones, marl, and dolomitic limestone [14, 1929]. Authigenic rutile, brookite, anatase, sphene, pyrite, epidote, &c., are as familiar, and accepted, as authigenic quartz, feldspar, calcite, siderite, dolomite, ankerite, gibbsite, sericite, chlorite, barytes, gypsum, glauconite, &c.; and the list of authigenic species grows apace: it now includes even tourmaline,

garnet, and staurolite—which figure with such monotonous regularity among species presumed to be exclusively 'detrital'.

The fact to be noted here is that laboratory routine may trap both authigenic and detrital grains of a particular species but fail to discriminate between the two categories. Moreover, conditions in one layer of a sediment may be favourable to only one category; or they may be hostile to both—in which case, an item of detrital evidence is liable to be obscured or even obliterated; in some other layer the same kind of evidence may be preserved, or even reinforced.

It is helpful to realize that the micaceous, chloritic, and clayey fraction of a sediment is likely to be in some measure authigenic—in the special sense that it may include the residuum or relics of antecedent species which, had they survived, would have ranked as material evidence. The extent to which such relics may betray their ancestry and can be figuratively 'reconstructed' or integrated to vanished species is a genetic problem with its analogues in the fields of igneous and metamorphic geology, where genetic evidence is habitually sought in relics of antecedent species [3, 1936].

The obscurity which still characterizes the silt and clay grades in sedimentary rocks is scarcely an excuse for discounting their significance as potential sources of supplementary evidence. Such material invites more serious study—by every means available.

The difficulties opposed to the fractionation and identification of clays, &c., have been considerably reduced in recent years [10, 1935]; but the additions to our knowledge concerning the specific character of clays, &c., in bedded sediments accumulate only slowly. Comparatively little is known concerning the 'heavy' minerals present in either clays or shales. Hence, serious attempts to co-ordinate arenaceous facies with silt and clay layers alternating with them have yet to be made. These attempts are not only warranted by the expectations based on them: they are actually encouraged by modern refinements of technique [10, 1935] and the abundance of diagnostic data available. The character of supplementary evidence to be gleaned from clays is outlined in the following sections:

(*a*) The solid relics of mineral change commonly include a high proportion of the layer-lattice species—chlorites, micas, and clays [5, 1937; 13, 1930]. As these relics often occupy the sites of change, their identities and habits—co-ordinated with syngenetic by-products such as rutile, limonite, epidote, calcite, silica, &c.—may contain hints which can be profitably followed up. Rutile-needles enmeshed by residual chlorite, white mica, or a clay species are familiar examples of 'residuals in place', but attempts to integrate them to some particular original species are infrequent. The interpretation of any particular occurrence—even when several residual species are still aggregated on the site of a mineral change—makes considerable demands on the researcher's background of knowledge: he sees only *some* of the terms belonging to the right-hand side of an equation of change; the problem of integrating these terms, without the aid of positive knowledge concerning the agents of change, can be as exacting as the integration of terms involved in an igneous or a metamorphic process [3, 1936].

(*b*) Clay-body is prone to 'trap' the more inert oxides such as titania, vanadia, ceria, and the oxides of manganese. Base-exchange capacity is variable, and its effects are usually occult, though they may 'seal' or 'dilate' a texture to a degree which may prevent, or promote, the migration of water, brine, gas, or petroleum [15, 1930]. Solutes such as phosphoric and boric acids may be incorporated in peculiar varieties of apatite; in ceria-rich and vanadia-rich pellets, streaks, and films, and in extremely minute pale-green prisms of authigenic tourmaline.

The interpretation of clays occurring in sedimentary rocks is seriously embarrassed by the dearth of information concerning the particular clay species likely to result from the break-down of any specified mineral (pyroxene, amphibole, feldspar, &c.) under particular conditions. In general, conditions themselves are perplexing: feldspars in granites are 'kaolinized' under conditions which are still in dispute; whereas a soda-granite related to the Dartmoor granite (locally kaolinized) carries montmorillonite—associated with topaz and petalite; both montmorillonite and beidellite characterize the bentonite clays evolved from trachy-andesitic and allied volcanic ash, &c., and these bentonitic types are more abundant than kaolin in surface soils.

It is to be admitted that in routine practice we do not always discriminate between kaolin and other clay species. Our 'kaolin' is liable to be a speciously precise label for any claylike mineral, particularly if present in only minor amount. To what extent field conditions admit of more exact determinative work on such material is an open question.

Equally doubtful determinations include a group which may be classed as the '-ic' type—leucoxenic, glauconitic, epidotic, chloritic, phosphatic, lateritic, bauxitic, &c. They can shelve so many difficulties that their value may be negligible. Many such uncertainties could be resolved by microchemical tests imposing little labour.

Treatment of varietalism is also liable to be superficial and indecisive. Garnet varieties, for example, are commonly dismissed as reddish, pink, colourless, &c., though colour, even if discernible in the smaller grains, is not diagnostic even of species; whereas density or refractive index may be, and the blow-pipe, or appropriate microchemical tests, may narrow down the species to some genetically significant variety. Other minerals, particularly pyroxenes, amphiboles, and basic micas, will afford more profitable studies when their varieties have been better characterized. Varietalism in zircon, rutile, tourmaline, staurolite, and sphene, though imperfectly understood, is usually well exploited. Some varieties of fluorite, monazite, zircon, allanite, aragonite &c., and even earthy matter associated with bitumen, display a characteristic fluorescence when exposed to ultra-violet rays. The irradiation of mineral assemblages can serve the useful purpose of directing attention to reactive species present in only minor amounts.

The considerations outlined above may serve to show that the mineralogical evidence usually brought to bear on correlation problems is at best partial, and frequently qualified by uncertainties. Unless reinforced by numerous and striking coincidences, distinctive key-minerals, and skilful handling of detail, it can but be equivocal. The degree of security afforded by such evidence may be relatively high in the case of the geologically 'younger' sediments in which variable frequency 'rings the changes' on a large number of species, and endows assemblages with variety. Here, statistical treatment comes into its own [e.g. 7, 1933]. Every identification established is an additional item of evidence, and an added security.

It is sometimes said that, for correlation work, it is less important to identify an unfamiliar mineral—particularly if it is scanty or rare, than to satisfy oneself that the

mineral is the same as another, which may be dubbed 'mineral X' without prejudice to the problem at issue. Such a doctrine is indefensible: to presume that the specific identity of an unfamiliar mineral is of no consequence is taking too narrow a view of the problem. No competent worker would ignore the genetic significance of numerous 'uncommon' minerals liable to spice assemblages of the commoner and more familiar minerals; nor would he restrict his examination to assemblages of 'heavy' minerals.

The task of correlating sedimentary rocks, or even of interpreting a single horizon, is liable to be underrated. It is a problem in genetics [2, 1933; 8, 1921; 12, 1929; 17, 1932], and requires a knowledge of both mineralogy and petrology to at least the standard exacted by corresponding problems in the fields of igneous and metamorphic geology.

All things considered, it would not be captious to suggest that, where the whole of the evidence assembled appears to be inadequate for the purposes of a correlation, the inadequate feature of the case may lie in the quality of the examination applied to it.

Reverting to the restricted range of 'heavy' minerals which may be described as 'common' in the older geological formations, two observational facts can be co-ordinated:

1. Mineral assemblages tend to be simplified with progressive sorting and reduction in grade size—processes which converge towards the segregation of silts and clays.
2. Further simplification occurs with the passage of geological time.

Thus facies of sediments, and geological age, are among the primary factors which determine the mineral assemblages we actually examine. The relative stability of minerals—like the 'order of crystallization' of magmatic minerals—is a theme beset with apparently conflicting observations and opinions. Contrariety in the 'relative' behaviour of some particular species (e.g. biotite) serves the useful purpose of stressing the complexity of factors concerned in the growth, the transformation, and the destruction of mineral species [3, 1936].

Much of the experimental work hitherto done on the relative stability of the common rock-forming minerals has presumed that, under natural conditions, the action of water as a destructive agent must be reinforced by solutes—among which have figured carbonic-acid gas, various mineral acids, humic extracts, &c. These in turn are reinforced by such pressures, and temperatures, as short-period experiments appeared to justify.

But cold water alone is found to be highly reactive towards dust-fine particles of most of the common rock-forming minerals [4, 1937; 6, 1937]: by aqueous extraction of their bases, accompanied by hydration, they are degraded towards layer-lattice end-products belonging to the sericite, chlorite, and clay-types.

The alkalinity imparted, instantly, to cold water by powdered glass is a commonplace fact—readily demonstrated by using water containing an indicator such as phenolphthalein. But a similar reaction, variable as regards intensity, is given by finely divided biotite, and other basic micas; amphiboles and pyroxenes; olivine, apatite, and sphene, and some varieties of tourmaline and garnet; chlorites, epidote, zoisite, calcite, and allied carbonates, and all feldspars and feldspathoids, &c.

Sericite, hydromuscovite, and true muscovite are among the less readily reactive species; but their reactivity increases in proportion to the fineness of their powders. Even these resistant species, in common with the basic micas, yield up an appreciable proportion of their bases (including alumina) on treatment with saline solutions such as brine [4, 1937].

The extent to which hydrolysis appears to depend on both grade size and the solutes present in the water suggests a possible explanation of the apparent scantiness of 'heavy' detrital species in such clays as have been examined. In some measure it must also determine the extent to which *original* mineral composition, and the character of parental rock-sources, can be safely inferred from the mineral assemblages isolated from any particular facies of sediment.

SECTION 8

GEOPHYSICAL METHODS OF EXPLORATION

GEOPHYSICAL METHODS

INTRODUCTION

By A. S. EVE, F.R.S.

Emeritus Professor of Physics, McGill University

THE applications of physics to the finding of oil have become so numerous and varied that a large volume would scarcely suffice to cover the subject. Under these circumstances it seemed wise to select writers, with sound theoretical knowledge and practical experience in the field, who would set forth the general aspects of the chief branches of the subject. Those who actually work in the field soon find that the principles of physics hold out of doors just as they do in the laboratory. The scale of the work changes, but not its character. There is, however, this marked difference. In the laboratory the experimenter works with selected materials, either elements or preparations which are homogeneous and of a known standard of purity. In the field the geophysicist must take things as they occur, and he rarely meets with a homogeneous material. For example, the electrical conductivity of rocks depends partly on the nature of the material, but more largely on the amount of water content and on the nature of the salts which are in solution. All these factors vary from point to point, and nature never repeats itself!

Except under unusually simple conditions a magnetic survey can throw little light upon geological structure, and yet there are cases where a magnetic dike or ore-body, or a larger mass with marked magnetic properties, can be readily traced or clearly defined though far underground. Two methods of comparatively recent introduction have made very rapid progress.

(i) The account of electrical coring, as given by the late C. Schlumberger, indicates how, by the use of electrodes on cables lowered inside an uncased drill-hole, it is possible to obtain striking indications of the successive layers underground which even drill-cores might fail to reveal.

(ii) An artificial blast, due to high explosives near the earth's surface, will give rise to seismic or shock waves which are reflected back from successive layers or discontinuities, and produce records with the help of electrical seismometers or other earthquake recorders. This method has had wide applications in finding the depths of successive layers and in working out the underground structure of oil-fields. The electrical seismograph detects vertical motion by the movements of a wire or small coil suspended in the magnetic field of a magnet or electromagnet resting firmly on the ground. The shock causes a relative motion of the wire across the field, and a current is thereby induced which, possibly amplified, causes a deflexion in some type of galvanometer, and this in turn moves a beam of light affecting the running film of a camera. It is noteworthy that a good *vertical* seismograph is not too greatly affected by the *horizontal* waves which come rolling along the surface of the earth from the shot-point not far away. The same instrument is highly sensitive to the waves which have gone down a much larger distance to some reflecting layer and echoed up again almost vertically to the recorder. Moreover, it is possible to tune the oscillator to the reflected longitudinal compressional waves and, during amplification, to filter out the undesired transverse surface waves which have a different periodicity. The technical skill and high accuracy of the records both in seismic and torsion-balance methods are well matched with the intelligent interpretations of the geophysicists. Those who wish to pursue the matter further may consult the recognized text-books or read the geophysical papers published by the American Institute of Mining and Metallurgy and by other societies. In the south of the United States there are vast regions of a fairly uniform type, and approximately horizontal, wherein massive domes of rock-salt have been thrust up from below and yet have their caps hundreds or thousands of feet beneath the surface of the earth. Oil and sulphur deposits are frequently associated with the upper surfaces of such domes, so that a most active search for them has been made successfully, and it still continues. The rock-salt has a low density and a high elasticity as compared with the surrounding strata, and on both counts the shock waves have a higher speed in the rock-salt. In the refraction method the detectors may be arranged in a straight line or spread out in a fan shape. A shot fired from a point at a known distance affects a number of these electrical seismometers, and calculations reveal whether or no there is a salt-dome beneath any of the lines of fire. Discovery, if made, is followed by further work with torsion balance or seismometer in order to obtain the precise position, shape, and depth of the dome, after which in due course drilling occurs under advantageous circumstances with a minimum of cost. Moreover, the best place in which to store oil is where it occurs underground, until it is needed, and a large company prefers to obtain control of a whole salt-dome rather than to pump oil feverishly against an adjacent rival company.

The following seven articles are arranged in the usual order—without suggestion of any order of merit—magnetic, electrical, gravitational, and seismic. The authors belong to various nations and have worked in various countries, and omissions have not been intentional.

The titles of the articles and the names of the authors are as follows:

Petroleum Geophysics. DONALD C. BARTON, Ph.D., M.Inst.P.T., Geophysicist, Humble Oil and Refining Company.

Magnetic Methods. W. P. JENNY, Geophysicist.

Electrical Prospecting for Oil. C. SCHLUMBERGER, M.Inst.P.T.

Electrical Coring. C. SCHLUMBERGER.

Gravitational Methods of Prospecting. DONALD C. BARTON.

The Refraction Method of Seismic Prospecting. J. H. JONES, Ph.D., D.Sc., Chief Geophysicist, Anglo-Iranian Oil Company.

The Reflection Method of Exploring Subsurface Geology. BURTON MCCOLLUM, B.Sc., A.A.A.S., Geophysicist.

In the first article of this series on Geophysics Dr. Barton draws on his extensive practical experience in the

field and gives a summary of the main methods available to geologists and prospectors for oil. He takes his examples from the southern regions of the United States where success has been well achieved, perhaps owing to a certain simplicity of structure, lending itself particularly to the two methods—torsion balance and seismic.

Dr. W. P. Jenny, writing on 'Magnetic Methods', advocates the subtraction of regional from total magnetic vectors so as to obtain the residual vectors which are due to the local distribution of magnetic material underground. His method of plotting such vectors, so as to show the residual horizontal and vertical components in direction and magnitude, is worthy of careful study. There are regions where the magnetic method is useless, because of an unequal distribution of magnetic material in rocks of similar geological age and structure. There are other regions where the magnetic method, altogether apart from the search for iron, nickel, and cobalt deposits, may be of great assistance in tracing the extension of known massive beds far underground, as has been successfully done in Germany and South Africa.

One of the pioneers of Electrical Prospecting, C. Schlumberger, has died since he wrote his two articles. In prospecting for oil electrically it is essential to use an indirect method and to search for oil-bearing strata by detecting differences in their relative conductivity. For this purpose direct or alternating current is passed through the earth between two well-separated electrodes connected to a generator. The potential difference between another suitably placed pair of electrodes is measured by a potentiometer, and a calculation leads to a knowledge of the *average* resistivity of a large block of underground material. A note on this method is added at the end of this introduction. The nature of the rock may be inferred because different strata have a wide range of conductivity—the reciprocal of resistivity. It is hopeless to attempt a direct search for oil by electrical means which are at best but an aid to the geological interpretation. On the whole it may fairly be said that at present both magnetic and electrical methods hold a secondary place as compared with gravitational and seismic methods, at least so far as oil-prospecting is concerned.

On the other hand, Schlumberger rightly insists upon the importance of the recent developments of 'Electrical Coring'. Spontaneous polarization can be detected and measured between two electrodes (non-polarizable) placed on the surface of the earth and connected to a potentiometer. It is rare to find two points which are at the same potential, such points indeed lie on equipotential lines which can be plotted on a map. This method was first used with success in the search for such minerals as are chemically affected by the action of underground water, for detectable effects often reach the surface of the earth.

When drilling for oil it is sometimes possible to extract and examine cores at successive depths, but these samples are necessarily small in diameter. It is, however, also possible to lower a cable with a wire leading to a suitable electrode in the drill-hole while the upper end is connected to a potentiometer, the other side of which is joined to a fixed electrode on the earth. As the cable is lowered in an uncased drill-hole the potential at successive heights is indicated and recorded by the potentiometer with camera and film. This natural- or self-potential is mainly due to the water and dissolved salts in the cavities of the surrounding strata, which have various degress of 'permeability'—a word which must not be confused with magnetic permeability, for it indicates the extent to which water penetrates a material. The permeability to water varies greatly for such materials as sand and clay. Moreover, an oil sand behaves very differently from a sand containing water. This may be seen in the diagram which Schlumberger gives of actual records. This, however, is but half the story. The resistivity method may also be used in an uncased drill-hole. A cable with three electrodes not far apart is lowered gradually into the hole. A fourth electrode is earthed near the operator. It is to be understood that this electrode and the lowest one in the drill-hole are current electrodes, excited by a generator. The remaining two electrodes are potential electrodes, connected to a recording potentiometer. By this means it is possible to measure and to record the resistivity of the rocks in the neighbourhood of any part of the boring. The two methods, self-potential and resistivity, need but one cable, and both records may be made at the same time as the cable is raised or lowered. The joint readings enable distinctions to be made between different strata, which in some cases a single record might fail to do. The actual detection of oil is possible, and the difference between oil sands and water sands, between water and oil, between clay and sand, &c., are well marked. The best evidence in favour of this scheme is the rapidity with which its use is spreading.

The next article on 'Gravitational Methods of Prospecting' is also by D. C. Barton, and it deals with the use of the torsion balance with which he has had much experience and success. There has been steady improvement in the instruments, technique, and calculations since the pioneer days when Eötvös used a torsion wire to suspend a light horizontal beam with equal weights at each end, placed, however, at unequal heights. The precise location of salt-domes, far underground, in Texas and Louisiana stands out as one of the greatest achievements in applied geophysics.

Seismic prospecting is presented under two headings. The first method to be widely adopted was 'The Refractive Method of Seismic Prospecting', here described by J. H. Jones of the Anglo-Iranian Oil Company. This scheme has led to the discovery of many salt-domes, in such regions as they occur, particularly north of the Gulf of Mexico. The times of travel from shot-point to a number of recording seismometers, at measured distances, reveal the presence of salt-domes by a detectable increase of speed.

In the last article is a description of the 'Reflection Method of Exploring Subsurface Geology' by Burton McCollum. This method at first met with indifferent success, but various improvements in the instruments and their use have led to great developments. The depths of reflecting discontinuities in strata can be accurately determined, and the dip of such layers may be ascertained. A comparison of records in two analogous localities may be made, and an unknown, undrilled place may be interpreted in terms of a well-drilled and successful oilfield. The actual seismometer record is published (p. 391) and deserves a careful study.

In fact, geophysics, wisely applied, may give valuable information perforce concealed from a geologist and only partly revealed by the more expensive method of drilling. The means employed must be adapted to the existing circumstances, as when speed-boats are used to explore seismically the bayous or lagoons along the coast of Louisiana. The best possible instruments must be used, and these require capable men both to operate them and to calculate and interpret the results. Great frankness is also

essential, so that geophysicists may be ready at all times to state to what extent methods may be helpful, the nature of the difficulties to be overcome, and under what conditions failure may be expected.

The following text-books may be of service:

Elements of Geophysics, by RICHARD AMBRONN, translated by MARGARET C. COBB, pp. xi, 372. (McGraw-Hill, New York, 1928.)

The Principles and Practice of Geophysical Prospecting, by A. B. BROUGHTON EDGE and T. H. LABY (1931).

Applied Geophysics in the Search for Minerals, by A. S. EVE and D. A. KEYS, pp. x, 296, 2nd edition. (University Press: Cambridge, 1933).

A NOTE ON THE MEASUREMENT OF GROUND RESISTIVITY.

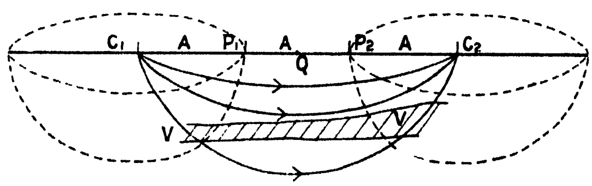
It is possible to determine the average resistivity of the ground by means of four electrodes placed in a straight line on the surface of the earth and making good contact with it. Two electrodes C_1, C_2 are current electrodes and they are connected either with a generator or a battery, for it is possible to use either alternating or direct current. The other two P_1, P_2 are potential electrodes connected by well-insulated wires to a suitable potentiometer. It is convenient to make the three intervals between the four electrodes each equal to any desired length A. The theory of this method was first given by Wenner in 1916. If ρ is the uniform resistivity of the ground; I the total current flowing in the ground between the electrodes C_1 and C_2; V the difference of potential between P_1 and P_2; then for any selected value of the intervals A, it can be proved that, for homogeneous ground,

$$\rho = \frac{2\pi AI}{V}.$$

An ingenious proof by L. V. King is given in *Applied Geophysics*, by Eve and Keys, p. 274, 2nd edition (C.U.P., 1933).

The principle of this method is illustrated in the next column, where the lines with arrows indicate the current in the ground spreading outwards between C_1 and C_2. The bowl-shaped figures, outlined by dots, surrounding C_1 and C_2 are a pair of equipotential surfaces through P_1 and P_2, and it is the *average* resistivity of the ground between them that is determined. The equipotential surfaces are not spherical nor are C_1 and C_2 their centres. The current lines cut the 'bowls' at right angles.

If VV represents a good conductor, either a metallic ore-body or a layer of salt-water, then the average resistivity of the region will be much less than if no such body were present. Hence by traversing an area with the four electrodes, keeping the electrode intervals A constant, the scheme becomes a detector of underground conductors. It may thus find salt pools, and theoretically it might detect the presence of bad conductors, such as oil, but actually the amount present is insufficient for detection at depth.



It is also possible to remain at one place such as Q, and to increase the value of A, so as to search more deeply in the ground for lower conducting bodies. Another plan is to place one electrode C_2 a long way (say, 1,000 yards) from C_1, and to measure the potential difference V between P_2 and P_1, when at distances a and b from C_1. In this case the average resistivity is given by

$$\rho = \frac{2\pi ab}{a-b}\frac{V}{I}.$$

By such means it is possible to explore for conducting bodies in the region round and below C_1. This method is closely allied to electrical coring in uncased drill-holes.

PETROLEUM GEOPHYSICS

By DONALD C. BARTON, Ph.D., M.Inst.P.T.
Geologist and Geophysicist, Humble Oil and Refining Co.

INTRODUCTION

THE geophysical methods of prospecting are the most recently developed schemes which the petroleum geologist has available for use in the oil prospector's search for petroleum. Geophysics strictly is earth physics; and the term is used broadly to include a wide range of sciences: hydrology, meteorology, geodesy, seismology, terrestrial magnetism, vulcanology, all of which are united by a bond of interest in some special phase of the physics of the earth. The applied geophysical methods which are used in prospecting for oil comprise a special group of four main methods: the seismic, the magnetic, the gravitational, and the electric (inclusive of the electro-magnetic) methods, which consist in the application of extremely sensitive physical instruments and special physical techniques to the problem of mapping concealed geological features.

CONTENT OF PETROLEUM GEOPHYSICS

Each of the methods follows essentially the following general procedure:

(1) Measurements are made, with appropriate instruments of sufficient sensitivity, so that a survey can be made, horizontally or vertically, of the variation of some physical quantity due to unseen causes beneath the surface of the earth.

(2) From the data of that field survey, certain conclusions can be drawn in regard to the subsurface variation of some corresponding physical property. The distribution of physical properties in areas of undisturbed horizontal beds tends to be constant horizontally within any single formation, but to vary vertically from formation to formation. Structural deformation produces deformation of that horizontally uniform distribution of physical properties. Irregular distribution of certain physical properties, therefore, gives a clue to geological structure.

(3) If the subsurface variation of the physical property is correctly interpreted, it is possible in many cases to draw certain conclusions in regard to concealed geological features.

(4) From the interpreted subsurface structure, the oil geologist can draw certain conclusions in regard to the possibilities of the occurrence of commercial deposits of petroleum.

The physical quantities whose surface variation is measured by those four methods are : (*a*) in the seismic method, the travel time of artificial seismic waves; (*b*) in the gravitational method, the relative intensity of gravity, the horizontal gradient of gravity, and a function of the curvature of the level surfaces; (*c*) in the magnetic method, the relative intensity of the vertical component of the terrestrial magnetic field, less commonly the horizontal component; the angle of dip, and rarely the declination; and (*d*) in the electrical methods, some quantity associated with electrical or electromagnetic fields, either natural or imposed.

The physical properties which correspond respectively to these physical quantities, and whose distribution in the subsurface is interpreted from the variation of the corresponding physical quantity at the surface are : (*a*) in the seismic method, the velocity of transmission of seismic waves in the rocks of the subsurface, especially sharp discontinuity of that velocity at the boundary of formations; (*b*) in the gravitational method, the relative densities of the subsurface rock masses; (*c*) in the magnetic method, magnetic permeability and less commonly the permanent magnetism of the subsurface rock masses; (*d*) the electrical resistivity or conductivity; and in the electrical logging of wells, either resistivity, or potential differences due to electrolytes.

These geophysical methods fall more or less into contrasting groups. In the one, the geophysicist uses an artificial stimulus, has considerable flexibility in applying it, and thus can focus its application upon the feature in which he is particularly interested. In the other he has to make use of a natural field, and cannot focus his application, but has to observe the sum total of the effects as he finds them. Thus, a single magnetic or gravitational observation consists of some measurement at a single point in space. The measured quantity is due to the combined effects, at that point, of small irregularities close to the instrument; of local structural features; of regional variations; and of the earth as a whole. The geophysicist, therefore, must interpret the whole complex system in order to interpret the local structural feature in which he is interested. Such a method has the disadvantage that it may 'see' and give too much, such as geological features hopelessly below the depths in which the petroleum geophysicist is interested. Observations may be made at many places, but everywhere there is the same composite gravitational or magnetic field, which the geophysicist has no power to alter. A single seismic or electrical observation (except in electrical logging) consists of observation between two points whose position and distance apart are controlled at will by the geophysicist. The depth to which the method 'sees' at any observation is dependent upon the distance between those points and upon the amount of energy which the geophysicist chooses to put into the ground. The seismic geophysicist has the choice between the refraction and the reflection methods; and the electric geophysicist has the choice between a considerable series of different techniques. In the use of these latter two methods, the geophysicist uses an artificial field of energy, and can vary its intensity within certain limits at will, and he can vary his application of them in each case in the attempt to get sharper and clearer results.

The contrast extends also to the distinctness and sharpness of the interpreted picture of the structure. The structural picture which is obtained from gravitational and magnetic surveys is generally 'hazy' or indeterminate. Variations from the normal may be termed anomalies, and these depend upon the mass and the position of the causative bodies. The gravitational anomaly may not be entirely due to structure, but may be due to changes of density also. It is not usually a case of a single body with an excess or defect of density, but of a series of such bodies at different depths, and the observed anomaly is due to their integrated effects. It is not possible even with a single body to obtain a unique solution, for a similar body of eight times the

volume at twice the depth and with equal excess density might produce the same gravitational attraction. In fact, a series of a larger number of bodies, within certain finite limits, corresponds to every gravitational or magnetic anomaly. The limits may be so close together as to give a solution which is almost unique, or they may be too far apart to obtain a definite solution.

A much sharper picture of the structure is given by the seismic method. The seismic anomalies which are used depend upon discontinuity in seismic velocity at the boundaries of formations, and by manipulation of his technique the seismic geophysicist can limit his effects to those of the discontinuities above any chosen depth, and can intensify the effects from chosen horizons. The formulae and procedure which are used in the interpretation in practice give unique solutions.

The statement that the seismic method gives unique solutions, however, is not quite true. The formulae which are used in general are only crudely approximate, and they are based on the assumption of straight line paths, although the actual paths are curves. The velocity relations in the rock masses traversed, furthermore, are known only approximately. The personal element enters considerably into the reading of many reflection seismograms; and all reflection seismograms will not be read alike by different geophysicists; the different sets of readings may give radically different solutions; and as a matter of practical experience in the Gulf Coast, seismic crews of different companies get considerably different, in some cases radically different, pictures of the same structure. Different parties of the same company, using identical technique and equipment, may get different pictures of the same structure. The position of the first recognizable impact in refraction seismograms may depend upon the size of the shot. The presence of low-speed beds of at least moderate thickness, intercalated between higher-speed beds, precludes unique solutions in the refraction method. But in areas in which a good seismic key-bed is present and in which many wells go to that key-bed, accurate unique solutions may be obtainable with the reflection method.

These geophysical methods in the main are an indirect method of prospecting for petroleum. The seismic, magnetic, and gravitational methods are indifferent to the presence or absence of petroleum. A commercial deposit of petroleum, theoretically, will produce a disturbance in the distribution of seismic, magnetic, and gravitational properties, but quantitatively the magnitude of disturbance is so extremely small as to be non-observable, for the volume of petroleum in a petroleum deposit is relatively minute. Some highly refined electrical method ultimately may be perfected for the detection of petroleum in advance of drilling. Several methods have been advertised as able to detect petroleum directly in advance of drilling, but as far as the author knows no one of those methods has been proved to be usable as yet. The possibility of the use of an electrical method for the direct determination of the presence of petroleum in advance of drilling depends upon the high resistivity of petroleum, but the electrical logging shows that, practically, beds with high resistance are common in many oil areas; and in the Gulf Coast electrical logging of wells was not successful so long as it logged only resistivity. The possibility of the perfection of an electric method for general or broad applicability to the detection of petroleum in advance of drilling, therefore, seems small, although locally, electrical methods may be able to detect shallow oil and gas sands. The method of electrical logging does have a high degree of ability to detect the presence of oil or gas and to distinguish between salt-water, oil, and gas sands. But the method is applicable only in wells. The geophysical methods, except that of the electrical logging of wells, are not concerned with the direct detection of oil or gas, but merely with mapping of geologic structure.

HISTORY OF PETROLEUM GEOPHYSICAL METHODS

The use of the geophysical methods in prospecting for petroleum is less than two decades old, although the applied geophysical methods are much older; the magnetic method has been used for centuries in the search for magnetic iron ore; the first attempt to apply an electrical method to prospecting for minerals was made more than fifty years ago. Field surveys with the torsion balance were made in the eighteen-nineties. The first application of the geophysical methods in oil geology was a torsion-balance survey by Baron Eötvös of the Egbell oilfield, not far from Vienna, in 1915–16. From his studies of the domes, some of them gas bearing, in Transylvania, and from Baron Eötvös's torsion-balance profile across a part of Transylvania, Hugo de Boeckh recognized the geological significance of Baron Eötvös's measurements, and suggested the survey of the Egbell structure to see whether a torsion-balance survey would detect the petroliferous structure. In 1917 Baron Eötvös started his surveys in the Hungarian Plain, but no immediate practical results seem to have come from those surveys.

The real trial of these methods in petroleum prospecting began after the close of the World War. In September 1920 Mintrop made the first seismic survey for oil, at the gas-well at Neuen Gamme near Hamburg in north Germany, and followed it in October with a survey on the petroliferous Wietze salt-dome in the north German plain; and in 1921 and 1922 he made several small surveys for petroliferous structures in Austria, Baden, and the north German salt-dome oilfield area. The first considerable, and at first rather disappointing, trial of the method came in 1923, when he was brought by El Companie Mexicana de Petroleo, El Aguila (formerly the Lord Cowdray Company, and Mexican subsidiary of the Royal Dutch Shell), to the Golden Lane district of Mexico, and later in the year by the Marland Oil Company to Oklahoma and to the Powell fault-line district of Texas; and early in 1924 he was taken to the Texas–Louisiana Gulf Coast by the Marland Oil Company and the Gulf Production Company. In the meantime, the Anglo-Persian Oil Company, acting through the D'Arcy Exploration Company, obtained an exclusive oil and gas concession in 1921 for the whole of Hungary, and for two years employed the entire personnel of the Eötvös Geophysical Institute in making torsion-balance surveys in Hungary, and in 1923 sent a party from that Institute to India. In February 1922 the Royal Dutch Shell put a German torsion-balance party into the field in Egypt. In 1922 De Golyer, acting for the Amerada Petroleum Corporation and El Aguila, introduced Hungarian torsion-balances, and a month later the Royal Dutch Shell brought German torsion balances into the Texas-Louisiana salt-dome area. Early in 1923 El Aguila began torsion-balance work on the salt-domes of the Isthmus of Tehuantepec in Mexico. The modern magnetic method dates really from F. Schuh's mapping of the Lübteen salt-domes of north Germany in 1919. Minor application of this method in oil prospecting may have been made during the

next few years, but this is not known to the writer. Trial of the method was begun in America in 1924 under De Golyer of the Rycade Oil Corporation and the Amerada Petroleum Corporation (Lord Cowdray Companies). The first application of the electrical methods was in Roumania in 1923 on the problem of mapping the deformation of the base of the Quaternary gravels over a deep salt-dome in the Roumanian plain.

The extensive, practical application of the methods began early in 1925. Knowledge of the methods previous to 1924 was not widely spread, and until late in 1924 no startling successes had been achieved by them. By the end of 1924 German consulting geophysical companies and instrument makers were advertising the methods and instruments widely. In March 1924 the Nash salt-dome was discovered by the torsion-balance method; in October the Orchard dome was discovered by the seismic method, and the Long Point dome by the torsion-balance and seismic methods. The discovery of salt-domes in the Gulf Coast by ordinary methods of prospecting had become most difficult, and the current value of a new dome was between $500,000 and $1,000,000. The discovery of three salt-domes in relatively quick succession brought the technical value and commercial importance of the geophysical methods sharply to the attention of American oil companies. With the beginning of 1925, the use of the torsion-balance and seismic methods began to expand rapidly in America. In May 1925 the Amerada Petroleum Corporation founded the Geophysical Research Corporation, which rapidly began to take a commanding position in the application of the seismic method. The electrical induction seismograph and the wireless transmission of the time of the shot were immediately introduced by that company, and ultimately replaced respectively the mechanical seismograph and the inaccurate air-wave method of determining the time of the explosion; and made possible the brilliantly successful whirlwind refraction campaign of reconnaissance for shallow domes in Texas and Louisiana during 1927, 1928, and 1929, which covered marsh and inland and coastal waters as efficiently as dry land.

The first crude practical use of the reflection method was begun by the Geophysical Research Corporation in Oklahoma as early as 1926, although much pioneer experimentation with the method had been done by Karcher, Eckhart, McCollom, and Haseman in 1921; but the method was not perfected to a reliable and efficient field method, by that company, until 1929. The use of the reflection method then spread rapidly in the mid-continent petroleum area of the United States, but extensive use of the reflection method in the area of the unconsolidated beds of the Texas–Louisiana Gulf Coast did not begin until 1932. Other geophysicists, both American and European, developed seismic instruments and technique, but none of these had an effect on the development of seismic prospecting comparable to that of Mintrop in his commercial application of the refraction seismic method, and that of the Geophysical Research Corporation in subsequently perfecting that method, and in developing the reflection method.

By 1927 the magnetic method was in extensive use in North America, on account of the relative inexpensiveness of the instruments and of the magnetic surveys, and on account of the deceptive semblance of simplicity in observation with the magnetic variometer.

By 1931, in North America, the refraction method had successfully finished its task of rapidly discovering all the salt-domes which rise above a depth of 5,000 ft. in the Gulf Coast; it had not proved well adapted to prospecting for deep salt-domes or for mapping other structures than salt-domes; the use of the seismic method was still increasing; the use of the torsion balance had dropped slightly, chiefly outside of the Gulf Coast of Texas and Louisiana; the use of the magnetic method had greatly decreased; after many trials the American oil companies discontinued the use of the electrical methods as they were found to be inferior to the seismic and torsion-balance methods.

In the meantime, in oil areas outside of North America the Royal Dutch Shell Oil Company and the Anglo-Persian Oil Company had expanded their use of the geophysical methods in practically all areas in which they were working. The Russians were paying much attention to the application of the geophysical methods in oil work. Most large and many small oil companies throughout the world had begun to use geophysical methods.

The second great advance in the petroleum geophysical methods, after their first introduction, was the perfection of the reflection seismic method.

The third great step was the perfection by the Schlumbergers of their method of electrical logging of oil-wells, a method which is not yet fully appreciated, but whose importance will continue to grow.

At the time that this is being written the reflection seismic method, the gravitational method (chiefly the torsion-balance method), and the electrical logging of wells are in extensive use throughout the oil areas and surmised oil areas of the world. A moderate amount of magnetic mapping, and according to report, a certain amount of electrical mapping is being done.

THE SUCCESS OF THE METHODS

The Methods Collectively.

The success of the geophysical methods has been more than sufficient to win them a permanent place among the many methods which the oil geologist must use in prospecting for petroleum. But neither separately nor collectively are they a panacea for the difficulties of the discovery of petroleum. No one of the methods can determine from the surface whether petroleum is present or absent, although after a well has been drilled, the Schlumberger electrical log gives fair criteria for the presence of gas, oil, or salt-water in the sands within the vertical zone which has been logged. The geophysical methods have much in common with the purely geological methods in prospecting for petroleum. In both cases the search for petroleum is made indirectly by mapping geological structure. Each works brilliantly in some areas, moderately well in others, and poorly or not at all elsewhere. And one method may work well in an area or on a problem on which another one of the methods may work poorly; and vice versa. But although limited in scope, the geophysical methods have proved their ability in many areas to reduce greatly the chances against the oil prospector in his hazardous search for petroleum.

The success, but not the use, of the methods will probably reach a maximum within the next few years in North America and Venezuela. A law of diminishing returns applies to the success of practically all geological and geophysical methods; the most easily discovered structures are found first, and then the geologist or geophysicist must work with the more difficult and less definite structures; and in general the increase in his experience and knowledge and in the perfection of his instruments does not

compensate for the necessity of discovering and mapping the more difficult and indefinite structures. The tempo of the search for petroleum is increasing, in spite of the present over-production; and if the oil prospector wishes to continue the discovery of petroleum in the future, he must be willing to drill progressively poorer and deeper prospects and to have a steadily increasing number of failures. Increase in the perfection of the instruments and in the efficiency of the geophysicist is still compensating for the increase in the difficulty of discovering and mapping structure, and will continue to do so on the whole for a very few years more. But then the ratio of successes to failures should begin to drop, although on account of the increased necessity of discovering petroleum, the use of the geophysical methods should continue to increase. The Schlumberger and similar methods of electrical logging may be a partial exception to the preceding postulates. It will be a long time before oil-producing regions are fully drilled, and for a long time every additional well which is drilled and logged electrically will increase the possibility of discovering structure by subsurface correlation and study with the electrical logs.

Seismic Method.

The refraction method had brilliant, almost clairvoyant, success in reconnaissance for salt-domes which rise within 5,000 ft. of the surface in the Gulf Coast of Texas and Louisiana. The brilliance of that work in speed, success, and indifference to the difficulties of marshy and watery terrain probably will never be surpassed anywhere by any method. In that campaign of 1924–30, probably not more than two, and possibly not that many, shallow domes were missed in south-eastern Texas, southern Louisiana, and south-western Mississippi. The method now is known to have been doing good work in detecting the presence of uplift above the deep salt-domes, in spite of the crude technique of that day. The refraction method did good, but not brilliant, work in many other areas of the world in mapping structure and exploring the stratigraphic section in areas without deep wells.

The refraction method has a permanent place in petroleum geophysics. Although out of fashion at present, it may come back into more extensive use for certain tasks. The refraction method in general has definite superiority over the reflection method in determining the seismic section and the major features of the stratigraphic section down to depths of 7,000 ft. in areas without available deep wells, and in following and not jumping key-beds. It is therefore useful in mapping structure, and for some areas and for certain tasks it is preferred by some geophysicists to the reflection method. The technique of the refraction method is capable of further improvement. The technique in general use was designed for rapid reconnaissance of large anomalies and is crude in the light of the modern reflection technique, which is designed to make use of anomalies of thousandths of a second rather than of anomalies of a few tenths to many hundredths of a second. With the increased experience of the geophysicist and with the feasible extended refinement in technique, the efficiency, power, and field of usefulness of the method should be greatly extended.

The limitations to the refraction method are several. The method in general is not practicable for work to depths greater than 7,000 ft., for the costs and the technical difficulties begin to rise rapidly as the distance from shot-point to receiver exceeds 8 miles. The refraction equipment is more bulky and more difficult to handle than the reflection equipment in areas where continuous transportation by boat or automobile is not practicable; and the service of supply of the dynamite is difficult in inaccessible areas. The use of large charges of dynamite in well-settled areas produces many problems in dealing with the people and in the avoidance of actual or alleged damage to property and persons. The costs are greater in the refraction method than in the reflection method, and the efficiency in many types of detail mapping of structure is not as good.

The reflection method has had a brilliant record in the mapping of the top of the Viola (Ordovician) limestone in Oklahoma. The method has yielded fair results in the mapping of most types of petroliferous types of structure in the other oil areas of North America, but its record of success is not so consistent or so brilliant as in the case of the Viola limestone in Oklahoma; and in a few areas reflections are obtained with difficulty. The method works best on smooth structures with low or moderate dips. In thick sections of apparently homogeneous beds, such as those in the Texas–Louisiana Gulf Coast, it leads to good results in picking up usable seismic key horizons at various stratigraphic depths. It works least well on very complicated structure, on faults and badly faulted structure, and on steeply dipping beds. The technique of handling the so-called 'weathered zone' or 'aerated' 'super-water-table', or 'surface low velocity' zone which is strongly developed in some areas, has not been wholly mastered as yet.

Geologically, the reflection method has certain inherent limitations. It is based on the use of the determination of the dip or the depth, or both, of a seismic horizon, or several seismic horizons, at a discontinuous series of points. The reflections from most seismic key horizons do not have any characteristic feature which is distinctive of the reflecting horizon. The correlation of key horizons from one determination point to another in many areas involves the same guessing as in correlation from driller's log to driller's log, if no good lithologic markers and no palaeontologic data are available.

The reflection method has an extensive future before it. The skill of the seismic geophysicist in the application of his method and in the interpretation of its results is still growing rapidly; and in the writer's belief, the science and art of seismic prospecting are still young and will expand greatly in the future.

Gravitational Method.

The gravitational method has had good success, chiefly in the location of salt-domes. Detailed regional reconnaissance with the torsion balance in the Texas–Louisiana Gulf Coast would have discovered all but one or two of the shallow domes actually found by the refraction method on dry land and in most of the marsh country; and at the same time would have discovered the deep domes whose presence was not indicated or was very poorly indicated by the refraction surveys. Moreover the cost would have been less! But the torsion balance could not compete with the seismic method in speed, and in the practical advantage that the geophysicist could survey tracts several miles in diameter without going on them and, therefore, without paying for permission to prospect them.

The gravitational method has had moderate success in mapping non-salt-dome structures such as the Era–Munester–Nocona crystalline Ordovician ridge of north Texas and southern Oklahoma; the other major structures of southern Oklahoma, such as Healdton and Hewitt; the

Hendricks field in Winkler County, Texas, a structure on the top of a massive limestone field; Hobbs in Lea County, New Mexico; Lost Hill, San Joachin Valley, California.

Torsion-balance data which were well taken will never be obsolete as torsion-balance observations, and will be equally as usable as modern observations. The older observations with seismograph, magnetometer, and pendulum are somewhat obsolete in comparison with modern observations.

The pendulum and gravimeter will supplement, but will never replace, the torsion balance as the mainstay of gravitational prospecting under the more skilled interpreters. In areas in which fair torsion-balance results are obtained, the method gives the variation of relative gravity as well as does the pendulum; but the gradient gives a sharper picture of certain types of structure than does the relative gravity; and the differential curvature is particularly valuable in the interpretation of certain structural features; but many interpreters who specialize in gravitational prospecting are not competent to use the differential curvature.

Magnetic Method.

The magnetic method has had a modicum of success and probably is qualified for a slightly larger place in petroleum geophysics than that which is accorded to it at the present time. Magnetic surveys of proper accuracy are not easy to make, and their results are not so easily interpreted as they were commonly thought to be during the American boom in magnetic prospecting several years ago. The magnetic method has a definite field of usefulness in petroleum geophysics. It may be used with success in the detection and mapping of many undesirable volcanic intrusions, which may form the cores of structures; or the so-called 'serpentine' plugs of the Luling district, Texas, whose porous altered volcanic rock is the reservoir rock; or the buried crystalline ('granite') ridges, at least approximately. If a relatively permeable bed of considerable thickness lies at moderate depth below less permeable beds, structural deformation will produce a mappable magnetic anomaly at the surface. The method has the disadvantage that variation of magnetic permeability within the basement, and depositional variation of magnetic permeability in the sedimentary rocks, are greater than the variation of density, so that magnetic surveys show large anomalies of magnetic premeability which have no relation to structure. It is usually impossible to discriminate between the anomalies of structural and those of non-structural origin, at least by simple inspection. However, analysis and approximate calculations may throw some light on this matter. An advantage of the method is the ease, quickness, and cheapness with which a magnetic survey of a whole region can be made. A regional magnetic survey supplementary to extensive torsion-balance and seismic surveys is relatively inexpensive, and yet may give valuable additional information about the framework of the regional structure and possibly may give clues to local structures. The author is inclined to recommend a regional magnetic survey to supplement an extensive regional reconnaissance with the torsion balance.

Electrical Methods.

The electrical methods (inclusive of the electromagnetic methods, but exclusive of electrical logging of wells) have been shown to be moderately successful in the mapping of geological structures in prospecting for petroleum. As the result of extensive trials with the methods, the American geophysicists have come to the conclusion that in combined efficiency and cost the electrical methods are inferior to the seismic and torsion-balance methods. The electric methods have found little place in petroleum geophysics in America. They probably would have been of service, however, if the other methods had not been available. Considerable use of the methods is reported from Europe, but the author has no unbiased information in regard to the actual value of the results which have been obtained. The difficulties in the use of the electric methods increase with depth.

Electric methods have been advertised as capable of directly locating petroleum in advance of drilling. But as yet these claims do not seem to have been substantiated. According to the author's belief, some one or more of the methods may prove to be capable of mapping crudely the presence of petroleum deposits at a few hundreds of feet of depth in specially favourable areas, but in general, in most areas, and at moderate or great depth, the electrical or electromagnetic methods will not be able to map the presence or absence of petroleum.

The Schlumberger method of electrically logging wells is showing a high degree of success. Experience with it is still immature. The instruments, the technique of their use, and the interpretation of the electric logs are still being perfected. The limits of the field applicability of the electrical logs have still to be determined. The method has shown great power (*a*) in providing data for stratigraphic correlation, and (*b*) in detecting oil and gas sands, and in discriminating between them and salt-water sands. The electrical log has the advantage over the ordinary driller's palaeontological log in being continuous and not dependent in general on cores at more or less frequent or infrequent intervals, and in being independent of the presence or absence of fossils, particularly key fossils, within the relatively small space of a recovered core. Some of the author's colleagues, who have had much experience with the method, are discussing whether it may not be advisable (*a*) to abandon coring in the first wildcat and to depend upon the electrical log to detect the presence of oil and gas sands, and (*b*) to core only after production has been obtained, in order to identify the electrical key horizons, but as yet no one has adopted that practice. The power of the method to indicate oil and gas sands is known to be high, but how high is still a question which must wait for experience.

Other Methods.

Various further methods of less importance such as surveys of radio-activity and of earth temperature have been tried. Relations between the variation of earth temperature and structure have been demonstrated. None of these minor methods as yet, however, has been shown to be of practical, commercial importance.

The use of new and unconventional instruments, or methods, should be regarded sceptically by the oil prospector until the instrument or method has been approved, at least tentatively, by competent petroleum geophysicists (not all practising geophysicists in good standing will be competent to pass judgment). Useful new instruments and possibly a useful new method or two will be devised in the future. But in addition to instruments and methods which are faulty in principle, many instruments and methods will be proposed to the prospector which are almost good enough, which basically are sound in scientific theory, but which cannot attain the precision of measurement necessary

for the purpose for which they are devised and for which the oil prospector would use them.

Black Arts.

The success of the 'Black Arts' methods—witchwands, wigglesticks, dowsing, human reactions to mysterious rays or emanations—to find petroleum (or anything else) has still to be demonstrated to the satisfaction of the geophysicist in spite of the great antiquity of some of those methods. Wells which have been located by one of those 'Black Arts' methods, to be sure, have discovered deposits of oil and gas. But many wells which were located entirely by chance have discovered oil- and gas-pools also; an important West Texas oilfield, Big Lake, for example, was discovered because of a break-down of the transport equipment; the well was drilled at the place of the breakdown, while a subsequent test-well at the original location was dry. The geophysical methods are based on known scientific theory and data, and can be, and have been, repeatedly justified to and accepted by disinterested physicists. The 'Black Arts' methods postulate the existence of rays, emanations, attractions which either are unknown to science, or which postulate properties other than those which they are known by science to have. The whole basic theory of those 'Black Arts' methods is scientifically unsound. The practitioners of the 'Black Arts' methods rarely have consented to proper scientific tests of their methods; in the few tests under proper scientific control, the methods have not detected petroleum or thrown light on geological structure.

ORIENTATION IN A NEW AREA

Geophysical orientation in regard to an area is as necessary to the geophysicist as geological orientation is to the geologist. Many executives and geologists make the mistake of failing to realize that a geophysicist cannot go into a new area, about whose geophysical make-up he knows nothing, and begin immediately to turn out competent interpretation of structure. In an area about which he knows little or nothing, the geologist must spend some time in a preliminary study of the stratigraphic section and of the general geological framework of the region before he will feel himself competent to attempt the mapping of particular structures. In the same way, the geophysicist requires time to orient himself geophysically in a new region. As with the geologist, there are a few areas in which certain anomalies stand out so clearly and definitely that the geophysicist may feel justified in their immediate interpretation. But in general the seismic geophysicist must work for some time in an area before he can make reliable interpretation of his data. He may have to make several trials before he learns the trick of getting usable reflections. He must then work out his seismic section and learn, if possible, what usable seismic key horizons are present, how to recognize them apart, how persistent they are, and whether there is danger of a mistaken jump from one to the other among some of them. The seismic geophysicist and the stratigrapher are much alike; the speed and sureness of each in his correlation increases with his knowledge and experience in the area. It may take the seismic geophysicist several months, a year, or even longer, to get the hang of working the area. In gravitational and magnetic prospecting a wide areal reconnaissance survey of the region is necessary before the geophysicist can begin to make intelligent interpretation of particular features.

Geophysical orientation depends greatly on geological orientation; and the geophysicist usually needs some knowledge of the geology of the area in order to choose between various interpretations which are equally possible mathematically. In an area where the geology is little known, the geophysicist may have to wait for the drill to check his predictions and to help him to complete his orientation.

It is most important for the petroleum prospector to realize that the geophysicist is not clairvoyant and cannot dash into a new area and begin immediately to turn out competent mapping of structure.

CHOICE OF METHOD

The oil prospector should endeavour to fit his choice of method, or methods, to the particular problem in hand, with due regard to the general situation and to the money and time which he has available. The methods selected must be suitable for the area and for the immediate problem. The prospector's choice will be guided also by the technical advice of the geophysicist.

The range of tasks to which geophysical surveys may be applied is wide, for example: (*a*) regional reconnaissance to map the structural framework of a large area; (*b*) regional reconnaissance of a relatively virgin area to determine the more conspicuous structures; (*c*) more local clean-up reconnaissance of the less conspicuous structures in an area in which much geological and geophysical exploration has already been completed; (*d*) surveys to prove, or disprove, the presence of some local structure; (*e*) surveys to detail known structures; (*f*) surveys to check inconclusive suggestions of structure by other methods; (*g*) research surveys; (*h*) guerrilla sharp-shooting on competitor's prospects; (*i*) logging of formations and of oil and water sands in wells.

The physical problem before the survey is a factor of paramount importance in the choice of the method. The geophysicist must decide what types of structures are to be expected, and the kind of physical situation that will arise. For example, salt-domes may occur under a variety of conditions; thrust through an enormous thickness of unconsolidated sand; rising through limestone, sandstone, or anhydrite; surrounded by sediments of relatively high magnetic permeability; or resting on anticlines of diatomaceous or other shale. Physical conditions have a wide range of variability also, in such cases as—buried ridges of granite, or limestone, or shale; faults, folds, and intrusions. The geophysicist must not only decide what physical situation is to be expected, but how sharp and intense the respective anomalies in magnetic permeability, in density, and seismic velocities will probably be. If the anomaly of only one of those types of physical situations will be definite, only the corresponding method can be used; the so-called 'serpentine' 'plugs' of the Austin district of Texas, for example, are detected efficiently only by the magnetic method. But many types of structures produce workable anomalies of more than one type, and therefore, more than one method can be used; reconnaissance for shallow salt-domes in the Gulf Coast, for example, is feasible either by the torsion balance or by the refraction method. The same situation may require different methods in order to obtain information on specific points. The torsion balance, for example, is superior in reconnaissance for deep salt-domes in the Gulf Coast, but the reflection method is superior in detailing the deformation on horizons within the range of producing depth. Again, the refraction method

was a most brilliant success in rapid and efficient reconnaissance for shallow domes, but the torsion balance was superior in detailing the crest of the dome.

The terrain technically precludes or limits the application of a method or methods in certain areas, and economically affects their use in varying degrees. The seismic method is the only one of the methods which works essentially with equal technical success on land, on marsh, and in water. Torsion-balance surveys have been, and can be, made in shallow bodies of water, if the necessity for the data justifies the expense. A magnetic survey in the same way can be made under those conditions, but the author doubts whether the cost of such a magnetic survey would ever be justified. Too rugged relief precludes torsion-balance work; and the differential curvature is more easily affected than is the gravity gradient. The seismic method does not work well in some areas in which the so-called 'weathered' (or 'aerated' or 'low velocity') surface velocity zone is strongly and irregularly developed. The terrain, of course, greatly affects the ease, and thereby the costs, with which surveys by the different methods can be made. A magnetometer is carried easily wherever a man can go. The transportation of the torsion balance is much more complicated under unusual conditions of terrain, but is entirely feasible even if everything has to be transported by porters. The transportation of the reflection equipment is a little more complicated than that of the torsion-balance if the equipment cannot be permanently mounted on wagons or boats, but is entirely feasible. But the difficulties of service of supply of dynamite for the refraction method might easily preclude use of that method in difficult country. The lie of the land, furthermore, may limit the geophysical surveys, which may be possible along valleys through rugged mountains, but may be impossible on the mountains. Over a large area of the Llanos of Venezuela the linear north-west to south-east pattern of the drainage makes surveys in a north-east to south-west direction difficult or impossible except at very much greater cost than surveys parallel to the rivers.

Cost is necessarily a most important factor not only in the choice between methods, but also in the decision whether or not any geophysical work shall be done. The probable cost of the work must be weighed in terms of the expected value and usefulness of the results of the work to the prospector. The cost of such work must not be greater than that of some other method of prospecting which will produce results of equal value to the prospector. Several shallow wells, for example, can be drilled on a poor geological prospect at the same cost as a good geophysical detail survey, and if the producing sands are shallow those wells may not only prove the prospect, but, if dry, give as much positive evidence of the structure as the geophysical work. The cost of a reasonably good survey must be within the appropriation which the company has, or can reasonably make, for that purpose; the geophysical work, therefore, must be planned to keep the costs within the financial resources and policy of the company; and a small company may not be able to afford the more expensive methods, even if the probable results would be of high value. The usefulness of the results must be weighed against the cost of the survey, but even if the probable value of the results is low, a survey at low cost may be worth while in order to supplement other geophysical work, for the additional information may furnish one or two clues which will more than repay the expense of a low-cost survey.

Different types of cost must be considered. The gross cost must be used in fitting the geophysical work to the available appropriation and to the financial resources and policy of the prospector. The cost per barrel of oil which is discovered by the method is the ultimate test which will be applied by the average prospector. The cost per structure which is discovered by the method is a technically fairer test of the methods, for with the exception of the method of electrical logging of wells, the methods map structure and not the presence or absence of oil. The cost per acre is valuable in comparing different methods, but care must be taken not to compare cost per acre for reconnaissance by one method with cost per acre for detail work by another method. Speed at times may be more important than cost per acre, and the important cost will be a function of the reciprocal of the time necessary to work a prospect. The gross cost of the refraction seismic method in the Gulf Coast of Texas and Louisiana in reconnaissance for shallow domes, for example, was high, $15,000 to $20,000, per month per party, but the cost per acre was extremely low, although probably not so low as that of reconnaissance with the torsion balance for deep salt-domes and for the roots of shallow domes. But on account of the very great speed of the refraction method—in some cases more than 50,000 acres were covered efficiently in a day—the slightly higher cost per acre in comparison with the torsion-balance reconnaissance was of negligible importance.

Time may be a factor of paramount importance. Concessions and options run only for a limited period of time, which may be very short; and even if the term of the exploratory option be indefinite, the annual or semi-annual payments necessary to maintain the option may preclude time-consuming geophysical exploration. Highly competitive conditions may preclude the use of the necessarily slow-moving torsion-balance method and force the use of the seismic method for reconnaissance of prospects which are not controlled by the company.

One or more of a number of minor factors may have to be considered.

The use of dynamite or any high explosive is taboo in certain countries; or at times of unrest in other countries, its use might be put under too onerous restrictions and regulations for seismic prospecting to be practicable. Popular fear of the damage from the dynamite shots may cause the political banning of seismic exploration in certain jurisdictions.

The patent situation in one country restricts the prospector's choice, unless he comes to terms with the single licensee and believes in the latter's ability and experience with the modern developments of the method.

For some methods and for certain purposes permits to go on a tract are necessary in order to survey it, whereas by another method the survey of the tract can be made without going on it. In the refraction campaign for shallow domes by reconnaissance, in the Texas–Louisiana Gulf Coast, a shooting permit would be obtained for a tract of 20 to 50 acres, if possible; the detectors would be set along the edge of the public roads, and hundreds of thousands of acres would be covered without getting any sort of permit except on a few hundred acres. The gravimeter and magnetometer can in general work along public roads in reconnaissance without going on private land. Torsion-balance stations in general have to be set back away from the ditches and grading of public roads, and therefore have to be set on private land, and permits have to be obtained.

The secrecy with which a survey can be made may be of

importance; the little white torsion-balance houses which have to stand for 4 to 8 hours on a station are most conspicuous; but a gravimeter that works in an ordinary light delivery truck, and which requires from 5 to 10 minutes for the occupation of a station, can work along roads almost wholly unnoticed.

The question whether the possibilities of surface geological work have been reasonably exhausted should be carefully reviewed by the oil prospector. An exceptionally able (company) geologist and two assistants can be kept in the field for a year for the approximate cost of operation of a seismic reflection crew for 6 weeks. A structure based on good surface geology in general is preferable to most geophysical structures (but not all), and good geology may give good but inexpensive reconnaissance clues to structural features, which can be investigated by geophysics. The able geologist may need 6 months or a year to work out his stratigraphic section and criteria to split it into recognizable small units. He and his assistants may not be able to turn out tangible results inside of a year. A seismic crew may (or may not) be able to bludgeon in, pick up a key-bed, and check a prospect in its first 6 weeks in the area. But by the end of the year, the geologist in general will have covered more area than the reflection crew, at a lower cost. Surface mapping for structure is, of course, wholly barren of results in some areas, and in other areas is extremely slow and tedious.

PHYSICISTS, GEOLOGISTS, AND GEOPHYSICISTS

A distinction should be drawn between the physicist, the physicist-geophysicist, the geologist-geophysicist, and the geologist, and their relative functions in, and relations to, geophysical prospecting. Petroleum geophysics is a science which lies between physics and geology, and which uses physical devices to work geological problems. It has two differing types of tasks: the first, inventing and bringing to a workable degree of perfection instruments, techniques, and formulae for solving certain types of geological problems by physical means; and the second, applying those instruments, techniques, and formulae to the working out of particular geological situations.

The physicist-geophysicist ideally differs from the physicist proper in his additional knowledge of geophysical physics, and in an elementary acquaintance with geology. His particular function is the solution of new geophysical problems. Functioning as a geologist-geophysicist, he has the disadvantage that like all elementary students of science he has an over-simplified impression of that science and fails to recognize the many complications, difficulties, and uncertainties which are actually present. The physicist-geophysicist for a long time will have an important place in petroleum geophysics, for the instruments and the physical technique are capable of much further development.

The geologist-geophysicist ideally differs from the geologist in his additional training in mathematics, physics, and geophysics; and he differs from the physicist-geophysicist in being primarily a geologist rather than primarily a physicist, but as a matter of fact, he must be a pretty fair physicist. His particular function is the application of the geophysical methods to the practical working out of particular geological situations. Men of such special qualifications, unfortunately, are extremely scarce. Interpretation in practice is done by geologists who have had insufficient mathematics and physics, or by physicist-geophysicists who have had insufficient geology.

The petrographer is a practical example of how the relations of the physicist and geologist have worked out in one branch of science, which, however, has been geological so long that its geophysical nature has been forgotten. Both petrography and the seismic method, by the use of appropriate physical instruments and technique, draw certain conclusions in regard to the constitution of some section of the earth's crust. The petrographic microscope is as distinctly a physical instrument as the torsion balance, magnetometer, or seismograph. The theory of petrography involves as much (or more) mathematical physics and physics as the seismic, magnetic, and gravitational methods. The petrographer, the man who applies this geophysical method to the study of geological problems, is not a physicist, but is a geologist who has had special training in the physics, mathematics, and special technique and theory of petrography.

The geophysicist most likely to be successful in the long run, will be one like the petrographer, who is primarily a geologist, but who has had sufficient physics and mathematics to understand the physical mathematical theory of the geophysical methods and instruments. He must have been trained also in the special technique and theory of those methods and of the instruments which he uses. No geologist would think of attempting petrographic work with a physicist at the microscope and a geologist at his side to make geological interpretation of the former's physical determinations. The often recommended combination of a physicist in charge of the application of the geophysical methods and a geologist to make geological interpretation of the former's physical findings seems to the writer equally inefficient.

Geophysicists are of many grades; not all who term themselves, or are termed, geophysicists, are such, and not all men with long experience in geophysics are competent interpreters. In making use of geophysics, the oil prospector will be wise to ascertain what sort of geophysicist the man is whom he would employ. The most competent geophysicist, like the geologist, is not omniscient, but in general he is well aware of the difficulties and uncertainties of geophysics, and of the inadequacy of his knowledge. A competent physicist is not necessarily a competent geophysicist or geophysical interpreter, and his physically plausible interpretation may be highly improbable or impossible geophysically, and geologically. A geologist who has had a superficial contact with geophysics may be misled by the seductive resemblance of magnetic and gravitational isogams to structure contours, and may make an interpretation of magnetic or gravity survey which is plausible geologically but wholly impossible geophysically.

Field observers in geophysical work may be highly competent field observers of long experience, but that does not necessarily make them competent interpreters. They often are not aware of how much they do not know about geophysics. There are many 'practical' interpreters, perhaps engineers or geologists, who have attained considerable ability in interpretation through long and broad experience, without having learned much about the underlying theory. Their interpretation of stock solutions is good, but will tend to become inadequate in novel situations. The dowser and the fake, keeping abreast of the times, commonly, nowadays, term themselves geophysicists, and advertise their usually exclusive methods as 'geophysical' methods, even sometimes in the professional cards of reputable technical journals!

CONCLUSION

The applied geophysical methods will be found of great value to the petroleum prospector who uses them intelligently and wisely. They will not remove all difficulties in locating petroleum. If he mistakenly persists in regarding them as a panacea and in attributing clairvoyant powers to them, he is doomed to disappointment in the results of his use of them. But they definitely have shown their power greatly to reduce his difficulties in locating petroleum under a wide range of conditions. The methods as a whole have certain limitations, and each one of the methods has its individual limitations. If the prospector keeps this in mind in his use of the methods, he will tend in the long run to be abundantly satisfied with the results of his geophysical surveys. The methods employed are still young and their limits of applicability have not been fully established; the prospector must remember that those limits can be established in general only by pushing the application of the methods until they fail; and he must also remember that the utility of the methods in a new area in general can be learned only by trying them out. Reasonably good results have been obtained in areas which in advance looked rather unfavourable; and conversely, the methods have given poor results in areas in which good results might be expected. The most important single factor in the successful use of the geophysical methods is, of course, the geophysicist; and the prospector who in the long run will have the best success in his use of the geophysical prospecting will be the one who chooses his geophysicist the most wisely and carefully. And the geophysicist who will have the best success in the application of geophysical prospecting in the long run should be the one who is a geologist of broad training and experience, a fair physicist, and a geophysicist with good training in the theory of the method and with wide experience in its application.

MAGNETIC METHODS

By W. P. JENNY, Ph.D.
Consulting Geologist and Geophysicist

Introduction

In the light of present knowledge it seems permissible to assume that the magnetic field of the earth is induced somehow in connexion with its rotation and that the magnetic axis of the earth would coincide with its astronomical axis, if it were not for the varying chemical distribution (especially iron-content) and the tectonic dislocations within the magma-zone and the rock-zone of the earth [13, 1933; 29, 1934].

In agreement with the above assumption, the earth's magnetic field may be resolved mathematically into a 'normal' field, with its axis coinciding with the rotational axis, and a residual 'anomalous' field. The 'anomalous' field is found as the vectorial difference between the measured field and the 'normal' field at the respective latitude.

A magnetic vector which is directed away from the earth will be called a negative vector; a vector directed towards the earth, a positive vector; and a vector which has a horizontal direction, a neutral vector. Then a magnetic positive anomaly exists where the vectorial difference between measured and 'normal' vectors is a positive vector, and a magnetic negative anomaly exists where the vectorial difference is a negative vector.

The 'anomalous' field is composed of major positive and negative magnetic anomalies which extend over vast areas of the earth. It is interesting to note that the main trends of these major anomalies show a striking parallelism with the main trends of the alpine orogeny. Thus a positive major trend, which extends through the two Americas in a north-north-west to south-south-easterly direction, runs parallel with the Rocky Mountains and the Andes; a negative major trend, which extends in a west-easterly direction through Africa and the Indian Ocean, swings southwards through Australia, running parallel to the alpine trends of Eurasia and Australia.

Within the area of a continent part of a major anomaly may be designated as a continental anomaly. Thus Europe is magnetically negative, the two Americas are magnetically positive.

Considering the average continental field as 'normal' for a continent, there are large areas of a magnetically more negative or more positive character with reference to that field. Such areas are called regional anomalies. Thus the West Texas Permian Basins or Transylvania are negative regional anomalies; the California Valley or Wallachia are examples of positive regional anomalies.

Taking the average regional field as 'normal' there exist as a rule more localized magnetic disturbances, and these in turn may be further disturbed by intra-local anomalies. A granite ridge, for example, which creates as a whole a local anomaly may be faulted, and thus the 'normal' course of the local anomaly may be disturbed over the fault by an intra-local anomaly.

The major and continental magnetic anomalies are of interest in connexion with theoretical considerations about the nature of the magma-zone and its relation to the rock-zone; the regional anomalies disclose the tectonics and the petrographical character of the rock-zone, and the local anomalies lead to detailed investigations of a tectonic, petrographic, and stratigraphic nature within the uppermost layers of the earth.

Geological and Physical Problems in the Interpretation of Regional and Local Anomalies

Magnetic Susceptibility of Rocks.

The geological interpretation of regional and local magnetic anomalies is based upon the fact that the rocks which constitute the outer crust of the earth vary greatly in their magnetic susceptibility.

The average magnetic susceptibility of basic igneous rocks and of some magnetite-bearing crystalline schists is generally assumed to be from 10 to 100 times stronger than the average susceptibility of sedimentary deposits, granites, and of the majority of metamorphosed rocks [25, 1930].

It is, however, fundamentally wrong to assume that magnetic anomalies are almost exclusively due to igneous rocks. Igneous rocks ('Basement') are buried at depths ranging from 6,000 to over 20,000 ft. in the oil regions of the United States, for example, and the magnetic effect of local structures is about inversely proportional to the square of their depths.

Unfortunately, only a few data about the susceptibility of sedimentary deposits are available to-day. However the susceptibility of some dolomites is from 20 to 50 times weaker than that of some blue shales or ferruginous sandstones; and the susceptibility of limestones is very low if compared with that of shales and sandstones.

Moreover the magnetic susceptibilities of rocks seem to be considerably stronger in the weak magnetic field of the earth than in the strong laboratory fields [27, 1929], and, with increasing temperature, (depth), the magnetic susceptibility increases in such weak fields [7, 1934, p. 160; 30, 1911].

Even though the susceptibility in itself is small, such large relative differences in the susceptibilities of the shallower sediments should fully suffice to create magnetic anomalies clearly discernible with modern instruments, especially if the 'Basement' lies at great depths.

Since this conception is not yet generally accepted, we are glad to cite a few references which strongly support these views.

Weiss [31, 1934]: 'The application of the magnetic method in the Witwatersrand has met with considerable success, especially in the locating of Post Karroo dykes and in determining the approximate location of the sub-outcrop of three very strongly magnetic shale beds in the lower Witwatersrand system: the Water Tower Shales, Contorted Beds, and West Rand Shales. By means of these magnetic key-beds it is possible to delineate indirectly the zone of the approximate position of the Main Reef. The above three magnetic markers can be detected even if they are covered with 1,000–2,000 ft. of younger sediments, and consequently the magnetic method is of great

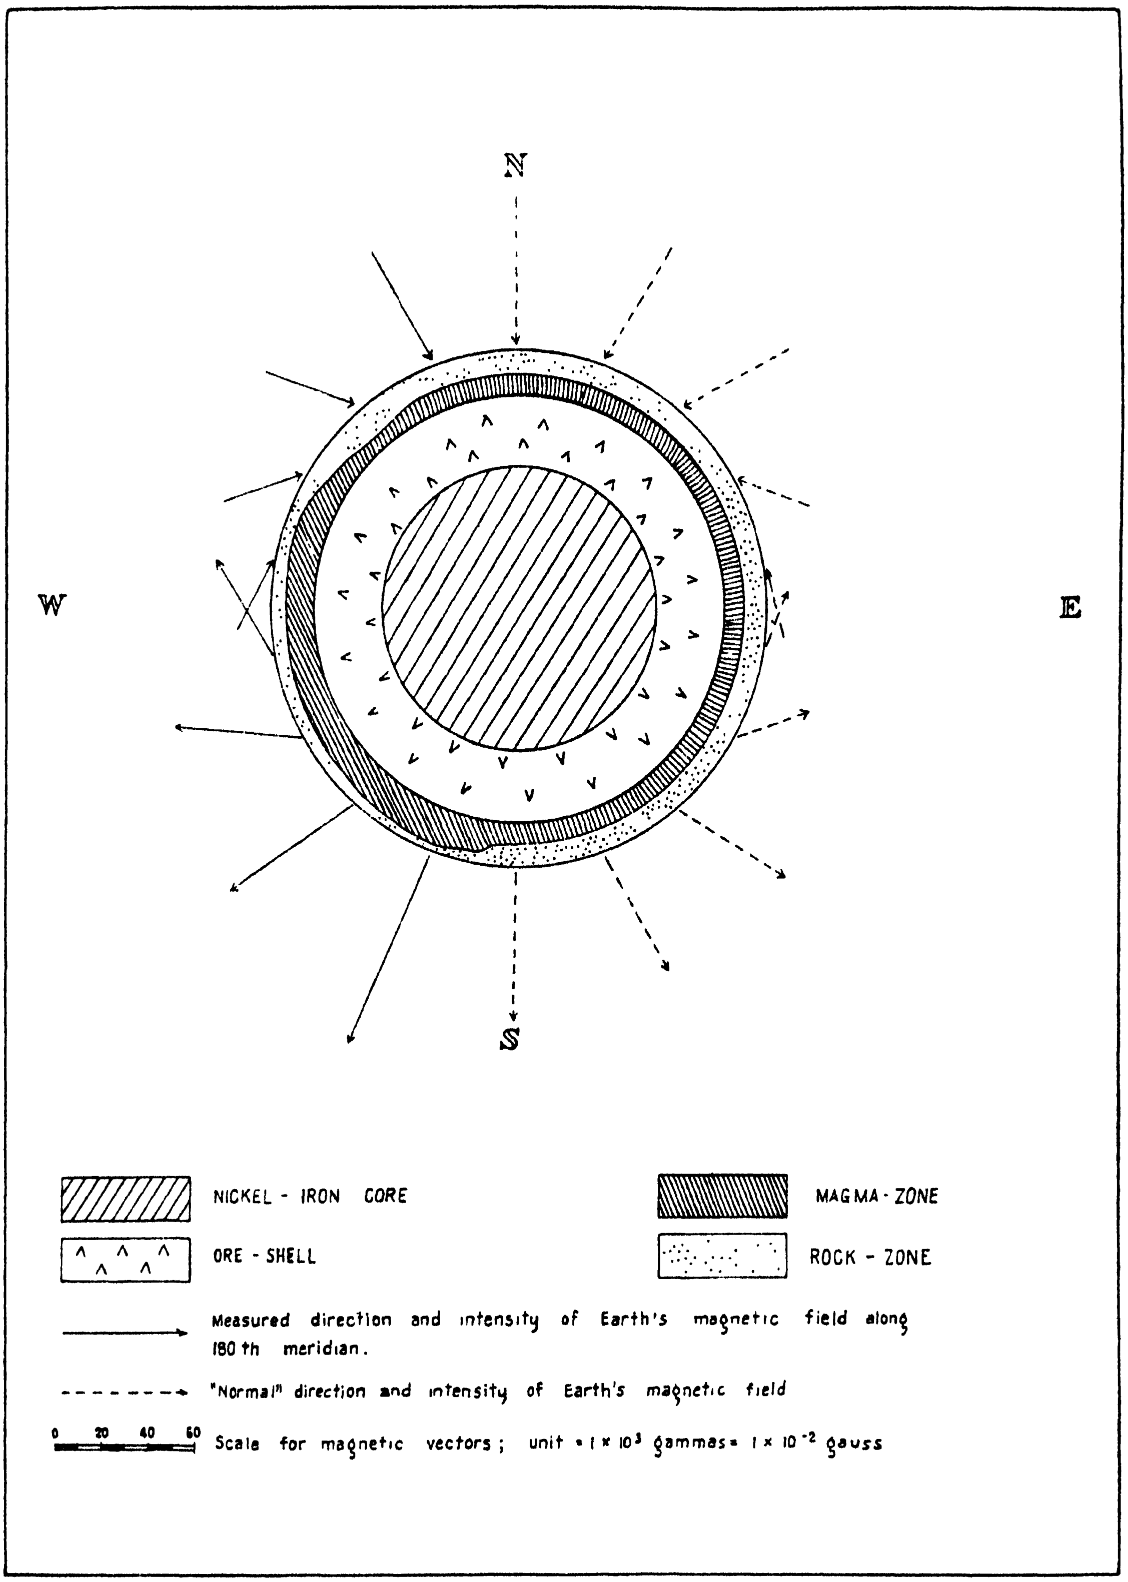


FIG. 1. Structure of the earth, 'normal' and measured intensity and direction of the earth's magnetic field.

value in prospecting areas, where Karroo beds and Dolomites rest unconformably on the Witwatersrand system.' Lynton [22, 1931]: 'General conditions for the use of magnetic geophysical methods in California are good, as there is marked variation in the magnetic susceptibility of the sedimentary rocks of economic interest. In Tertiary rocks, the magnetic susceptibility varies from 14×10^{-6} in the Saugus of the Upper Pliocene to 412×10^{-6} in the vivianitic sandstone of the McKittrick group of the Pliocene. This variation is sufficient to give a definite

magnetic contrast at several horizons. "Magnetic marker beds", such as this vivianitic sandstone, beds of volcanic tuff, and interbedded basaltic flows, extending throughout considerable areas, have been found, which are sufficiently thick and magnetic to cause anomalies of several hundred gammas at surface exposures and recognizable indications under deep cover.'

Rieber [26, 1930]: 'Certain strata in the more recent fresh-water deposits of the Tulare Series, in the San Joaquin Valley, California, which contain material only slightly more magnetic than the adjacent strata, show sufficient magnetic anomalies in the vicinity of known faults and folds to give promise of extensive usefulness of magnetometer surveys in the exploration for oil.'

The basic idea, prevalent in former years, that the magnetic effect is due almost exclusively to the chemical properties or the tectonic dislocations of the 'Basement' rocks underlying the oil areas, has led to many misinterpretations and has in many places discouraged magnetic prospecting, first, because under this assumption the station net was laid out on a too wide scale and therefore would not permit the location of anomalies due to shallow, local influences; and secondly, because the field measurements were not sufficiently accurate.

Stratigraphic, Petrographic, and Structural Anomalies.

Magnetic anomalies may be produced by lateral variations in the ferruginous content of a sedimentary bed, by lateral differentiations of igneous rocks, by thickening or thinning, or by the normal dip of a certain magnetic horizon. Besides these anomalies of a petrographic or stratigraphic origin, magnetic anomalies may be due to structural features. A magnetic shale bed may be brought close to the surface on the up-thrown side of a fault. Practically non-magnetic dolomites may be uplifted along an anticlinal axis and thus displace stronger magnetic shales and sandstones. A nephelinsyenite plug may intrude into much less magnetic sedimentary beds, or old igneous ridges may be covered by sedimentary deposits of a much smaller magnetic susceptibility.

Relationship between Depth and Size of a Disturbing Mass and its Magnetic Anomaly.

It is evident that the lateral extent and the amount of a magnetic anomaly must have some relation to the magnetic susceptibility, size, depth, and structural arrangement of the rocks which produce it.

A number of methods have been developed for the geological interpretation of magnetic anomalies. Though there are a large number of possible theoretical interpretations for any anomaly, yet geological conditions will, as a rule, restrict this number to only a few probable solutions which are compatible with the generally known subsurface conditions.

Lee's Graphical Method. Lee [20, 1932] has published an elegant graphic method for the calculation of the horizontal and vertical magnetic intensity, particularly above dykes and other related geometrical forms. From Lee's study it follows that an extended thin horizontal magnetic layer theoretically has no magnetic effect along the surface of the earth, and that the magnetic effect of an extended infinitely thick horizontal magnetic layer is constant for any depth of the upper boundary of this layer.

Nippoldt's Method. The study of Nippoldt's method [23, 1930], which is based upon a sequence of magnetic poles, is most instructive and elucidates the relationship of structural features with their respective anomalies.

Nippoldt begins with the basic formula:

$$F_E = \frac{P}{r^2},$$

where F = magnetic force, exercised by
P = magnetic intensity of a single pole;
r = distance between the single pole and point E of observation.

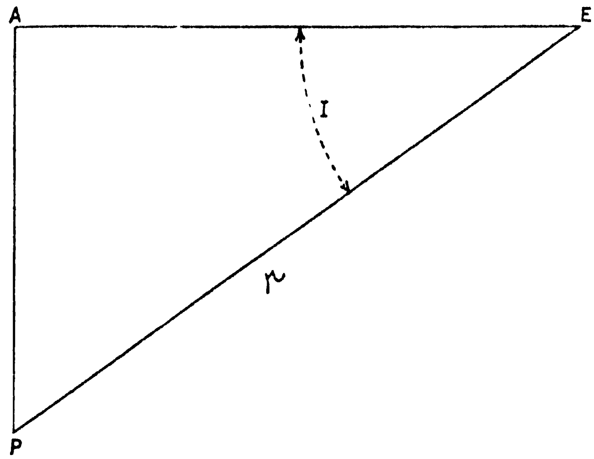

FIG. 2.

If I = angle between r and the horizontal,
Z = vertical component of magnetic force F,
H = horizontal component of magnetic force F,

then $Z = F \sin I$ and $H = F \cos I$.

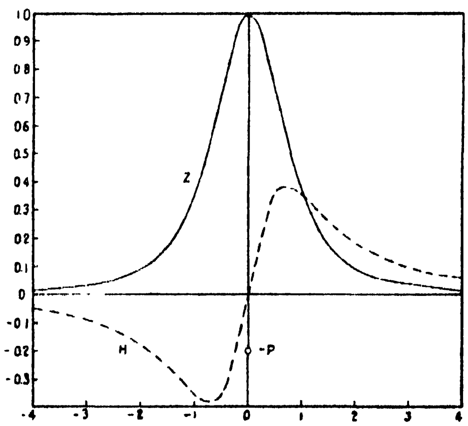

FIG. 3. (After NIPPOLDT.)

Fig. 3 shows the curves for the vertical and horizontal magnetic intensities which are produced along the surface by a unit pole, buried at unit depth. The maximum intensity is directly above the pole and is taken as unity. At about the unit horizontal distance the vertical intensity amounts to about ⅓ of the maximum intensity, whence the old depth rule: The depth to the origin of a magnetic disturbance is equal to the distance between the centre of the magnetic anomaly and the points, where the anomaly is ⅓ of the maximum at the centre.

Fig. 4 shows the curves for the vertical and horizontal magnetic intensities along the surface due to two poles, of which the negative pole is buried at unit depth and

the positive pole at 3 times unit depth. Owing to the negative influence of the lower pole both the Z- and the H-curves are of smaller amplitudes than those of the unit pole.

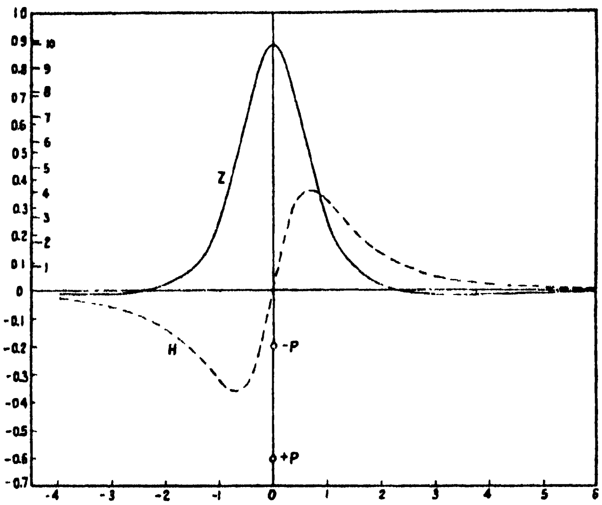

FIG. 4. (After Nippoldt.)

Fig. 5 shows the magnetic curves for a system of pole-couples arranged so that the negative poles lie along the upper side of an inclined plate and the positive poles along the lower side. Such an arrangement should closely approach the actual magnetic influence of a continuous magnetic layer.

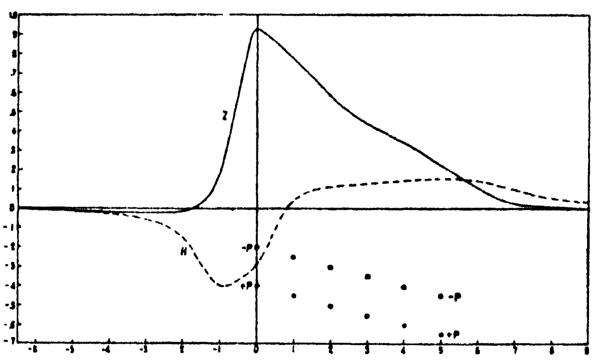

FIG. 5. (After Nippoldt.)

Induction by the Earth's Magnetic Field.

Beds with a high magnetic susceptibility will, as a rule, create positive magnetic anomalies in the northern hemisphere, but occasionally the outcrop of a highly magnetic bed may be characterized by a negative anomaly. Until recently, electrical earth currents, permanent magnetization, &c., were used to explain this phenomenon, though already four decades ago it was correctly assigned to the effect of induction by the earth's magnetic field [6, 1897], the direction and intensity of which are shown in Fig. 1.

Since the rocks are subject to induction by the earth's magnetic field, it follows that, according to the dip and strike of a given ferruginous bed, or on account of its magnetic latitude, various magnetizations may be induced.

Fig. 6 shows the induced polarity of surface outcrops of magnetic bodies in various positions in the earth's field. Broderich [2, 1918] explains that a neutral bar of a magnetic substance, placed parallel to a magnetic field, acquires an induced polarity (*a*), such that the positive pole would be near that end of the bar, to which a free-moving north-seeking pole in the field would move. As the bar is rotated from the parallel position, the polarity becomes related more to the sides and less to the ends, until finally, when the bar is perpendicular to the field, it is entirely related to the sides (*f*). However, if the bar is turned but a few degrees from the perpendicular position, the ends will show some polarity.

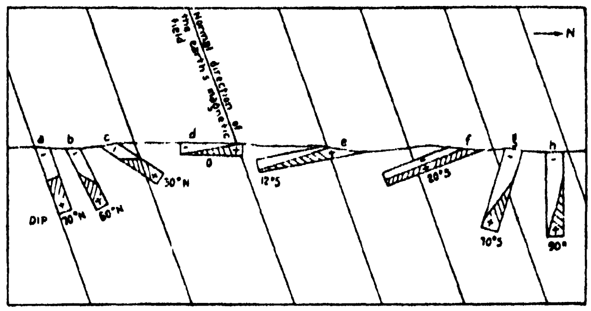

FIG. 6. Induced polarity of surface outcrops of magnetic bodies in various attitudes in the earth's field. (After Broderich.)

Fig. 7 shows schematically the curves of the vertical magnetic intensity over a granite ridge with different orientations and latitudes [15, 1934].

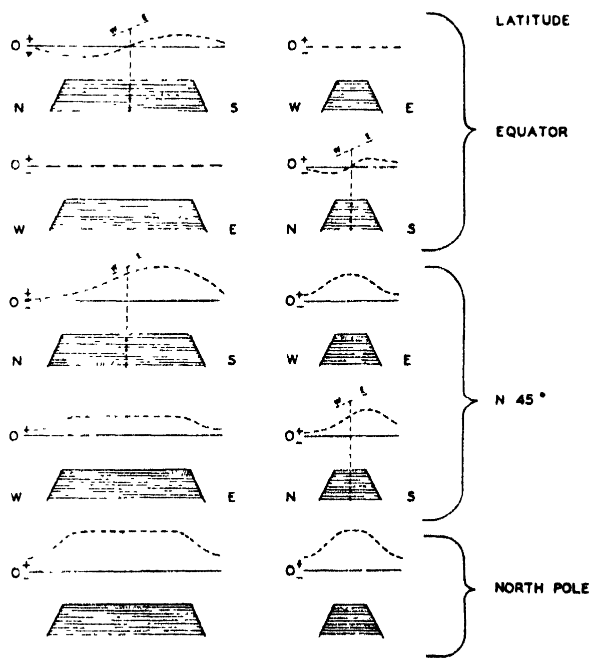

FIG. 7. Schematic curves of vertical magnetic intensity over Granite Ridge with different orientations and latitudes.

Haalk's Method. According to present conceptions, the direction and intensity of magnetization of geological bodies is generally due to the induction by the earth's magnetic field.

Haalk [7, 1934] has developed a method of interpretation of magnetic anomalies which takes into account the direction of the inducing earth's magnetic field. The method is based upon the theorem of Poisson, and makes use of an analogy between the gravitational and magnetic potentials. In this way magnetic interpretation is closely allied to the gravitational torsion-balance methods [5, 1908]. The

drawbacks of Haalk's method, especially for irregular geological bodies, are the assumption of homogeneous magnetization and the tediousness of calculation.

Fig. 8 shows the vertical and horizontal intensities calculated by Haalk for a magnetic dyke which dips (*a*) parallel and (*b*) at right angles to the earth's magnetic field, having an inclination of 45°.

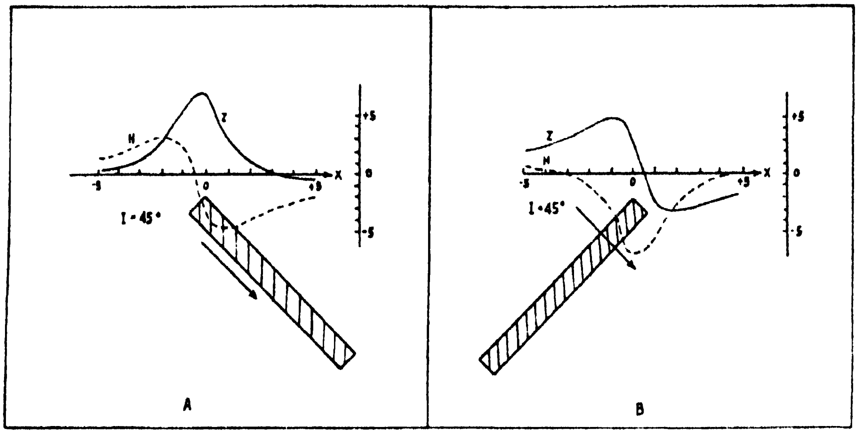

FIG. 8.

Instruments and Methods for Magnetic Observation

Absolute Measurements.

The direction and intensity of the earth's magnetic field is defined by any three of the seven elements shown in Fig. 9.

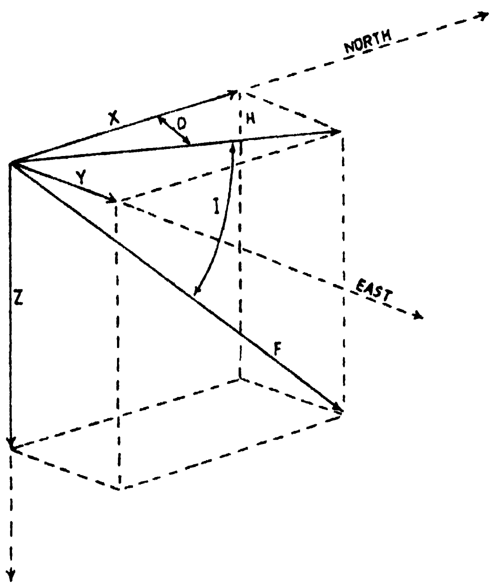

FIG. 9. *D* declination. *I* inclination. *F* total intensity. *Z* vertical intensity. *H* horizontal intensity along magnetic meridian. *X* horizontal intensity along true meridian. *Y* horizontal intensity perpendicular to true meridian.

As a rule *D*, *I*, and *H* are measured; the other four elements are computed from the observed data. *I* is observed with a dip circle or with an earth inductor, *D* and *H* are measured with a magnetometer of special design. The essential part of this magnetometer is a hollow cylindrical magnet which hangs in a horizontal position in a stirrup suspended by a silk fibre or fine metal ribbon. The declination is the angle between true north, as determined by the north star or magnetic north found by the sun, and the cylindrical magnet. From the time of oscillation of the cylindrical magnet and the amount of deflexion produced on an auxiliary magnet, the total horizontal intensity may be computed. A detailed account of the instruments and methods used for the absolute measurements of the earth's magnetic field is given by Hazard [9, 1930].

Relative Measurements.

Applied geophysics is, however, primarily interested in instruments and methods for the relative measurement of the earth's magnetic field. In order to survey in a simple and speedy manner local disturbances of the earth's magnetic field, special instruments (magnetic local variometers) have been designed. The oldest instrument of this type is the Swedish mining compass, which was used as early as the seventeenth century for the location of iron-bearing formations. The old dip-needle has more recently been perfected into the Hotchkiss Superdip. The old Thalen-Tiberg magnetometer and the Lloyd balance have been replaced by the Askania magnetometer, devised by A. Schmidt in 1915. The Askania magnetometer has been gradually improved during the past decade to such a point that it is generally considered to-day as the leading instrument. Heiland [10, 1926; 11, 1929] gives a detailed account of the theory of this instrument, and a simple derivation of the working equations is given by Lester [21, 1928].

In Fig. 10 is shown a cross-section through the Askania magnetometer for vertical and horizontal measurements.

The essential part of this instrument is the swinging system. It consists of a cubical metal block carrying two thin magnets (blades), adjusting screws, and a mirror. The whole system oscillates about a quartz knife-edge, resting on semi-cylindrical agate bearings.

For the measurement of the vertical magnetic intensity a horizontal balance is used, and for the horizontal magnetic intensity a vertical balance. The sensitivity of the instrument may be increased by approaching the centre of gravity of the swinging system to the fulcrum by means of the adjusting screws on the metal block.

Since the magnetic force along the earth's surface varies from place to place, the balance will be deflected one way or the other from a certain initial position determined at a base station. The deflexions are measured by means of an optical system. From the constant of the instrument and the amount of deflexion, the differences of the magnetic vertical or horizontal intensities with respect to a certain base station may be found. In different latitudes, or above large magnetic disturbances, the swinging systems may be brought back to their horizontal or vertical positions by auxiliary magnets, which may be placed below the instruments.

The horizontal magnetometer measures the horizontal magnetic intensity along the magnetic meridian. If the direction of the magnetic meridian varies between two stations, this variation is brought about by a horizontal force which is at an angle with the magnetic meridian. Of such a force only the component along the meridian is

measured by the horizontal magnetometer. In order to find the east-west component of the total horizontal variation, we have to measure the variation of the declination between the two stations.

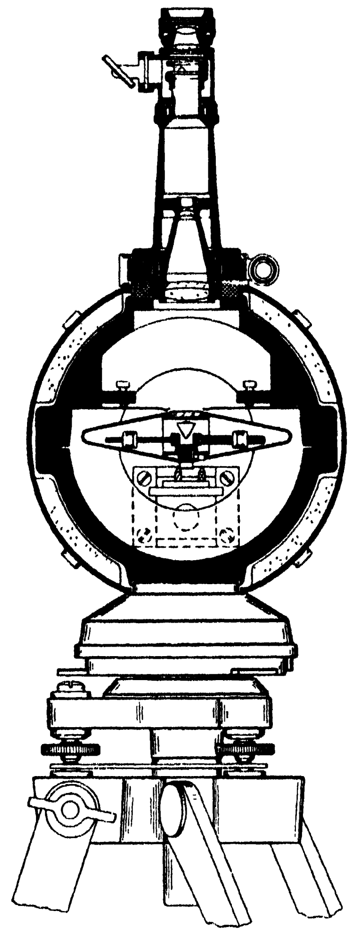

FIG. 10. Askania Magnetometer.

From Fig. 11, where

H_B = total horizontal force at base station,
H_{II} = total horizontal force at second station,
H_T = total horizontal variation (vector) between base station and second station,
H_M = horizontal component of H_T along magnetic meridian of second station,
H_D = horizontal component of H_T at right angles to meridian of the second station,
δ_D = angle between the two meridians, in radians.

then for small angles:

$$H_D = \delta_D \times H_B \quad \text{and} \quad \sqrt{(H_D^2+H_M^2)} = H_T;$$

if $H_B = 40{,}000$ gammas, $\delta_D = 10'$, or $\pi/1{,}080$ radians, then $H_D = 116$ gammas.[1]

Measurements of the declination are made by means of theodolites, which contain a very sensitive horizontal magnetic needle. The angles, α_1 and α_2 between the magnetic needle and the line connecting the two stations are measured at both stations. The variation of the declination is then found by the relation (Fig. 12):

$$\alpha_1+\alpha_2 = 180+\delta.$$

Field Procedure.

The magnetic stations may be arranged along profiles or in a network, according to the accessibility of the terrain, or the purposes of the survey. If only large magnetic anomalies are looked for, the field work is relatively simple and can be done speedily. Utmost care must be taken,

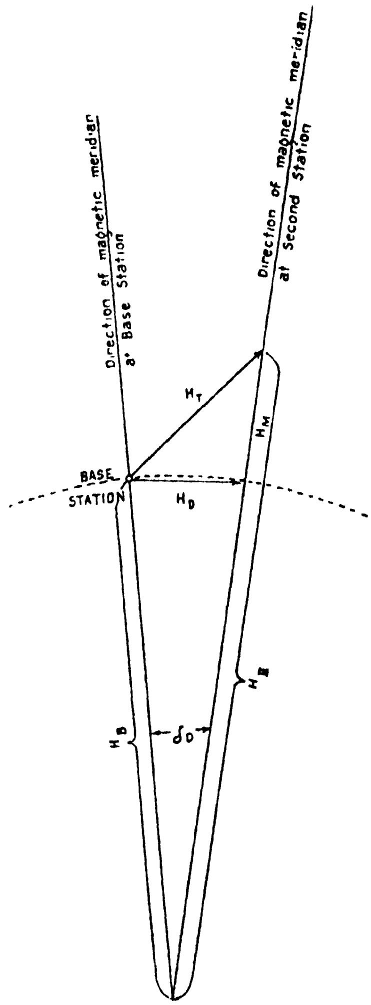

FIG. 11.

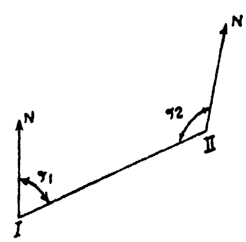

FIG. 12.

however, to locate small anomalies, ranging from 10 to 30 gammas, which have been found to indicate structures within the sedimentary column of the oil regions. Unfortunately, the observer is often under the spell of a large local or regional anomaly and neglects small variations of the magnetic intensity. Such minor variations may, however, prove to be of much more economical significance than the large anomalies, as is schematically explained in Fig. 13.

It is best first to cover the area under investigation by an equally spaced net of vertical intensity measurements and to supplement them later, if necessary, by typical profiles, along which all three magnetic elements are measured. For purely qualitative investigations the vertical intensity measurements will, as a rule, suffice; for quantitative investigations all three elements should be observed, if possible, over the whole area.

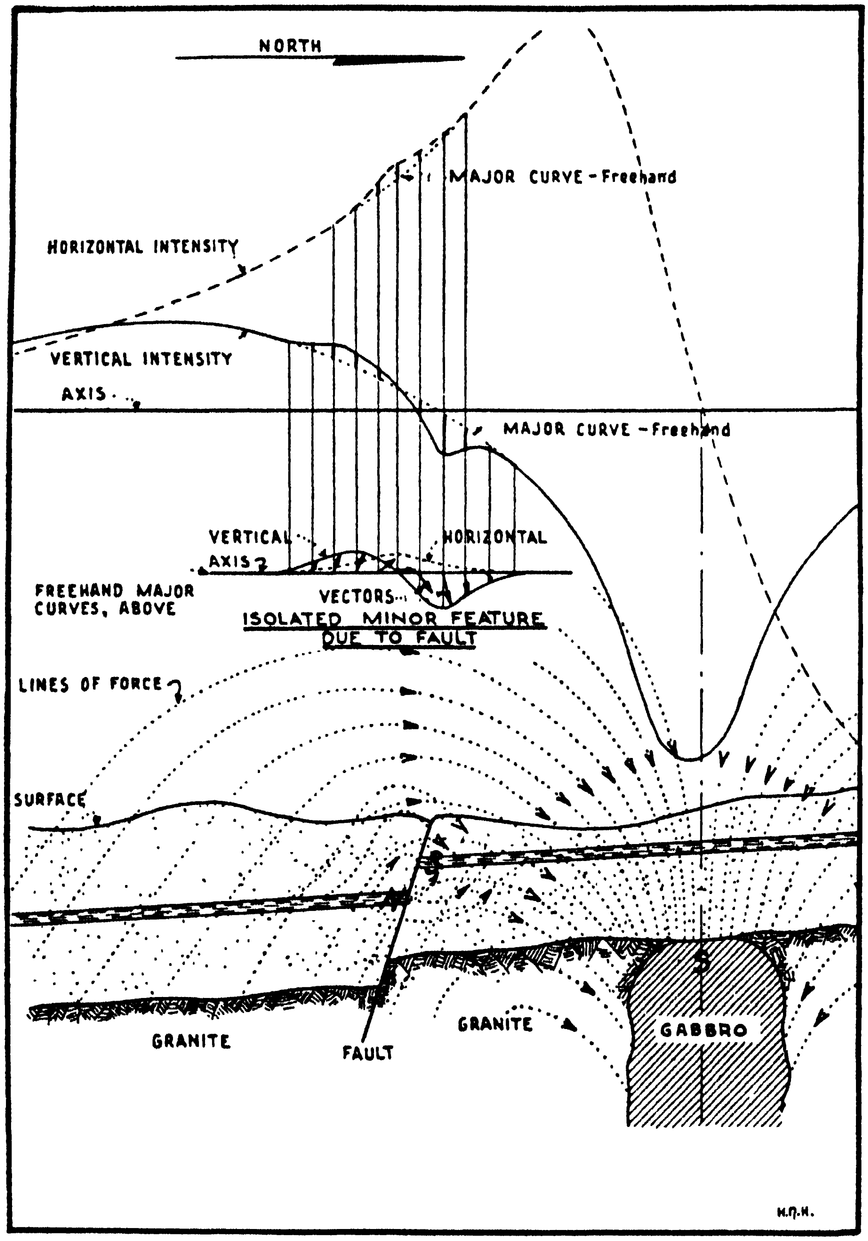

FIG. 13. Separation of local and intra-local magnetic anomalies. (After Lynton.)

To the field data a number of corrections must be applied:

(1) *Diurnal Variations.* The vertical magnetic intensity is subject to daily fluctuations. In the northern United States, for example, it is strongest at noon, when, in the southern States, it is weakest. The variation ranges from 10 to 30 gammas. The declination and the horizontal intensity are subject to similar fluctuations. Though the monthly average of these fluctuations is fairly constant, they may greatly vary from day to day, or, on the same day, from station to station. It is best to eliminate the daily variation by observing a number of stations repeatedly during the day.

(2) *Magnetic Storms.* Besides the periodic daily fluctuations, irregular and often sudden disturbances may affect the earth's magnetic field. They may amount to 300 gammas for the vertical intensity.

(3) *Normal Variation.* Due to the earth's magnetic field, there is a normal increase of the vertical intensity with latitude, which amounts for Texas to about 15 gammas per mile. Similar variations occur in the horizontal intensity and in the declination.

(4) *Temperature Variation.* In the latest type Askania instruments the influence of temperature variations upon the balance system has been eliminated for practical purposes. In the older type instruments it is corrected with the diurnal variation. For declination measurements it may be eliminated if two instruments are used simultaneously.

Magnetic Vector Method for the Representation and Interpretation of Magnetic Anomalies.

Deduct from the measured absolute values of the vertical and horizontal intensities and from the declination at a certain station the respective values of a 'normal' field. The differences between measured and 'normal' vertical intensities, south–north horizontal intensities, and west–east horizontal intensities may be represented by a magnetic vector in space [12, 1932]. The size and direction of this vector are dependent upon continental, regional, or local anomalies, all according to the definition of the 'normal' field.

Fig. 14 represents a cross-section through two anticlines separated by a syncline, and demonstrates schematically the paths of the magnetic lines of force and the local magnetic vectors as due to the local 'structures' only, after the 'normal' magnetic field of the earth has been eliminated. The total local vector is resolvable into two components —the local vertical and the local horizontal vector.

In order to determine the components for the vectors the local magnetic curves are smoothed to form terrestrial curves. The 'normal' values, as interpolated between the terrestrial curves, are then subtracted from the observed values at the respective stations. The differences represent the regional or local anomalies of the vertical and north–south horizontal intensity and of the east-west horizontal intensity.

For a clearer understanding, let it be assumed that the magnetic effects of the two anticlines and the syncline are

equivalent to the effects of two negative ($-P$) poles and one positive ($+P$) pole, as shown in Fig. 14.

Above the negative poles the local magnetic intensity is directed perpendicularly downward towards the poles (positive vector). Above the positive pole the magnetic intensity is directed perpendicularly upwards, away from the pole (negative vector). Along the surface, half-way between the positive and negative poles, the two vertical tendencies compensate each other and only a horizontal component remains, directed from the positive towards the negative pole (neutral vector). Between the vertical and horizontal directions of the intensity there occurs a gradual change, as shown in the diagram. As long as the vector is still directed downwards, it may be called a positive vector; if the direction is upwards, a negative vector.

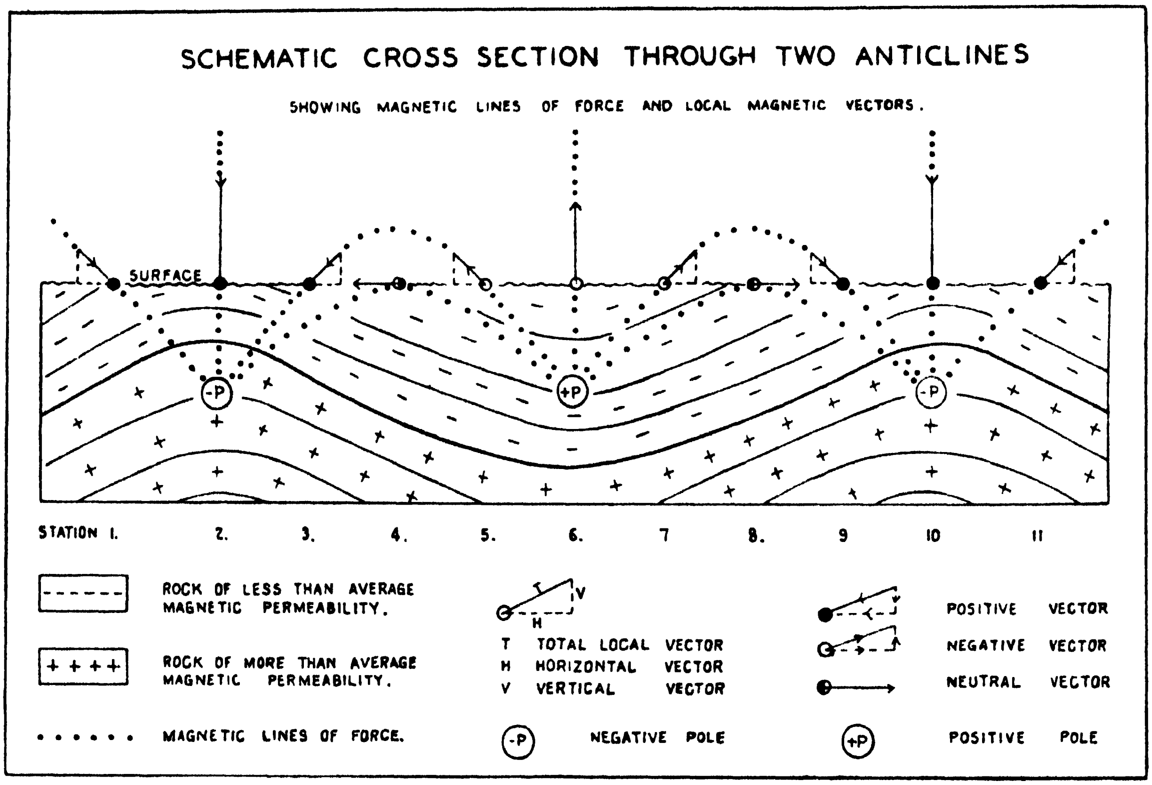

FIG. 14.

Magnetic Vector Maps.

The local magnetic vectors may be plotted at their respective stations on the maps in the shape of vector triangles, if each triangle shown in Fig. 14, is turned through 90° around its horizontal component, which is represented by the dashed lines beginning at the station point.

The representation of the anomalous magnetic local forces by vector triangles is of decided advantage, especially if the distance between stations is great, which is the case for most of the magnetic surveys made by the different States.

In the United States, in European and other countries, extensive absolute magnetic surveys have been made by the Surveys of the respective countries. The distance between the station points of these surveys varies from 10 to 50 miles.

Extensive studies of the anomalies of the vertical intensity, as revealed by these surveys, and their correlation with geology have been made [19, 1933; 24, 1927; 28, 1928–9]. But though a definite connexion between broad structural features and magnetic anomalies of the vertical intensity could be made, such studies could only incidentally yield any information about the more local or semi-regional type of structure, because the distances between the magnetic stations were far too large.

It is quite evident that two, three, and more magnetic 'highs' and 'lows' may occur between stations placed at such distances, and the lines of equal vertical magnetic intensity, drawn on the basis of such stations, as a rule veil, rather than set forth, smaller magnetic anomalies, which are of particular interest to the commercial geologist.

A study of Fig. 14 will make the previous statement clear. It might happen that stations 1 and 11 had been occupied by the State Survey. As both stations have the same magnetic vertical intensity, they lie on the same isogam which would pass over the entire structure without indicating any change. The same would happen if also stations 3 and 9 had been surveyed. Any other combination of the vertical intensity of two or three stations would give widely varying indications of some anomaly. Most of the 'structures' which create local anomalies, however, lie at depths ranging from 2,000 to 15,000 ft., and their magnetic effect is felt within a horizontal distance from the edge of a 'structure' of only about twice its depth. Therefore it is reasonable to assume that, within a distance of 10–50 miles, only one station is occupied, as a rule, on a particular 'structure', and there is little use to combine the measurements of the different stations unless broad structural features are suspected.

Contrary to the opinion of some magneticians, the writer holds that with such large distances between stations much more detailed information may be obtained by studying the horizontal intensity than by studying the vertical intensity, and thinks that this is confirmed by a study of the

horizontal intensities in Fig. 14, especially if it be realized that the anomalies are three-dimensional.

The best information is, of course, obtained by a combination of the horizontal and vertical intensities to form a magnetic vector in space. The magnetic anomaly at Grand Rapids, Michigan [16, 1934], offers an example for the vectorial representation of both local and regional magnetic anomalies.

The United States Coast and Geodetic Survey [8, 1925] has made observations of the magnetic elements at the county seats of the State of Michigan and also at seven auxiliary stations near Grand Rapids.

In studying this vector map, it should be considered that, as shown in Fig. 14, there exists somewhere along the prolongation of the horizontal vector either a magnetic 'high' or 'low', which corresponds to some kind of geological feature of structural or petrographical character.

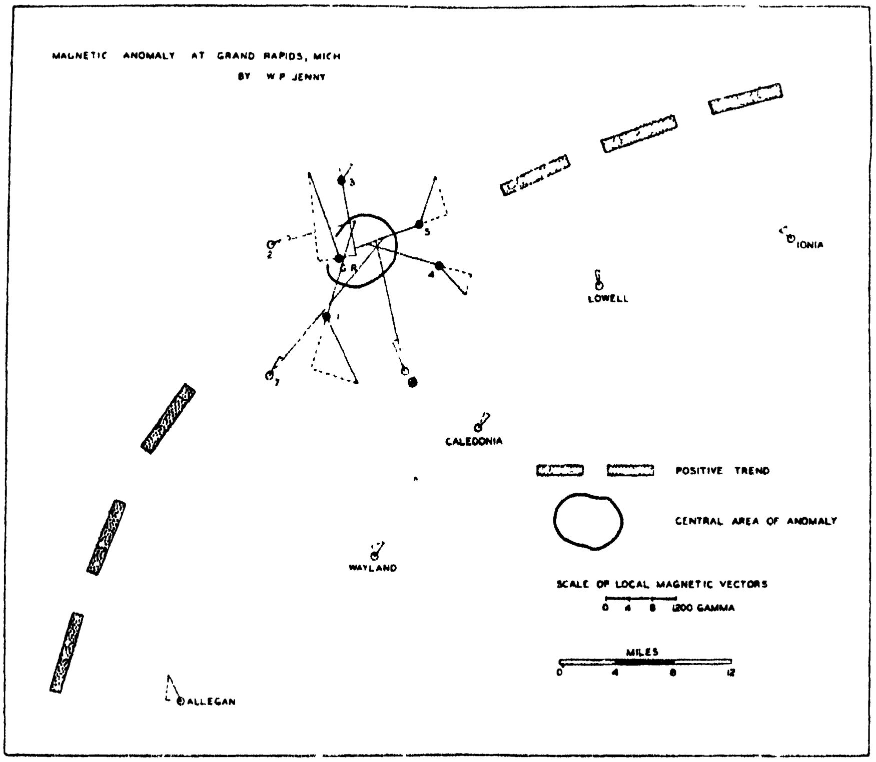

FIG. 15.

Due to the long distances between some of the stations, it is necessary to use the most probable geological interpretation. Though two, three, or more local 'highs' and 'lows' are possible between two neighbouring stations, it is probable that regional geological structures extend at right angles to the horizontal magnetic components, where the majority of the latter are nearly parallel to one another over a large area; or a common geological feature is probably responsible for a series of vectors if they are all directed towards or away from the same point.

The horizontal components of the negative vectors at Allegan, Wayland, Caledonia, Lowell, and Ionia are directed towards the west, north-west, and north, and thus indicate magnetic positive anomalies along a line of magnetic positive trend, as shown in the diagram. Along this regional trend occurs the large positive anomaly of Grand Rapids. The vectors at Grand Rapids and at the seven auxiliary stations all point towards a positive area with its centre slightly east of Grand Rapids. It seems safe to interpret this anomaly as a large domal uplift along a regional anti-clinal trend.

The vector maps assist in the first place in the investigation of regional magnetic anomalies. If the original data are of sufficient accuracy, valuable detailed information may, however, be gained from each individual vector.

It is to be regretted that the accuracy of the magnetic stations as observed by the Surveys of the respective States is not always adequate to our purposes, as is seen, for example, from a comparison of the local vectors along the Gulf Coast [12, 1932] with the magnetometer map of this area [17, 1934], or of the regional magnetic map for southern Bavaria [1, 1934] with the respective vectors [14, 1933], which are based on Nippoldt's data [24, 1927].

Experimental Interpretation of Magnetic Anomalies.

The representation of the anomalous magnetic local forces by vector triangles is also of decided advantage for interpretation purposes.

If magnetic interpretations are made by the methods of Nippoldt or Haalk, there are three main reasons which explain the additional difficulties encountered in the interpretation of magnetic anomalies as compared with the interpretation of gravimetric anomalies.

In the first place, the induced magnetic field is so highly dependent upon the angle between the strike of the magnetically active structure and the direction of the inducing field that the same structure, according to its strike or geographical location, may yield entirely different magnetic anomalies (Figs. 7, 8); secondly, the specific gravity of rocks may be determined with a much higher degree of accuracy than their magnetic susceptibility; thirdly, the assumption of homogeneous magnetization applies only to bodies limited by surfaces of the second degree.

But since, in contradistinction to the gravitational field, the magnetic field may be surveyed by relatively simple means in three dimensions, the above-mentioned drawbacks are largely counterbalanced. This circumstance has not yet been taken into due consideration.

In the case of homogeneous masses the *size* of the magnetic vector in space is proportional to the *susceptibility* of a given mass, whereas the *direction* of the vector is dependent upon the *shape* of such a given mass [7, 1934; 23, 1930].

This point leads to results of considerable importance for the geological interpretation of magnetic anomalies, because it is possible to determine by relatively simple experiments the relationship between the direction of the magnetic vectors in space and the shape of a magnetically active structure.

Interpretation for Vertical Direction of Inducing Field. Regional magnetic anomalies will in many instances be the

result of the tectonics of the 'Basement' complex, which may be compared with an extended magnetic plate of large thickness supposedly cut into a series of vertical magnetic columns, or bar-magnets. These in turn may be displaced vertically so as to imitate tectonic dislocations of the Basement, such as anticlines, synclines, faults, grabens, &c.; it is possible thus to examine the influence of such tectonic features upon the direction in space of the respective vectors. In reality the problem will mostly be just reversed, i.e. the direction of the magnetic vectors will be determined through measurements in the field, and the tectonics of the underground deduced from the direction of these vectors.

Fig. 16 represents a cross-section through an apparatus indicating the qualitative and quantitative interpretation of magnetic anomalies, if the direction of the inducing earth's magnetic field is assumed to be vertical.

The vertical bar-magnets, representing segments of the 'Basement', for example, are first set to scale at the normal depth of the 'Basement'. The 'normal' effect thus produced upon the dip-needles is compensated by counter-weights on the negative side of the freely suspended needles, so that they are all horizontal. The bar-magnets are next displaced along the vertical until the various dip-needles assume the direction in space as before measured in the field and indicated by the respective pointers below the needles. The depth to the poles may then be read from the ribbons by which the bar-magnets are suspended. By connecting the depth readings of the individual poles, contour lines may be constructed on the looked-for structure, which is represented by an anticline in the figure.

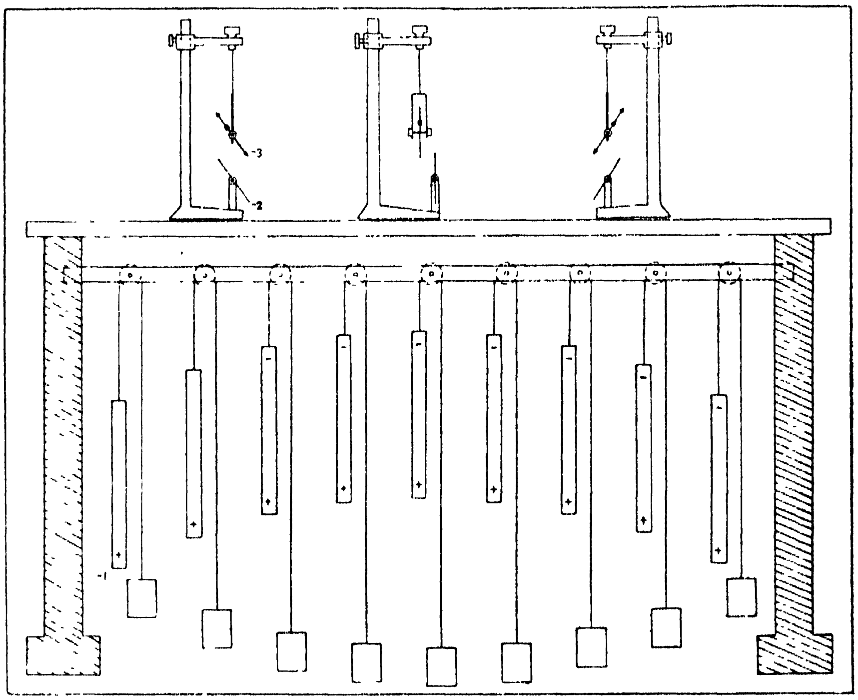

FIG. 16. Apparatus for the experimental interpretation of magnetic anomalies for vertical direction of inducing field.

1. Bar-magnets representing, for example, segments of the 'Basement' complex. 2. Indices, giving the direction of the anomalous local magnetic force as measured in the field. 3. Dip-needles, assuming the direction of the respective indices, after the bar-magnets are adjusted to represent local structure.

Interpretation for Optional Direction of Inducing Field. In practice the interpretation of magnetic anomalies is quite complicated, first, because the direction of the earth's magnetic field differs from the vertical, as was assumed for the inducing field of Fig. 16, to an extent depending on the latitude, and secondly, because there usually exists above the 'Basement' complex a series of layers with varying magnetic susceptibilities.

An artificial magnetic field approaching the actual conditions may be created by placing the apparatus within an electrically induced magnetic field with its axis parallel to the earth's magnetic field.

The determinations of the absolute magnetic susceptibility of the different layers above the 'Basement' complex offers great difficulties, but it is relatively easy to estimate their relative susceptibilities. The direction of the local magnetic vector is alone determined, so that it is sufficient to know the relative susceptibilities. Such a method has advantages over other methods which aim at the geological interpretation of magnetic anomalies on the basis of relative vertical or horizontal intensity measurements.

In Fig. 17 the bar-magnets are replaced by more or less continuous layers of a plastic material which has been mixed with iron particles, in proportion to the relative magnetic susceptibility of the respective layers in the stratigraphic column of the area under investigation. The layers have been cut into segments, which may be displaced in a vertical direction. The apparatus is placed within the homogeneous field of a large coil, as indicated in the figure. The direction of the induced field is parallel to the earth's magnetic field of the respective area.

First, all the layer-segments are placed to scale at normal depth, and the 'normal' influence of the horizontal layers and of the artificial homogeneous field upon the dip-needles is compensated. Next the layer-segments are individually raised or lowered until the dip-needles all assume the directions in space as measured before in the field and indicated by their respective indices.

This experimental interpretation takes into due account the inhomogeneous magnetization of a structure and the polarizing effects produced by the various directions of the earth's magnetic field.

These models have been devised as an aid to the solution of problems encountered in structural geology, but they may prove of value in some mining problems.

Practical Examples

Garber and Oklahoma City Fields.

As examples of magnetometer work in the oil regions of the United States there are shown the magnetic profiles and geologic cross-sections for the Garber field (Garfield Co.) and the Oklahoma City field (Oklahoma Co.), both in the State of Oklahoma.

Both structures lie along the southern extension of the

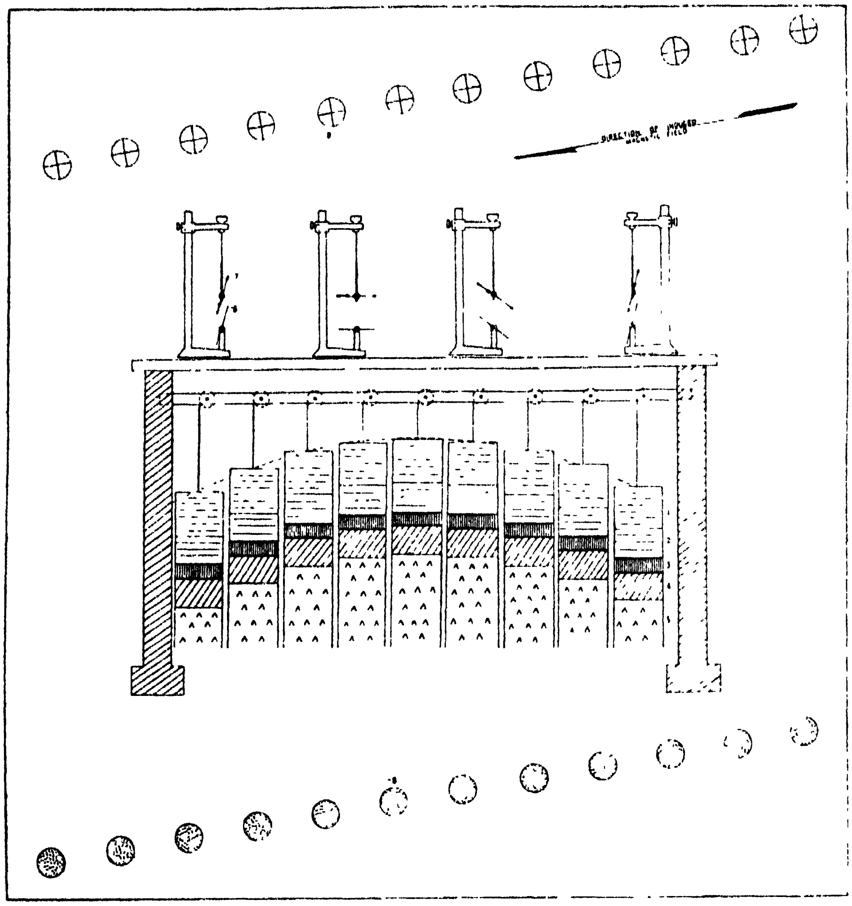

FIG. 17. Apparatus for the experimental interpretation of magnetic anomalies for optional directions of the inducing field.

1–5. Layers of plastic material mixed with iron particles in proportion to the relative magnetic susceptibilities of the represented subsurface layers. 6. Indices, giving the direction of the anomalous local magnetic force as measured in the field. 7. Dip-needles, assuming the direction of respective indices, if layer-segments are adjusted to represent local structure. 8. Coil for the induction of the artificial inducing field.

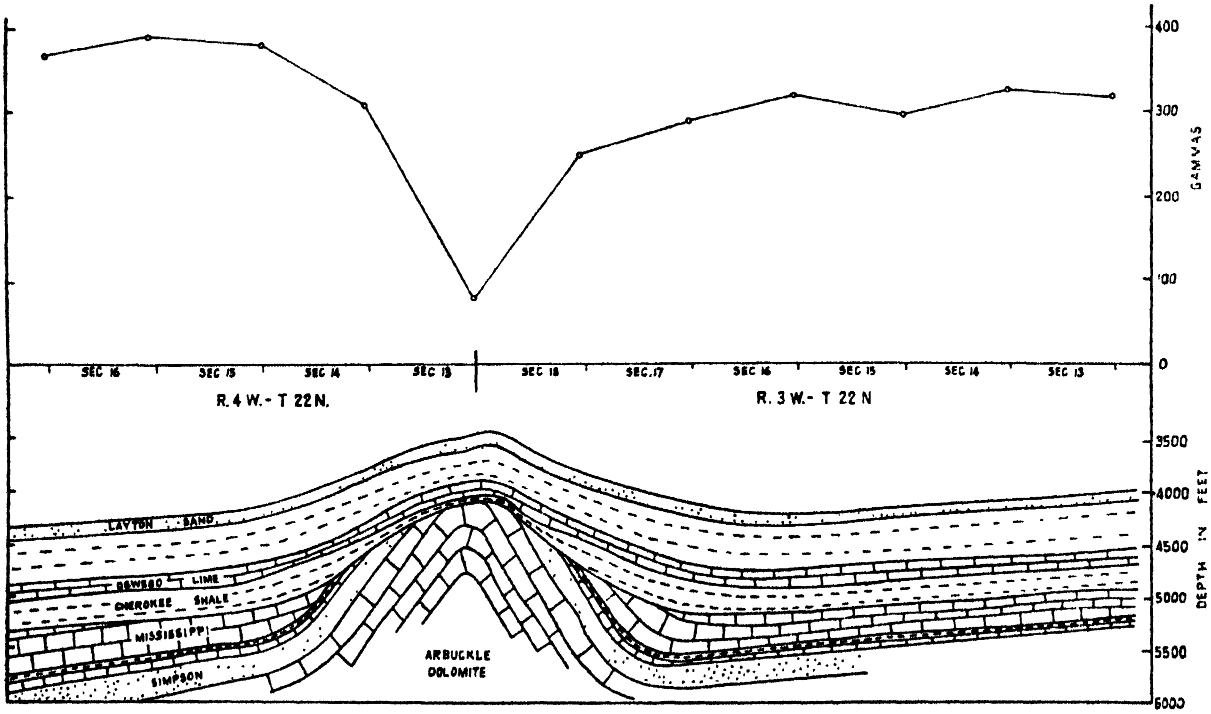

FIG. 18. Profile of vertical magnetic intensity and geological cross-section across the Garber field. (After Spraragen.)

Nemaha granite ridge, which extends in a south-south-westerly direction across the State of Kansas. Results of deep tests in the Garber field have indicated a relatively thin section (1,250 ft.) of Arbuckle limestone on top of the pre-Cambrian granite, and similar conditions may also be assumed for the Oklahoma City structure.

In both anticlines the Arbuckle Dolomite has been uplifted by about 2,000 ft. The east flank of the Oklahoma City structure is cut off by a fault with a throw of about 1,800 ft.

Hobbs Field.

The next example is the Hobbs field, Lea County, New Mexico. In Fig. 20 are shown the magnetic isogams and the contours drawn on top of the 'Brown Lime'.

The Hobbs anticline has a north-westerly direction and about 250 ft. of uplift. The stratigraphical section is composed of Tertiary sands capped by Caliche (200 ft.), Triassic, and Permian Red-beds (1,300 ft.), Potash-bearing salt

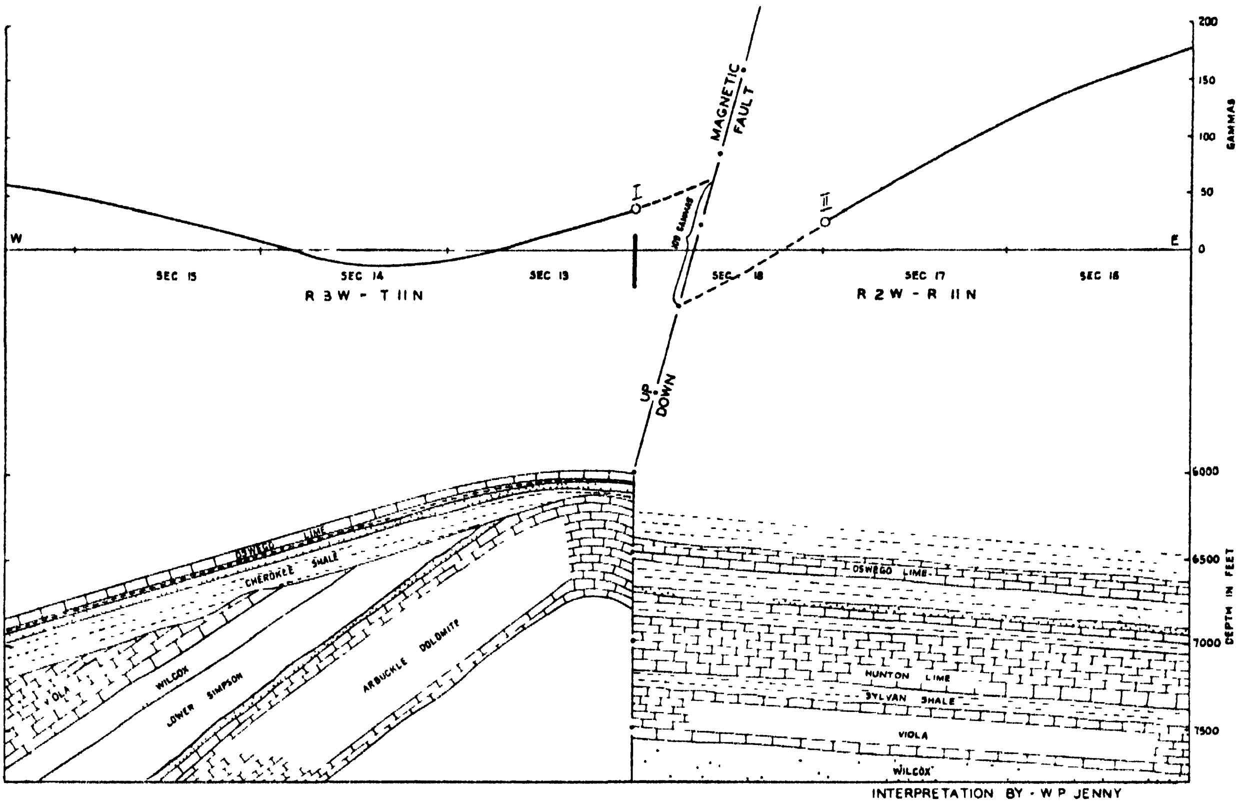

FIG. 19. Profile of vertical magnetic intensity and geological cross-section across the Oklahoma City field. (Magnetic data from Clifford's map, geological cross-section after Charles.)

The magnetic survey of the Oklahoma City structure was made before the development of the field [3, 1932]. The survey of the Garber structure [28, 1928–9] was made after development of the field, and therefore the minimum reading might be about 50 gammas lower than that which would correspond to the structure.

The striking feature of the magnetic profiles is that both structures show up as most decided magnetic 'lows'.

These 'lows' could be explained by the assumption that the granite protrudes through stronger magnetic schists.

Inasmuch as the thick Arbuckle Dolomite, which may be assumed as practically non-magnetic, is normally overlain in the area of the two structures by about 6,000 ft. and 8,000 ft., respectively, of partly highly ferruginous shales and sandstones, the writer ventures to suggest that the Arbuckle anticlines, piercing into and displacing higher magnetic shales and sandstones, might be the reason for these magnetic 'lows'. This suggestion is supported to some extent by the magnetic fault to the east of the Oklahoma City structure, since the higher reading at station 1 seems to indicate that a relatively shallow magnetic horizon has been uplifted on the upthrown side of the fault.

(1,400 ft.), Anhydrite with limestone, sand, and shale (1,200 ft.) underlaid by the producing horizon, the 'White Lime'. The 'Basement' is vaguely assumed to lie at about 10,000 ft.

The fold is magnetically indicated by a pronounced 'maximum' in the south-westerly part and a 'minimum' in the north-westerly part. The writer is inclined to interpret these features as due to the induced polarity in a deep anticlinal ridge, which lies essentially below the producing structure. The small uplift in the shallower beds probably does not materially affect the magnetic picture.

Yoast Field.

The above three magnetic anomalies are very pronounced and amount to several hundred gammas. Minor structural features produce, as a rule, much smaller anomalies, of which an example is given by the magnetic survey of serpentine mass at Yoast field, Bastrop County, Texas (Fig. 21).

Inasmuch as the centre of the 'high' of the vertical intensity anomaly occurs over the fault near the highest

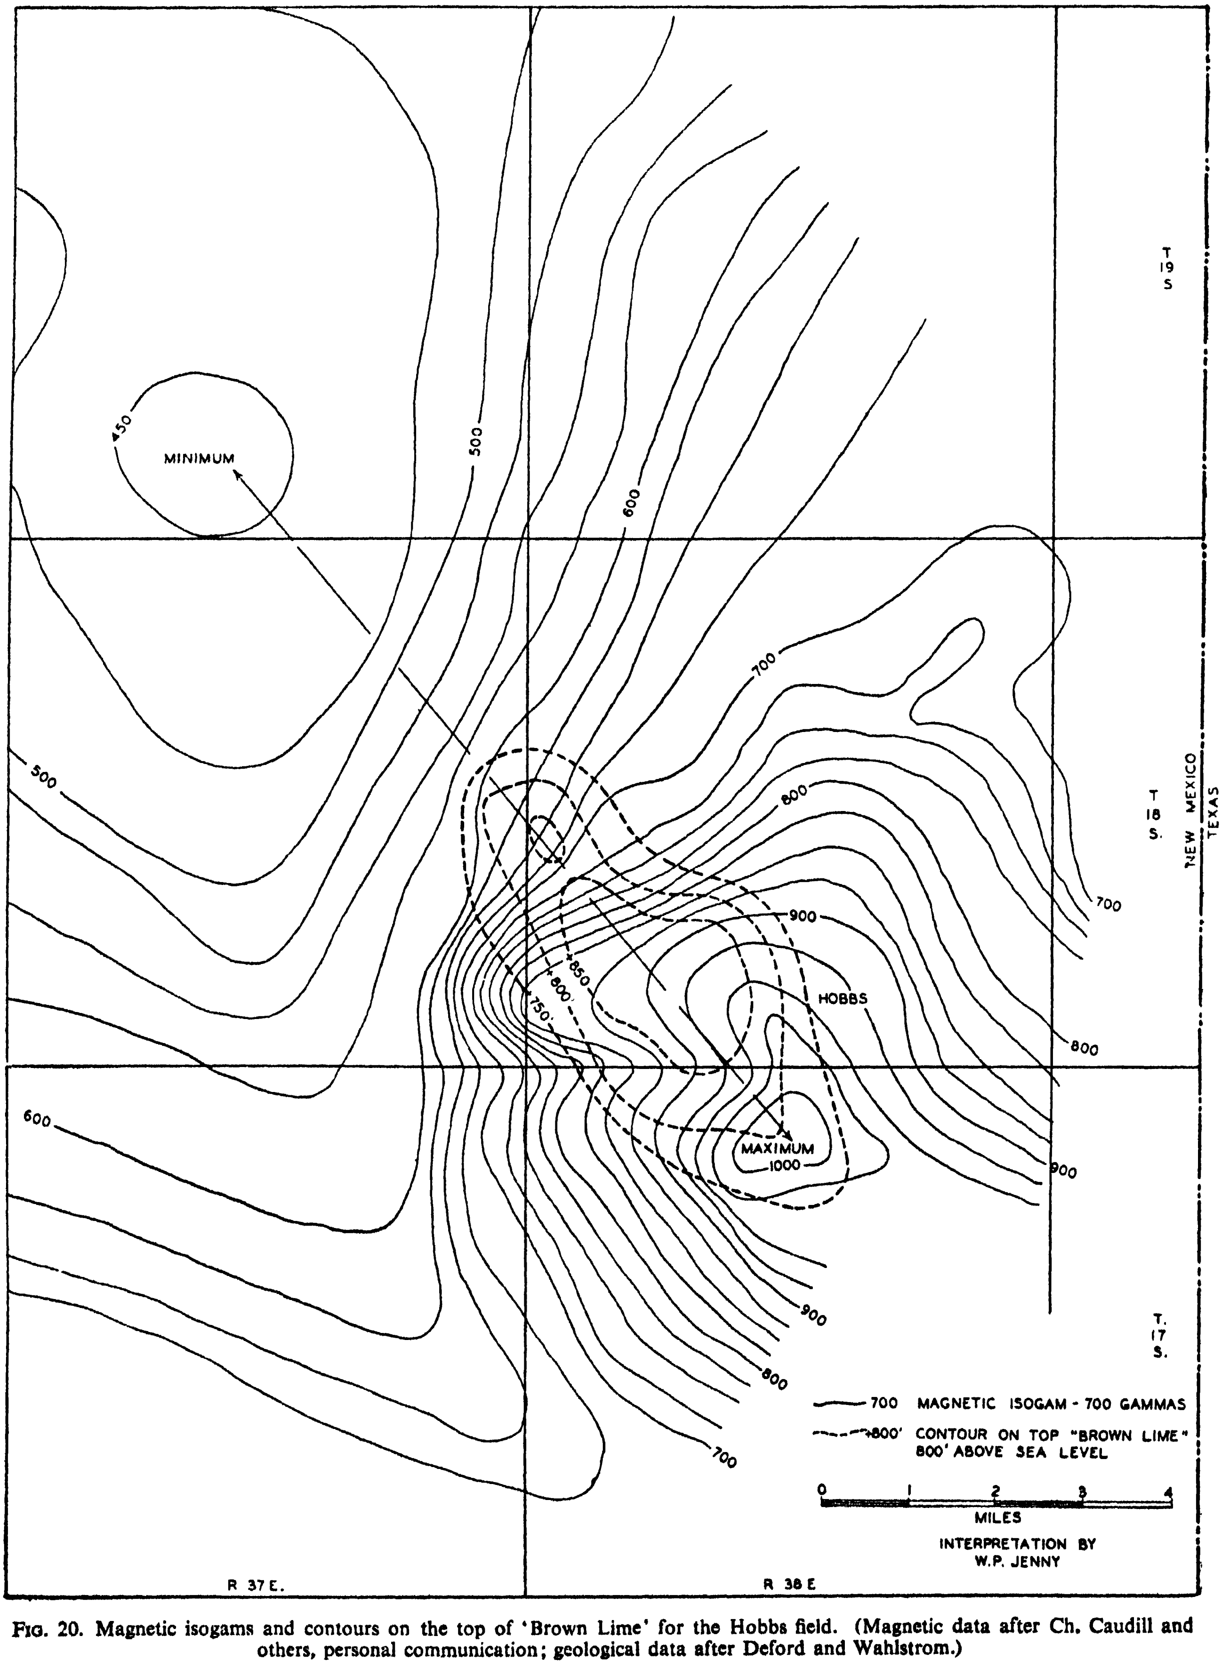

FIG. 20. Magnetic isogams and contours on the top of 'Brown Lime' for the Hobbs field. (Magnetic data after Ch. Caudill and others, personal communication; geological data after Deford and Wahlstrom.)

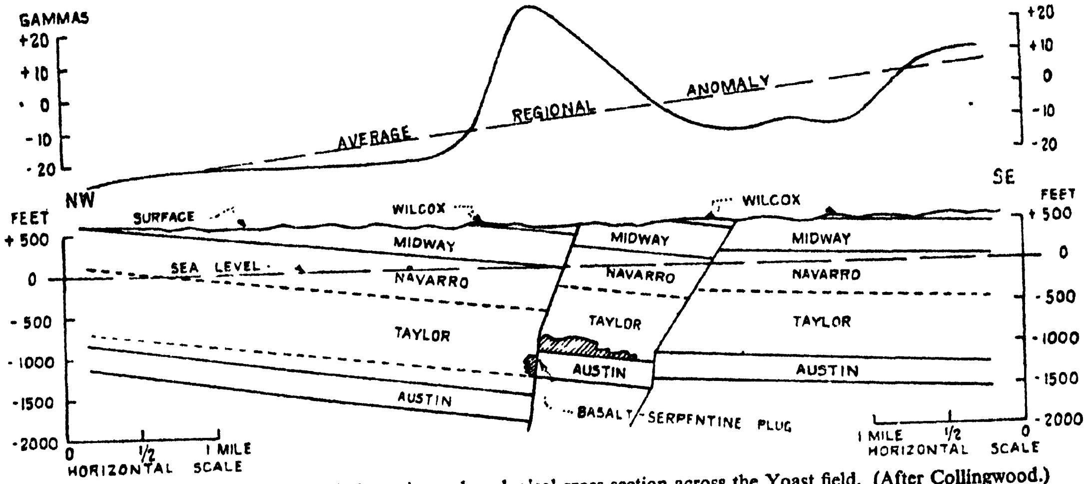

FIG. 21. Profile of vertical magnetic intensity and geological cross-section across the Yoast field. (After Collingwood.)

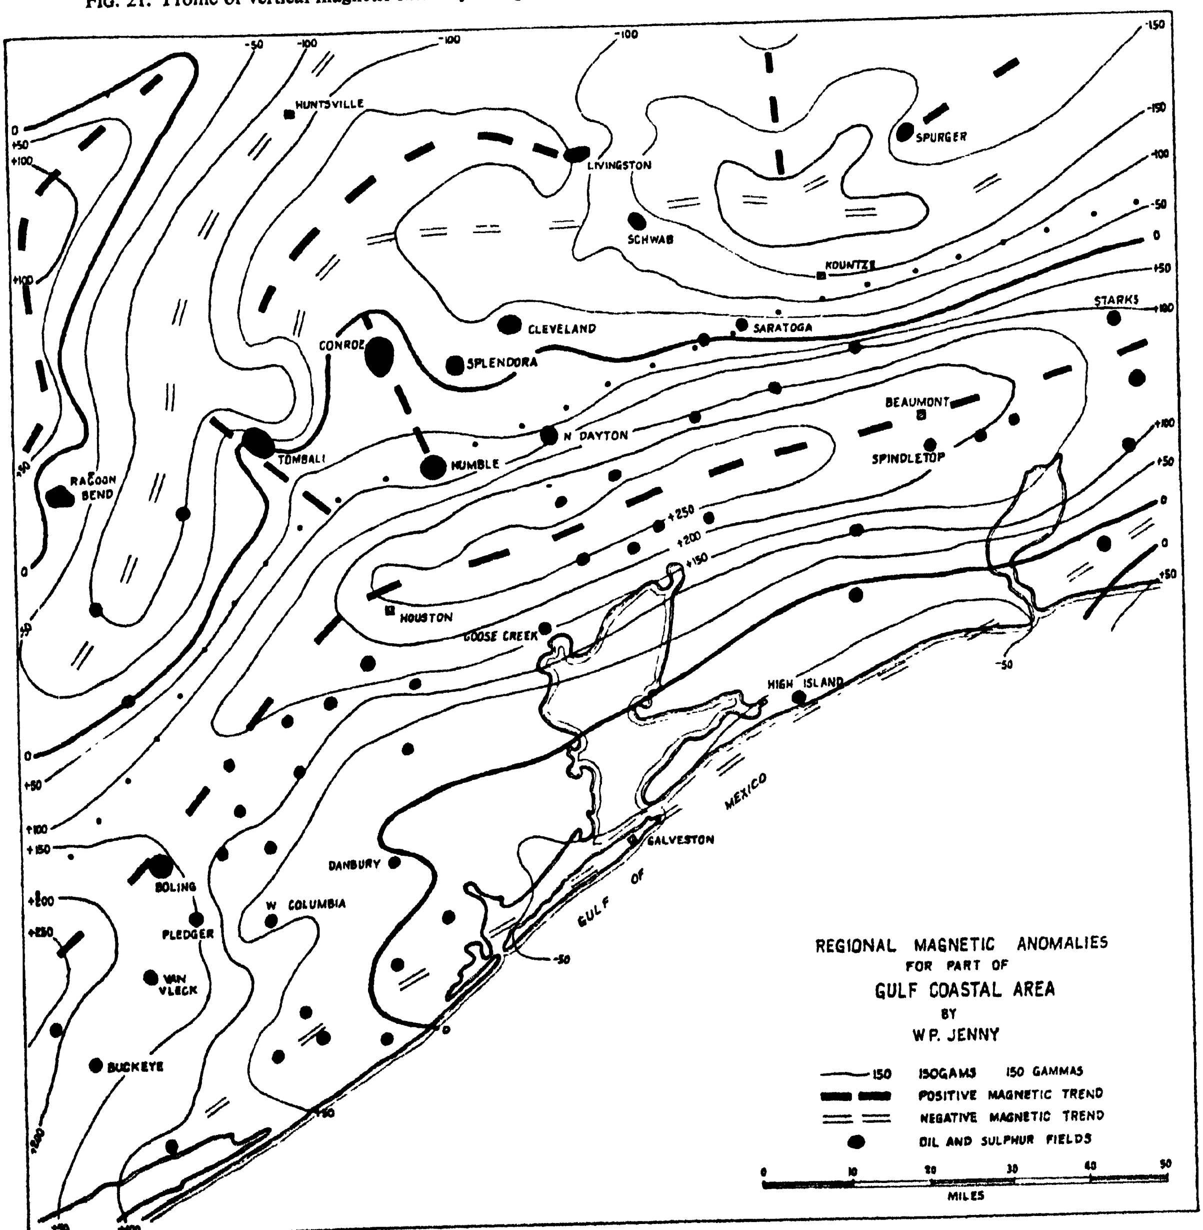

FIG. 22.

part of the mushroom top of the serpentine mass, Collingwood [4, 1930] infers that this high anomaly is due to a small neck or vent fillings of igneous rocks in the fault plane, below the top of the Austin chalk.

Regional Map for Part of Gulf Coastal Area.

Fig. 22 represents the regional magnetic anomalies for part of the Gulf Coastal area of Texas, in the general neighbourhood of Houston.

The writer [17, 1934] is inclined to interpret the magnetic positive trend, to the south of the dotted line, as due to a thickening of the highly ferruginous sediments of Eocene and younger age, and the magnetic negative trend through Galveston as due to a thinning of these sediments. Thus the magnetic 'high' between Houston and Beaumont would indicate a basin, and the magnetic low trend at Galveston an anticlinal trend in the deeper Gulf Coastal strata. The depth to the 'Basement' is estimated at from 20,000 to 30,000 ft.

To the north of the dotted line, magnetic high trends seem to represent anticlinal, and magnetic low trends synclinal structures.

The main fields, Conroe, Tomball, Livingston, and Spurger, lie along magnetic high trends. It is interesting to note that these fields are gravimetric minima. This might indicate that they are deeply buried salt-domes along anticlinal structural axes. On the other hand, a large number of tests drilled on gravimetric minima which lie along magnetic low trends, for example, along the region which extends from a point west of Conroe towards the Schwab area, were found to be structurally normal. In these cases the gravimetric minima were probably not produced by a salt uplift, but by the magnetically indicated syncline.

The position of the dotted line has been determined on the strength of magnetic and stratigraphic data. Along this line a sharp flexure in the deeper strata is presumed by the writer.

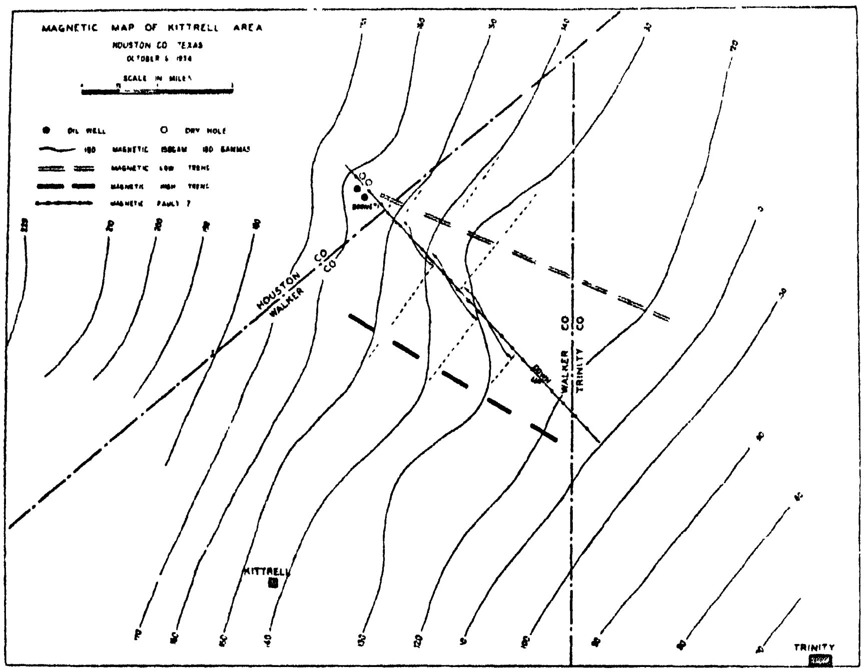

FIG. 23.

Kittrell Field.

Like other geophysical methods, the magnetic method does not always yield results as definite as the examples shown above. A structure of appreciable size seldom fails to produce a magnetic anomaly of at least 10 to 20 gammas, yet such anomalies may not always be readily interpreted in terms of structure. As an example, the magnetic diagram of the newly discovered Kittrell field is here given (Fig. 23). The field lies in south-western Houston County, Texas, about 25 miles north of Huntsville, and consists so far of two producers and a number of dry holes.

There is a uniform increase of the magnetic intensity from the town of Trinity towards the north-west. Two miles to the south-east of the discovery well Boone No. 1, the equal spacing of the isogams is interrupted. A magnetic 'low' is developed between the 130 and 120 isogams. The axis of this 'low' trends towards the discovery well. About 2 miles south a parallel high trend seems to be indicated. These two trends were tentatively interpreted in the early stage of the field as indicative of a cross-dip fault, as shown in the diagram. Further drilling did not prove or disprove this suggestion. The fact that until now little oil has been found, and only in the north-western, i.e. updip, areas of the supposed fault would rather be in favour of this theory, since such a cross-dip fault might be a poor trap for oil. The magnetic diagram could, however, be explained in many different ways. The only conclusion that seems to result fairly definitely from the magnetic survey is the probability of some structural feature to the south-east of the discovery well.

Such vague information may not be significant enough for the location of wells, but it might be of some importance in an economical plan for reflection seismograph and torsion-balance surveys, especially where the time element plays an important role.

Micromagnetic and Gravimetric Profile through a Gulf Coastal Prospect.

Clear evidence of the importance of magnetic prospecting along the Gulf Coast is given in Fig. 24.

A gravimetric minimum between stations 4 and 5 is indicated by a southern tendency of gradients 1 to 4 and by a northern tendency of gradients 5 to 7. Between 7 and 8 a marked reversal takes place.

Between these two stations also the micromagnetic profile indicates clearly a sudden break, which must be interpreted as a fault. The top of the magnetically indicated structure coincides well with the area of the torsion-balance minimum. Thus the corroborative structural evidence furnished by the two methods strongly supports the conclusions, which may be drawn from the results of each method by itself.

The total magnetic anomaly along the above profile amounts to 10 gammas. The term 'micromagnetics' is

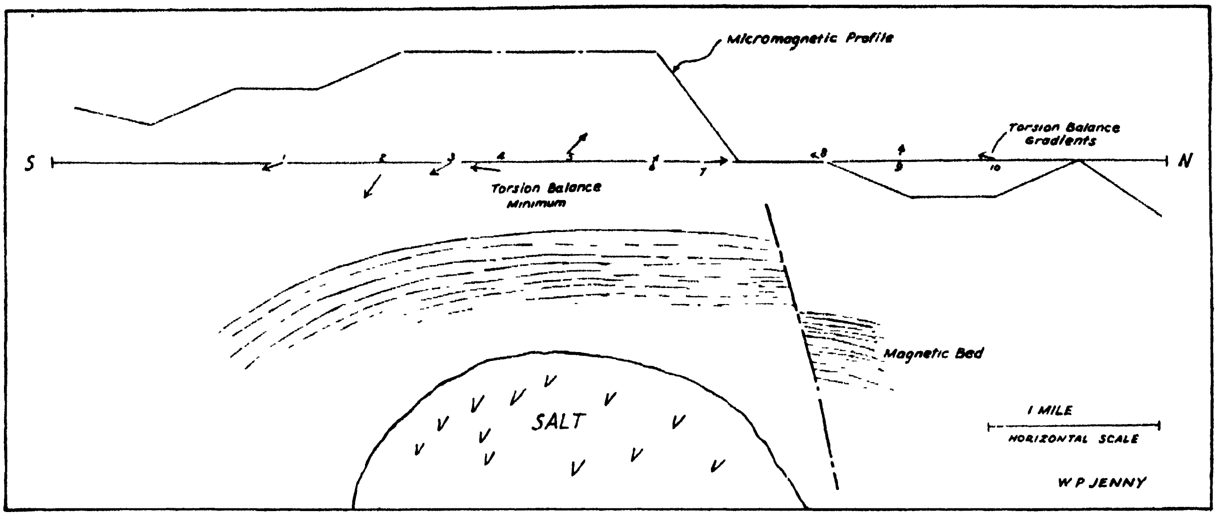

FIG. 24 Micromagnetic and torsion balance profile through a Gulf Coastal Prospect.

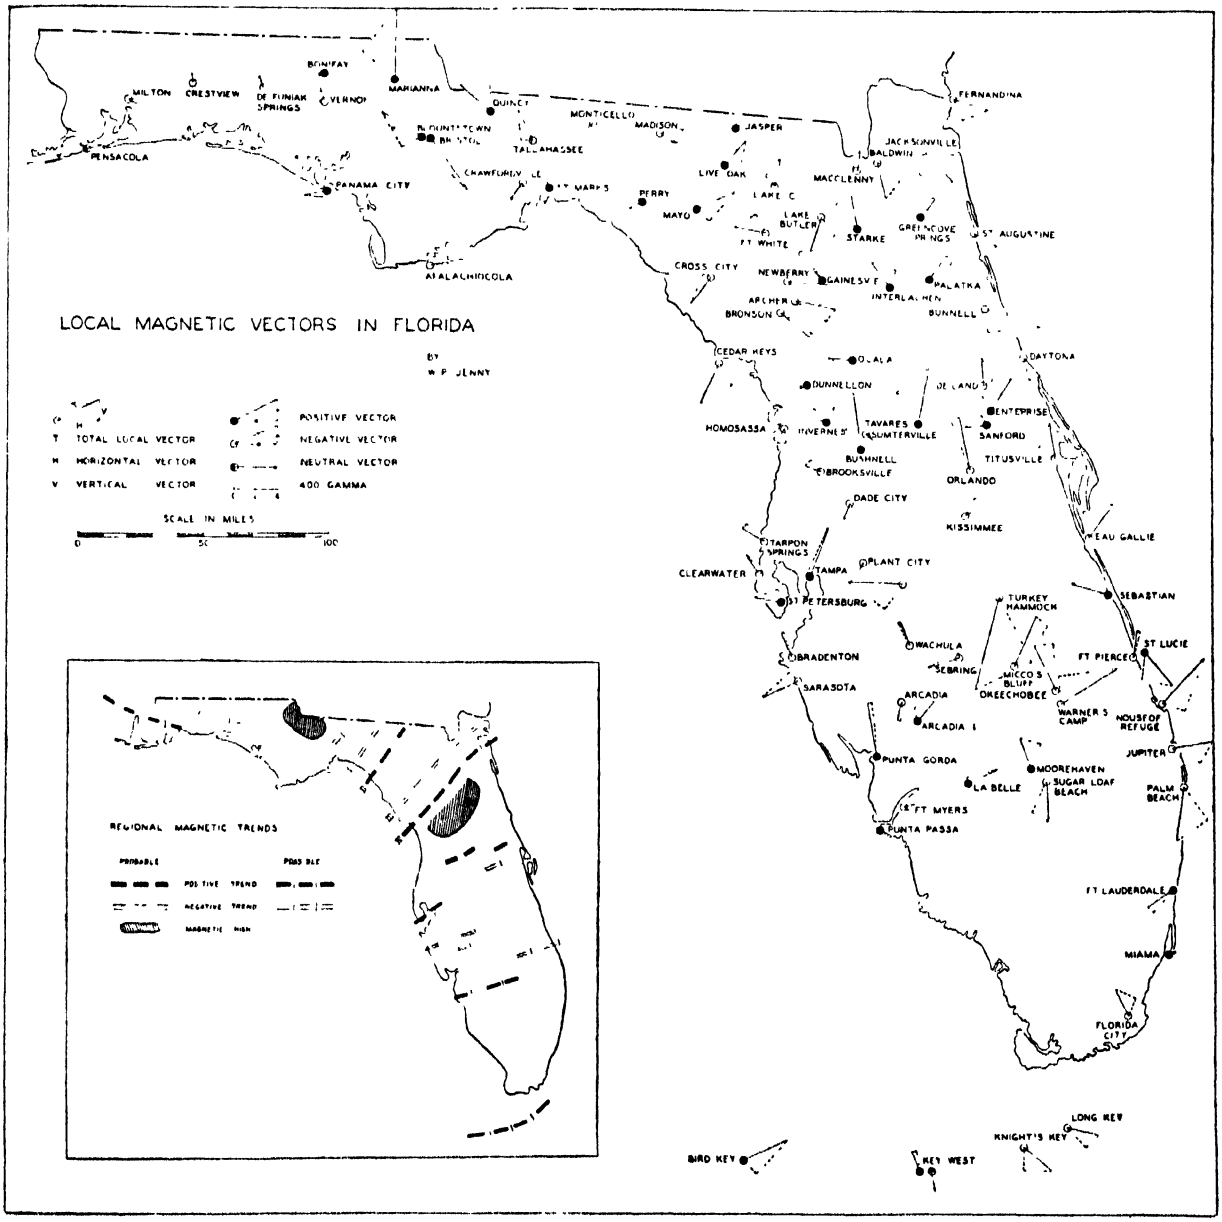

FIG. 25.

therefore suggested in order to contrast the extremely accurate recent magnetic work with the less accurate surveys of former years.

From the small horizontal extent of the magnetic and gravimetric anomaly above the fault there results conclusively that the source for both the magnetic and gravimetric anomaly must lie at relatively shallow depths.

Vector Map of Florida.

Interpretation of the vector map of Florida according to the principles explained before (p. 343), shows that these magnetic vectors indicate a number of deep structures [18, 1934], which are shown as regional magnetic trends on the inset of Fig. 25.

In the central part of Florida the main direction of the horizontal components of the vectors is north-west to south-east, which indicate regional structures with a north-east to south-westerly direction.

In southern Florida the main direction of the horizontal components is about north–south, which suggests regional structures with an east-westerly direction.

The generally assumed tectonics of this area suggest that these magnetic trends are caused by block-faults; however, taking into due consideration both the intensity and the direction of the vectors, it appears more reasonable to interpret the positive trends as anticlinal structural axes of the 'Basement' and possibly also of the overlying strata, and the negative trends as synclinal structural axes.

Since the direction of the northern trends shows a striking parallelism with the Appalachians, they probably represent structures connected with the Appalachian orogeny.

In southern Florida no continuous structural trends can be observed, but a number of parallel east-westerly anticlinal and synclinal trends of various length and intensity are possible, as indicated on the inset.

From the vector study it would therefore seem that early folding under that area of the peninsula as far south as Ocala, contrary to general opinion, was parallel to the Appalachians, trending north-east by south-west. From Ocala or south the province seems to change in type from the Appalachian to the Antillian.

The study of magnetic vectors suggests that, contrary to general opinion, the early folding under southern Florida as far south as Ocala was parallel to the Appalachians, north-east to south-west.

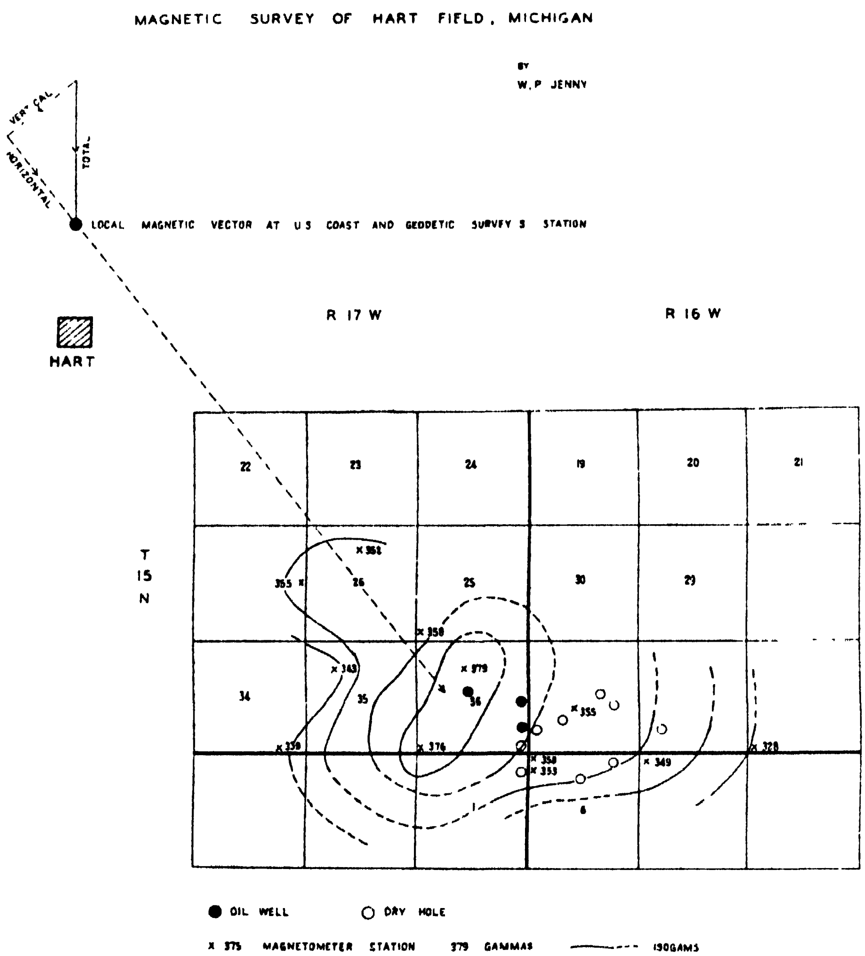

Fig. 26.

Survey of Hart Field.

A final example of the use of magnetic vectors is taken from a study of the recently discovered Hart field, Oceana County, Michigan [16, 1934].

The direction of the local magnetic force as indicated by the vector at Hart suggests a magnetic 'high' to the south-east, which might correspond to an uplift with a possible north-east to south-westerly axis. A short magnetic survey of the area (Fig. 26) has fully confirmed this suggestion.

ELECTRICAL PROSPECTING FOR OIL

By the late C. SCHLUMBERGER, M.Inst.P.T.

INTRODUCTION

ELECTRICAL methods, when first used, appeared especially suitable for prospecting metallic ores. Actually they have become more and more used for the geological prospecting of the great sedimentary basins, and, as a consequence, of oilfields. Present-day electrical methods are often better suited to the study of deep and wide structures, even if the resistivities of the formations in question do not differ widely, than to the investigation of mineral deposits, whose form is frequently unexpected, and whose total volume is always very small compared with that of the surrounding rocks.

Metallic ores sometimes give rise to specific electrical reactions (spontaneous polarization) [3, 1920] by which they may be recognized, whereas the characteristic properties of oil have as yet played no part in its detection. In particular, the high resistivity of oil sands cannot be used as a basis of diagnosis, because this property is concealed by the great conductivity of the surrounding beds, generally rich in salt, and much thicker than the oil layers. It is only when local measurements are made inside drill-holes that the high resistivity of the oil can be used to discover petroliferous beds (see article on Electrical Coring). To sum up, the electrical prospecting of an oil region amounts simply to the geological study of a structure, as is the case with other geophysical methods. The salinity of the formations, also, may easily be determined electrically. This fact is to the advantage of electrical methods, as experience has shown that saline formations are a condition almost necessary for the presence of oil.

Numerous electrical methods are now in common use for oil prospecting. They may be grouped into two classes, according to the nature of the measurements:

I. **Electric Field.** Determination, at the surface, of the potential difference set up between two elecrodes by direct or alternating current passing conductively through the soil between another pair of ground electrodes. At the present time, these studies are carried out chiefly by the resistivity method, with its two applications, the Resistivity Map and the Electrical Sounding, in which the earth resistivity is measured.

II. **Magnetic Field.** Determination of the magnetic vector created by alternating current, sent either conductively into the ground, or applied inductively by means of a horizontal loop.

The present article will be devoted in particular to the resistivity method, and only a brief outline of the electromagnetic methods will be given. Other processes, such as the 'Equipotential Map' and the 'Potential Drop' methods, will not be described, as they have not been, as yet, widely applied to oil prospecting, and are similar in many respects to the resistivity method.

To avoid confusion, it should be mentioned that prospecting for oil *inside* a drill-hole is described in detail in the article on Electrical Coring (p. 352).

RESISTIVITY METHOD

Resistivity of the Rocks [4, 1931] (see also on this subject the article on Electrical Coring). Nearly all the electrical methods are based on the differences of resistivity existing in the various rocks. Rocks are conductive only on account of the water impregnating them, and the resistivities are inversely proportional to the total quantity of salt dissolved in this water, per unit volume of rock. As petroliferous formations are generally very saline, they are also very conductive, and this is immediately noticeable in electrical prospecting for oil. There is, however, one exception to this rule, that of petroliferous limestones, which may be very resistive on account of the salt-water which is collected together in fissures and does not impregnate the general mass of the formation. As an example, the resistivities, expressed in ohms per cubic metre, of the formations encountered in the Roumanian oilfields are given:

Quaternary Terrace	75 200 ohm-metre
Levantine (succession of shales and sands)	15–50 ,, (average 20)
Dacic (sandy shales)	8–10 ohm-metre
Pontic (shales) . .	2–3 ,,
Meotic	3 ,,
Limestone	100 1,000 ,,

The first question which arises is the extent to which resistivity is a characteristic coefficient of a given formation. One point to be considered is the influence of the temperature, an increase of which results in a decrease of resistivity. As a rule, this influence does not constitute a serious inconvenience in a survey conducted from the surface of the ground. The effect of the permeability, on the other hand, must not be overlooked. Impervious rocks contain approximately the same amount of water throughout, and this water, which is firmly held in place by capillarity, possesses almost the same chemical composition everywhere. The resistivity, depending on this absorbed water, keeps a constant value over a wide area, and constitutes a specific and reliable parameter of such rocks. If we now consider a very permeable formation such as, for instance, a sand, the percentage of water contained therein will depend on its position with respect to the water-level. The water itself will have a varying composition: pure rainwater in some places, water more or less rich in dissolved salts in others. The resistivity of a permeable layer, therefore, is not always a reliable indication of its lithological nature.

The measurements of resistivity under discussion will always involve very large volumes of ground, and consequently represent average values. Under these conditions, regular figures are obtained and the measurements have a geological significance, avoiding local singularities. It should also be observed that the sedimentary rocks are more conductive parallel to their strata than perpendicular thereto; the ratio between these two conductivities frequently reaches 1·5 or even 2. This anisotropy [2, 1932, 1934] sometimes constitutes a serious complication, but may, however, be used to estimate the dip of the strata.

Measurement of the Ground Resistivity. The quadripole technique, first described by Wenner in 1916, is generally used to determine the ground resistivity. Its principle is quite simple. Between two ground electrodes A and B set up at the surface of the soil, an electric current i is sent into the ground by a battery S (Fig. 1). The flow of this current

creates, by ohmic effect, a potential drop ΔV between two measuring electrodes M and N placed at the surface, generally between A and B. This drop is measured by a potentiometer P. From the known values of i and ΔV, it is easy, by a simple formula, to compute the resistivity of the ground, the latter being supposed homogeneous and horizontal in the entire volume taken in by the measurement. Since the ground generally does not fulfil these conditions, and is more or less heterogeneous, the value given by the formula does not correspond to the actual resistivity of a given rock, but to an average resistivity of the various rocks included in the measurement. This average is called the 'apparent resistivity' of the ground between M and N.

Let us discuss more accurately the concept of the volume taken in by the measurements. It is obvious that the parts of the ground nearest to the measuring-device play the most important role, whilst those situated at some distance from the instrument do not have any appreciable effect on the result. In any case, the law of decrease with distance is very complicated. It cannot be expressed in an exact mathematical formula, and we must, therefore, be satisfied with approximations. We give herewith the simplest. Let us suppose that the measuring-device be such that M and N are situated on the line AB, and on either side of its centre. As may be seen in Fig. 1, it is almost as though all the lines of current going from A to B were concentrated

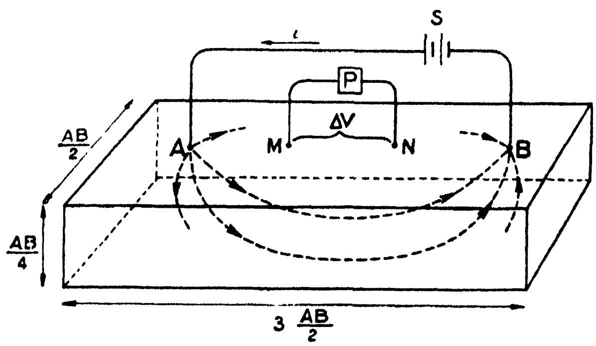

FIG. 1.

inside of a parallelepiped, possessing a width of $AB/2$, a depth of $AB/4$, and a length of $3AB/2$. At the centre, where the ohmic drop is measured, the lines of current are approximately parallel to AB. The volume taken in by the measurement is the parallelepiped. The ground outside of this volume does not play an important part. The thickness $AB/4$ of the parallelepiped is often called the 'investigation-depth' of the measuring-device. Although this scheme only gives a rough idea of the facts, it serves, nevertheless, to clarify the following essential considerations.

Resistivity Map Method [4, 1931]. The resistivity map of the soil gives the value of the apparent resistivity of each point where a measurement has been made. It is similar to a geological map, but, in place of the lithological or palaeontological characteristics which normally serve to differentiate the terrains, it substitutes the value of a physical parameter, the resistivity.

In order to draw up a 'resistivity map' the 'apparent resistivity' of the underlying ground at a series of stations is measured by means of a constant quadripole $AMNB$, that is to say, with a constant 'depth of investigation'. This constitutes a horizontal exploration of a uniformly thick layer of ground. The measurements are plotted on a topographical map. Equiresistivity curves are traced by interpolation. It is often an advantage to establish 'profiles of resistivity' taken along a given line, which are interpreted as a cross-section of the terrains, and to draw up two resistivity maps with two different depths of investigation for the same region. [Greater depth of search is secured by increase of the lengths AB and MN.] The work at shallow depth concerns the superficial formations, that at greater depth the deeper subsoil. The map must cover the area to be studied without any gaps in order to give a general picture free from all preconceived ideas. It therefore constitutes a systematic and intensive study, frequently comprising many thousands of readings.

Electrical Soundings [2, 1932, 1934]. An electrical sounding consists in taking, at a central point on the surface of the ground, a series of resistivity measurements by means of a quadripole $AMNB$, whose length, and thereby whose investigation depths, are progressively increased. The apparent resistivities thus obtained are marked as ordinates on a diagram, the lengths of AB being marked as abscissae.

The interpretation of such a diagram consists in computing the values of the resistivity of the rock at the different depths beneath the measuring-station. Once the solution is known, it is easy to draw useful geological conclusions, such as the depth of a key horizon formed by the contact of two sedimentary formations with different resistivities. The tectonic map of a region, and particularly of a petroliferous structure, can therefore be established from a sufficient number of electrical soundings.

Obviously, such a problem has a real meaning only if the volume of soil beneath the quadripole, affecting the measurements, is formed of a succession of homogeneous and horizontal superimposed layers. These conditions are never exactly fulfilled, but experience has shown that with slightly sloping formations, electrical soundings still give sufficiently correct results if certain precautions are taken.

Even with homogeneous and horizontal formations it is possible to give a single and definite interpretation of an electrical sounding only if certain simplifying hypotheses are adopted. At least, so some mathematicians claim to have proved. On the contrary, the reciprocal problem has been solved exactly. It is possible to compute mathematically the electrical sounding diagram for a soil composed of a number of horizontal layers of known thickness and resistivity. The calculation, made by using Maxwell's Theory of Images, is only possible in practice if the number of layers is not too great, and if the deepest one is supposed infinitely thick.

For a practical survey the following course is adopted. Certain simple hypotheses are assumed concerning the resistivity and the thickness of the beds in the region under consideration. A series of graphs is then calculated, each corresponding to different thicknesses of the layers. Finally, the diagram actually obtained in the field is compared with these graphs. If an electrical sounding corresponds to one of the theoretical graphs, the geological interpretation can be made. If the coincidence is insufficient, the values of the resistivities adopted *a priori* are modified, and new graphs are calculated. This is, therefore, a process of successive approximations. The work is greatly facilitated by the preliminary electrical coring of a hole drilled in the region, giving the real resistivity of the successive layers, and their approximate thickness.

Examples of Application

Resistivity Map of Aricesti Dome (Roumania). This structure was studied in 1923 by the resistivity map method

at very shallow depth. Since 1932 deep drill-holes have encountered oil in the Meotic formations (about 5,500 ft. average depth) giving quite a good production.

Fig. 2 gives, in the form of equiresistivity curves, the map established in 1923 with a line *AB* of 1,300 ft. (400 metres). The investigation, therefore, included a layer of ground about 300 ft. deep.

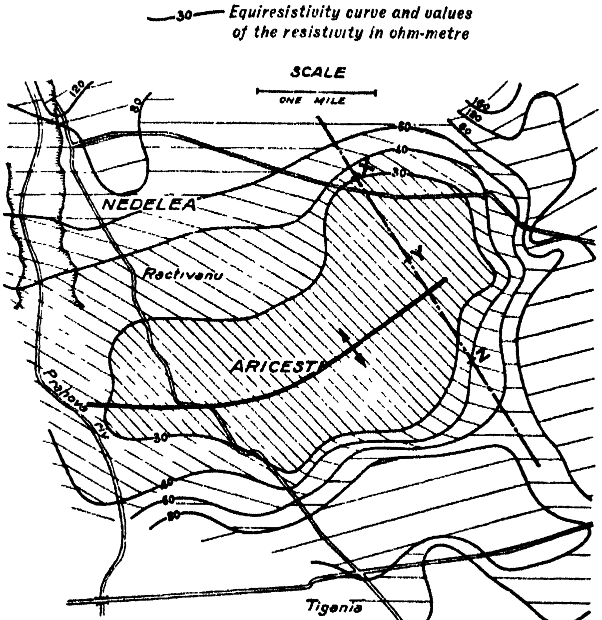

FIG. 2. Resistivity map of Aricesti Dome, Roumania, 1923. Length of line *AB* (see Fig. 1) is 1,300 ft.

The surface of the ground is very flat. It is formed of a Quaternary Terrace, with a resistivity of about 150, above Tertiary (Levantine) shales, having a resistivity of about 25 ohm-metres. As the Dome continued to rise during the Quaternary period, the terrace, constantly subjected to erosion, is thinner on the top of this structure than on the flanks (Fig. 3). It follows that the layer of ground studied electrically comprises at the top little resistive terrace and much conductive shale, giving an apparent resistivity of about 30 ohms; on the contrary, the terrace is thick on the flanks, and there are less shales, so that the apparent resistivity is higher, greater than 100 ohms in certain places. To sum up, the resistivity curves give quite a correct substructure map of the top of the Tertiary shales, but with an unknown depth scale.

Fig. 3 gives a cross-section of the Aricesti field along the line *XYZ*, as well as a resistivity profile also made along this line. This profile was established in 1933, that is to say, 10 years after the first electrical survey, and when the structure was known as a result of a number of drill-holes. The measurements were carried out with a line *AB* 7 miles long, corresponding to a very considerable investigation depth. The apparent resistivities found are rather low, this being due to the influence of the deep conductive formations. These reach about 10 ohm-metres on the top of the structure, which always appears on the diagrams as a point of minimum resistivity.

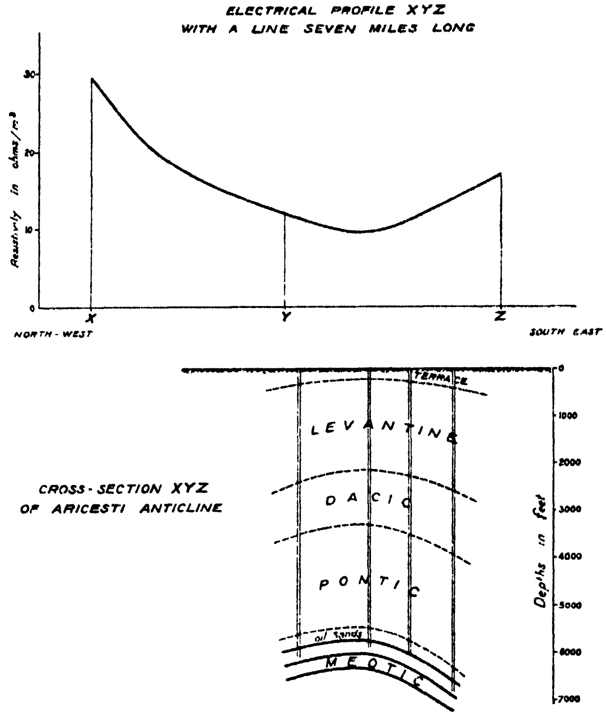

FIG. 3.

resistivities measured are, as usual, shown as ordinates, and the corresponding lengths of the line *AB* (see Fig. 1) as abscissae. It is seen that the resistivity decreases regularly as *AB* is lengthened, i.e. when the investigation depth increases. At the place of each electrical sounding I, II, III, a hole, drilled after the electrical survey, shows the exact depth of the Ducic/Pontic contact, which is taken as key horizon. At sounding I the depth is 5,550 ft., and the apparent resistivity 12·5 ohm-metres with a line *AB* = 10,000 ft. (3,000 metres); at sounding II the depth is 3,000 ft. and the resistivity 10·8 ohm-metres; at sounding III the depth is 1,800 ft. and the resistivity 8·3 ohm-metres.

Electrical Soundings in the Region of Bucsani (Roumania). Fig. 4 shows three electrical soundings executed in 1934 for the study of the tectonics of this region. The apparent

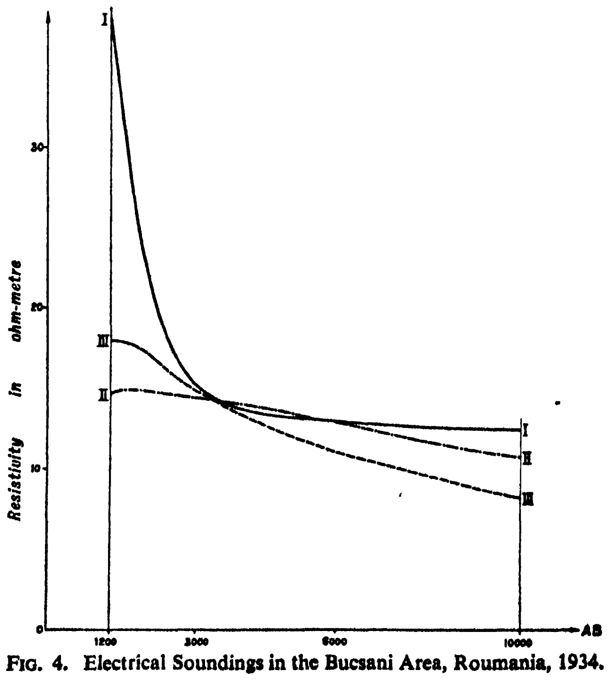

FIG. 4. Electrical Soundings in the Bucsani Area, Roumania, 1934.

The interest in this example is essentially a practical one. In spite of the very slight differences of resistivity that were measured, the interpretation of numerous electrical soundings made clear the structure of Bucsani, a region which has very recently proved itself to be a new oilfield with an excellent production.

Two remarks may be added about these electrical soundings.

The interpretation of the diagram was facilitated by the fact that electrical coring had previously given the mean resistivity of the different formations (Levantine, Dacic, Pontic, Meotic) of the region. Therefore the problem reduced itself to determining the thickness of these formations.

On a resistivity map made with a line $AB = 10{,}000$ ft., the Bucsani anticline shows up as more conductive than the surrounding formations, as does the Aricesti Dome. A map established with a line only 1,300 ft. (400 metres) long (like that used in 1923 at Aricesti) would have led to an erroneous interpretation. The station II would, in fact, have appeared to be at the top of the structure, whereas, in reality, station III is tectonically higher. This shows the utility of electrical soundings with a correct interpretation of the depth of key horizons.

ELECTROMAGNETIC METHODS

These measurements, which are based on the determination of the magnetic field produced by currents circulating in the ground, have for one particular object the study of the strata dips, a fundamental problem in prospecting for petroliferous formations. Two techniques which have been widely applied will be briefly described.

The Loop Method [2, 1932, 1934]. On the surface of the ground is placed a large loop S, composed of an insulated conductor, and comprising a device for the measurement of the electro-motive forces induced in S. This loop is an exact square, with each side 100 ft. or more. Along the two diagonals of this square, two straight wires AB and $A'B'$ are placed, from 300 to 2,000 ft. long, and grounded at both ends. If the soil under the loop S is formed of homogeneous, horizontal strata, an alternating current sent through AB induces no electromotive force in S, this by reason of symmetry. If the strata dip, the flow of the current between A and B has an average deflection corresponding to the dip, because of the anisotropy of the ground. The symmetry between the loop and the average flow no longer exists, and an electromotive force is induced in S. From the direction and value of this electromotive force the component of the dip of the strata perpendicular to AB can be estimated. In sending current through $A'B'$, the component of the dip perpendicular to this line may also be obtained. The resulting vector of the two components gives the real direction of the dip of the formations. The device is reversible. Alternating current may be sent into the loop S and the electromotive force of induction measured in the circuits AB and $A'B'$.

The process is only correctly applicable to fairly anisotropic media (interbedded shales) with more or less regular resistivities.

Fig. 5 gives the results obtained on the flanks of an anticline at Grozny (U.S.S.R.). The dip arrows coincide well with what is known of the structure.

Swedish Method [5, 1931]. This method gives the depth and the electrical properties of certain conductive key horizons, as well as their dip.

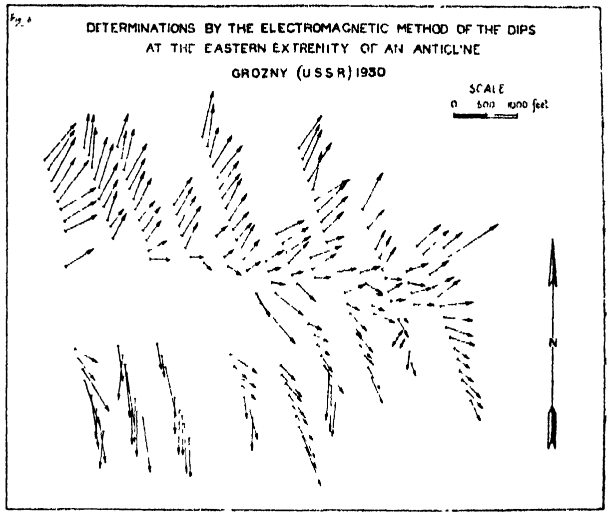

FIG. 5.

As can be seen from Fig. 6, which shows a perspective view of the device, there is placed on the surface of the ground a very long, straight, insulated wire, whose two ends A and B are grounded and through which is sent an alternating current of varying frequency. At a series of stations placed along a profile perpendicular to AB, the magnetic

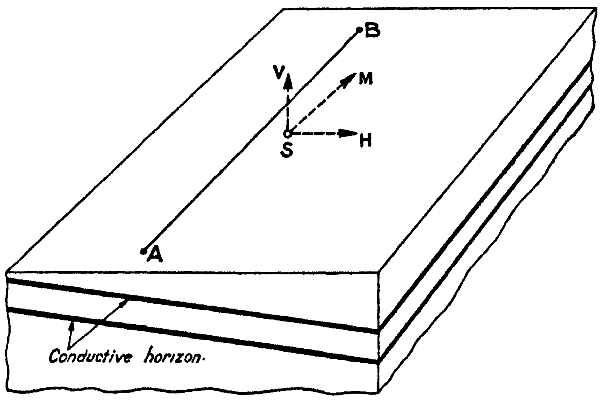

FIG. 6. Principle of Swedish Induction Method.

vector produced both by the primary current flowing through AB into the ground and by the secondary currents induced in the ground is studied. The line AB is 1 or 2 miles long; the distance of the stations from the line is several hundred feet; the frequency of the alternating current used varies from 10 to several hundred per second.

The magnetic vector M at the station S is the resultant of two components: the one V, vertical, and the other H, horizontal, the former being the more important. The two components V and H are measured in amplitude and phase, in relation to the primary current sent through the line. This determination is made by means of a search coil of a few hundred turns, provided with an amplifier and a compensator connected to the primary current.

The two components V and H may be calculated theoretically when the ground, from the point of view of its electrical conductance, is confined to one or two horizontal conductive planes, situated at known depths. These computations may be completed by laboratory experiments on reduced models. Graphs are then drawn which, for a

station *S*, give the depths of the conductive horizons as a function of the different magnetic factors.

In practice the geological interpretation of the measurements is made by supposing that the electrical conductivity of the ground is concentrated into three key horizons: one on the surface of the ground; another at shallow depth; the third at great depth, representing the formations to be studied. The depth of this last key horizon is, therefore, computed for different distances from the line *AB*. The repetition of these measurements at numerous stations allows the dip to be determined and the map of the structure to be traced.

Although this process may appear, *a priori*, to be based on rather theoretical simplifying hypotheses, it has been applied on a large scale and has rendered numerous services, particularly for the study of faults.

CONCLUSIONS

As has been shown in this short summary, electrical prospecting methods are complex and their many techniques lend themselves to very varied applications. Up to the present time, it is this branch of geophysics that has given rise to the most extensive theoretical and mathematical researches, and on reading some of the articles on the subject a wrongly pessimistic impression may be got that the intricate formulae conceal poor practical results. This is particularly striking when one compares it with the successful Seismic Reflection Shooting, whose theory still appears primitive, only the technical details and the construction of the apparatus having been studied thoroughly.

There is a great deal of room for improvement in electrical prospecting methods. One of the difficulties encountered in this direction, however, is the impossibility of conducting accurate experiments in already exploited oilfields, where the tectonics are well known. Casings and pipelines here form such a vast network of excellent metallic conductors that they completely upset electrical measurements, whilst they have no effect on seismic and gravimetrical experiments.

The latest improvements consist, above all, in the increase of the investigation depth, that is to say, in the use of longer measuring-devices. Lines 2 or 3 miles long, with an investigation depth of several thousand feet, are quite usual to-day, and lines of even 7 miles have been employed in certain favourable districts. Experienced operators obtain a relative precision of 1/20 in their measurements, despite the smallness of the difference of potential to be measured (a few millivolts).

Although the measurements remain correct, their geological interpretation becomes more and more delicate as the length of line is increased. These affect such immense volumes of soil that more than one structure may be included and the facies of the formations may vary. The computation of the electrical sounding becomes especially uncertain in cases where the sedimentary layers affecting the measurements can no more be considered as even roughly homogeneous and horizontal. Electrical studies at great depth can therefore only be applied to very gently sloping folds, such as those found in plains far from mountain ranges. As a matter of fact, these difficulties are encountered by all geophysicists, Seismic Reflection operators alone escaping this general misfortune.

The use of direct current or, at least, of very low-frequency alternating current (inaudible frequency) is imperative for exploration at great depth. In such a case, when a current is sent into the ground, the establishment of the potential equilibrium at the surface of the ground, according to Ohm's law, takes an appreciable time. As a result of skin-effect, i.e. the induction between different current lines, the electrical current first remains mostly at the surface of the ground, and only penetrates gradually. This action is more marked as the ground is more conductive, and, as petroliferous formations are nearly always very conductive, skin-effect is very noticeable in their case. With high-frequency alternating current, the flow changes its direction before attaining the permanent equilibrium, and the deeper layers barely affect the measurements at all.

Electrical prospecting for oil has been applied principally in the U.S.S.R. and Roumania, where important results have been obtained. In these two countries one finds vast shaly formations constituting very regular electrical key horizons. Also, the resistivities of the different superimposed layers decreases as the depth increases, and this condition is propitious for deep investigation. On the contrary, in the U.S.A. favourable electrical markers are often absent, whereas good seismographical ones are numerous; and this accounts for the very remarkable results of seismic surveys in that country. As can be seen, everything depends on local conditions, and it is difficult to say, *a priori*, without a careful study of the geology, what practical services electrical prospecting can render in a new oil region, where no electrical test has yet been made.

ELECTRICAL CORING

By the late C. SCHLUMBERGER, M.Inst.P.T.
Formerly President of Societé de Prospection Électrique

CONTENTS

I. INTRODUCTION

THE basis of the technique known as 'electrical coring' consists in determining the lithological nature of the formations encountered in a drill-hole by means of electrical measurements made inside this hole. In the case of oil exploitation, the only one which will be considered here, the essential problem is the determination of the characteristic geological horizons or markers and of the oil and water sands. The term 'electrical well surveying' is also used as well as 'electrical logging'. Literally, the words 'electrical coring' are not quite correct, but their meaning is obvious and they have already become a part of oil-field terminology. They lay stress upon the fact that the object of the technique is to substitute electrical measurements for mechanical coring.

Electrical coring, which was first studied in the small French field of Pechelbronn, was applied in Venezuela in 1929, and then in the U.S.S.R., where it rapidly became very widely used. It was introduced into Roumania in 1931, and then successively into almost all the oil-producing countries in the world. Up to the present, however, this method has been very little used in limestone fields, so that its possibilities in these formations are still imperfectly known.

The principal publications dealing with this subject are papers presented at different congresses; these are indicated in the Bibliography at the end of this article. To these papers could be added a long list of patents and numerous articles which have been published, chiefly in the U.S.S.R.

Even if electrical coring reminds one of surface electrical prospecting, there are essential differences between the two techniques. In surface prospecting for oil, one deals with roughly horizontal beds, that is to say, beds more or less parallel to the line along which the instruments are moved, and the ground must be explored to a great depth. For this purpose the electrodes must be placed great distances apart. Each measurement must, therefore, affect large volumes of soil. On the other hand, inside the drill-hole the device is moved more or less perpendicularly to the different beds. The electrodes are close to the formations to be explored, and a measurement of a local character only is required. The electrodes are, therefore, placed very near to each other, the volume of soil affected by the measurement consisting of only a few cubic metres at the most.

Geophysical problems inside drill-holes are comparatively easy to solve, due to the fact that the instruments are in close contact with the part of the soil to be studied. It might even be said that the measurement of the electrical properties is here carried out under conditions which, technically, are the most ideal, because of the regularity of the hole, which very often has a nearly perfect cylindrical form, and of the complete homogeneity of the mud. Owing to the possibility of moving the electrodes in the hole inch by inch, the precision is such that it almost gives a feeling of working on a laboratory table. At the same time, instead of connecting wires of a few metres length, such as are used in a laboratory, the electrodes and the measuring instrument are connected by a cable several kilometres long. The measurements must be taken very rapidly throughout a great depth, so as not to inconvenience the drillers, and in case caving-in occurs in the hole that is 'standing' without mud-circulation; and, finally, the operator is not working in a closed laboratory, but often in mud and rain, and he is still obliged to make accurate measurements with delicate apparatus, the presence of which amidst heavy drilling machinery seems rather paradoxical. This means that, although the theory of electrical coring is fairly simple, the practical execution is less so.

The two parameters in use at the present time in electrical coring are the specific resistivity of the formations in the immediate vicinity of the hole, and the spontaneous potentials (in brief, S.P.) which develop in the drilling-mud at the level of certain beds. These potentials are related to the permeability of the beds (as we shall see farther on), and it is often stated, rather incorrectly, that it is the 'permeability' (or even less correctly, the 'porosity') that is measured.

It is obvious that other electrical parameters can be utilized. In particular, it is possible to measure with a fair degree of accuracy a coefficient of the electrolytic capacity of the beds, and this differentiates clearly between sands and clays. Other physical properties, such as thermal conductivity, are also capable of giving rise, in the future, to new possibilities in the diagnosis of formations. However, as these different techniques have not yet been widely applied, the only measurements that will be described completely hereunder will be those of resistivity and 'permeability'.

II. PRINCIPLES AND TECHNIQUE OF ELECTRICAL CORING

(*a*) **Electrical Resistivity of Rocks.** The electrical resistivity of a rock (the word rock implies here any kind of

formation) is the resistance of a cylinder having unit length for height and unit surface for section. It is usual to take the metre as unit, and to consider resistivity in ohms per cubic metre (ohm-metre).

Different formations have widely differing resistivities—from a few tenths of an ohm up to several thousand ohms per cubic metre.

With the exception of certain metallic ores, rocks possess a conductivity which is exclusively electrolytic; in other words, the solid elements composing the rocks are virtual insulators, and only the interstitial absorbed water enables the current to flow through them.

The specific resistivity of rocks can be deduced approximately from the following law: The specific resistivity of a rock is inversely proportional to the amount of water contained in each cubic metre of the rock and to the conductivity of this absorbed water. It can be stated therefore that it is roughly inversely proportional to the amount of dissolved salts in each cubic metre of rock.

Such secondary factors as the geometrical distribution of the absorbed water in the interstices of the solid elements of the rock, the capillary action of these elements on the free ions, the chemical nature of the dissolved salts (sodium chloride, for the greater part, in oil-field formations), and finally the anisotropy existing in most sedimentary rocks have been omitted.

On the other hand, one factor which does play an important part is temperature. A rise of temperature causes a decrease of resistivity, which may be reduced to half its value by an increase in temperature of 50° C., and it is certain that variations of 50° C. are often met with in drill-holes.

It has been said that the resistivity of a rock depends essentially on the nature of the absorbed fluid. An extremely important factor in the electrical exploration of drill-holes results from this. Impermeable formations such as clay possess a constant resistivity, since extraneous liquids cannot filter into them; on the contrary, permeable formations (sands) have varying resistivities, according to the nature of the liquid they contain. These formations will be very conductive if the liquid is salt water; conversely, they will be resistant if the liquid is oil.

(*b*) **Resistivity Measurements in Drill-holes.** It must be recognized that resistivity and permeability measurements can only be made in the uncased part of the drill-hole. A metal casing forms such a perfect electrical conductor, in comparison with the surrounding rocks, that it acts as an impenetrable screen preventing any electrical investigation by means of apparatus placed inside the drill-hole. On the other hand, the resistivity can only be measured easily if the hole is filled with mud or water, thereby ensuring the electrical connexion between the electrodes and the soil. In an empty hole it would be necessary to establish reliable points of contact with the walls of the hole, a problem not easy to solve. Finally, the presence of water is indispensable for the creation of spontaneous potential phenomena which are related to permeability. From the above, it can be seen that electrical coring can be applied most advantageously to rotary wells, as these generally have a large amount of uncased hole, and are always full of water—or rather mud. On the contrary, cable-tool wells cannot be studied so easily, because there is usually only a small length of open hole between the casing-shoe and the bottom.

The resistivity of the rocks penetrated by drill-holes can be measured in different ways. Devices with one, two, three, or four electrodes that are lowered into a drill-hole have been suggested. Details will be given of the three-electrode method which, up to the present, is the most commonly applied in practice. A few words will be written about the one-electrode method, which has been experimented with for a special purpose.

Fig. 1 shows the principle of the three-electrode device.

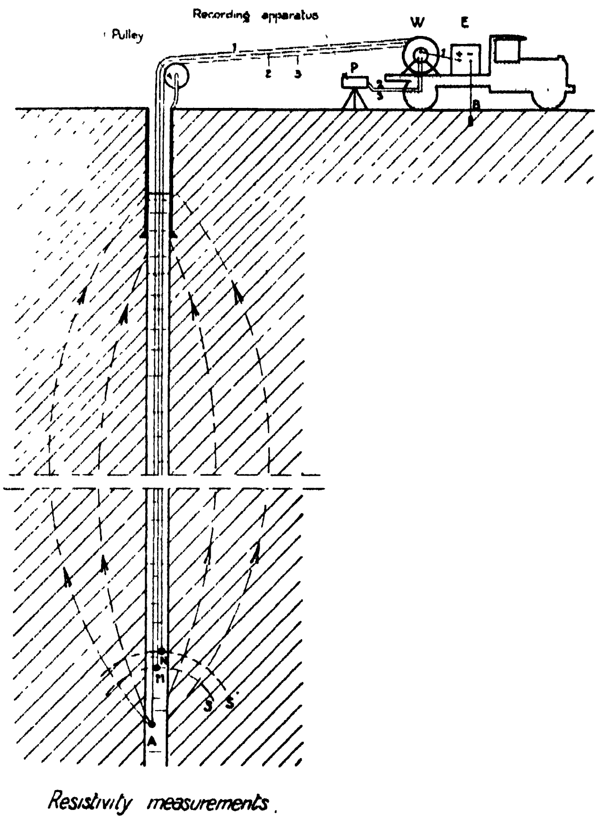

FIG. 1. Scheme of electrical coring device.

A cable composed of three conductors, 1, 2, and 3, wound on a winch W at the surface, is lowered into the drill-hole. To the ends of these three conductors are attached three electrodes A, M, and N, which thus hang in the drilling-mud, and can be raised and lowered by means of the winch. The distances $AM = r$ and $AN = r'$ are constant and are chosen so as to be relatively important as compared with the diameter of the hole. By means of conductor 1, electrode A is connected to a source of direct or alternating voltage E, whose other pole is connected to a ground-electrode B, placed in the neighbourhood of the drill-hole. The upper part of the casing already in the hole is generally taken as ground electrode. The current sent out from electrode A spreads into the ground all around A and, by ohmic effect, creates between M and N a difference of potential, which is measured at the surface by a potentiometer P, adapted to the kind of current produced by E (direct or alternating, as the case may be).

The distance r and r', the intensity i of the current, and the difference of potential ΔV between M and N being known, the specific resistivity ρ of the formations in the vicinity of the measuring-device may be computed if the surrounding formations are homogeneous. The formula is established in the following manner. In flowing away from

electrode A, the current i gives rise to a series of equipotential surfaces around A. In the region of the electrodes M and N (that is to say, neither too near nor too far from A) these surfaces are, for reasons of symmetry, spheres centred on A. The presence of the column of mud or water in the drill-hole brings about no important distortion of these surfaces, particularly if the resistivity of the water does not differ too much from that of the formations. In these conditions, the reading of the potential drop between M and N corresponds to a measurement made inside the formations between the same distances r and r' from electrode A. The application of Ohm's law to the spheres S and S', passing through M and N, leads to the formula:

$$\rho = 4\pi \frac{\Delta V}{i} \frac{rr'}{r'-r}.$$

Up to the present it has been supposed that the formations in the neighbourhood of the device were homogeneous, and that the disturbing effect due to the presence of water or mud was negligible. But these hypotheses are never quite exact. Therefore the formula does not give the real resistivity, but a species of mean resistivity affected by all the elements present in the region under consideration (mud, water, different rocks). This mean resistivity is distinguished from the real resistivity by the name of 'apparent resistivity'. According to circumstances, it can be either smaller or greater than the real resistivity of the most resistant or of the most conductive elements present.

The problem of calculating the real resistivities from the apparent resistivities which have been measured is treated by means of the general mathematical theory of Newtonian potentials. Particular account must be taken of the diameter of the hole, the resistivity of the mud or water filling the hole, the thickness of the bed whose real resistivity is desired, the position and the dimensions of the measuring-device. The results which are obtained in this way are often very startling, and sometimes even seem paradoxical. In practice, fortunately, it is often possible to give a geologically correct interpretation of the readings based entirely on the apparent resistivity. Naturally, the size of the measuring-device must be suited to the particular problem to be studied; likewise the person who interprets the readings must be conversant with the possible peculiarities of the apparent resistivity. It may be concluded from these remarks that resistivity measurements, which at first sight appear very simple, are, in reality, rather complicated when a great degree of accuracy is desired.

The method of resistivity measurement by means of a single electrode lowered into the drill-hole is based on the following principle: The electrode A is attached to the lower end of an insulated cable C, whose upper end is connected to a ground electrode B (usually the casing of the hole). The resistance R of the circuit, comprising the cable C, its two ends A and B, and the formations between A and B, is measured by means of a suitable apparatus. This resistance R is the sum of three terms:

(1) The resistance R_1 of the cable C, which must be measured beforehand.

(2) The resistance R_2 of the ground-electrode B (the ground *around* B) which is negligible if this electrode is of large size (for instance, the casing), and which can in any case be measured exactly by well-known methods.

(3) The resistance R_3 of the ground-electrode A (the formations *around* A).

The known resistance R of the circuit is therefore:

$$R_1+R_2+R_3.$$

The part of the formations between A and B, but distant from these two electrodes, has practically no effect. In fact, its ohmic resistance is absolutely negligible, because of the very wide section offered to the current.

To summarize, we have the formula:

$$R_3 = R-(R_1+R_2).$$

Now R_3 is of the form $K\rho$, where ρ is the resistivity of the formations in the neighbourhood of A, and K is a geometrical coefficient depending on the shape of the electrode A, which can be either measured or calculated beforehand. The resistivity ρ can, therefore, be deduced from the value of R_3 and hence from the measurement of R.

This method, which is much less accurate than that employing three electrodes, was first described in the Schlumberger U.S. Patent No. 1,819,923, and then experimented with under the following form (Karcher Patent No. 1,927,664): The bit is taken as electrode A, and is electrically insulated from the drill-pipe. Cable C is fixed along the drill-pipe. The resistance R of the circuit is measured by reading the intensity of the current produced by a source of known electromotive force. The system can obviously only give rough results. It could be applied during normal drilling operations if all technical problems involved were practically solved. The greatest difficulty is the insulation of the bit, and the whole process is still in an experimental stage.

(*c*) **Spontaneous Potentials in Drill-holes.** A curious phenomenon was discovered during geophysical studies in drill-holes: that of natural currents existing spontaneously in the drilling water or mud at the level of permeable beds. By ohmic effect in the liquid, these currents give rise to differences of potential which are very easy to measure. The current may reach the value of several milliamperes, corresponding to differences of potential of 1 to 200 millivolts. The part played by this phenomenon in the electrical exploration for oil is easily understood. In fact, the determination of permeable beds is absolutely essential for the recognition of oil and water sands and for the correct placing of water-shut-offs.

Two different phenomena for explaining these spontaneous potentials are considered, and have been investigated thoroughly in the laboratory. They are electro-filtration and electro-osmosis.

(1) *Electro-filtration.* When, by exterior pressure, an electrolyte is made to filter through a dielectric, for instance water filtering through sand contained in a glass tube, an electromotive force E is observed between the two ends of the tube, and is given by the formula

$$E = K\rho(P-p),$$

wherein K represents a coefficient depending on the nature of the dielectric and the viscosity of the filtering liquid, ρ the resistivity of the latter, P the pressure at the entrance, and p the pressure at the end of the tube. This phenomenon, which has been known for a long time, is due to the friction of the liquid against the grains of the dielectric.

In drill-holes (Fig. 2), and at a given level, the mud filling the hole exerts a pressure P, which is generally higher than the rock-pressure p at the same level. Under these conditions,

the water of the mud penetrates into the permeable bed, and this percolation produces an electromotive force. The water of the drilling-mud acts as the electrolyte and the permeable bed as the dielectric. In particular, the electromotive force is proportional to the resistivity of the water of the mud and to the difference between the pressures P and p. The electric current flows in the same direction as the filtration, that is to say, in general, the lines of current enter the layer. Thus, at the level of a permeable layer, everything takes place as if the wall of the drill-hole were becoming charged with negative electricity. As a result, a vertical section of the potentials, taken throughout a drill-hole, will show up a negative irregularity at the level of a permeable layer.

As a matter of fact, the irregularity can sometimes be of the opposite sign. The existence of a positive centre indicates the presence of a layer whose liquid tends to flow into the drill-hole, that is to say, a high-pressure formation.

(2) *Electro-osmosis*. It is known that, when two electrolytes are in contact, an electromotive force is observed, having the value:

$$E' = K' \log \frac{\rho'}{\rho}.$$

ρ' and ρ are the resistivities of each of the electrolytes, K' is a constant depending on the chemical composition of the fluids and on the nature of the contact existing between them.

In a drill-hole the electrolytes are generally the drilling-mud, and the salt water existing in the permeable layers. This water obviously exists in water sands, but it also exists, in capillary form, in most oil sands.

In the usual case, where the water of the permeable layer is more salty than that of the mud, the lines of current have a tendency to penetrate into the layer and, under such conditions, the potential profile shows a negative irregularity. Consequently, the separate effects of electro-filtration and electro-osmosis are additive. The reverse is of course also possible.

Generally, electro-filtration is stronger than electro-osmosis, but it has not yet been possible to determine exactly the part played by each in the production of the spontaneous potentials measured in a drill-hole. When the pressure P of the mud is increased, for instance, by means of a pump, after closing-in the casing-head, the electromotive force of filtration E is increased. If the salt content of the mud is changed, the electromotive force E', of osmotic origin, is modified. The resulting variations of spontaneous potentials produced by a permeable layer should make it possible to compute either the pressure p existing in this layer, or the salinity of the water absorbed by it. In any case, it may be said that these determinations present certain difficulties and have as yet no widespread application in practice.

From these considerations it follows that, although the measurement of spontaneous potentials proves *qualitatively* that the wall of a drill-hole is permeable, it does not in any way constitute a *quantitative* measurement of this permeability, that is to say of the rate of flow of a fluid of known viscosity under the action of a known difference of pressure. A detailed discussion has shown the complexity of the problem, but, as in the case of apparent resistivity, it is not necessary to go right to the root of these questions before being able to draw very interesting practical conclusions from the spontaneous polarization, and thus give a correct geological interpretation.

(*d*) **Permeability Measurements.**—The measurement of spontaneous potentials is a simple operation; its technique is seen on Fig. 2.

An electrode M is lowered into the drill-hole by means of an insulated electric cable, and a second electrode N is placed at the surface. The two electrodes are connected to a potentiometer P which, for each position of the electrode M, gives the difference of potential between M and N. As N is always kept at a fixed point and its potential is thus invariable, all that is necessary in order to obtain a relative profile of potentials throughout the drill-hole is to mark on a diagram the different readings taken between M and N.

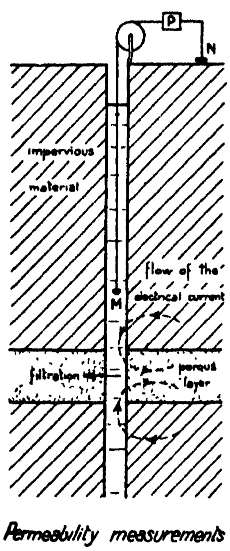

FIG. 2. Scheme of electrical coring device.

When great accuracy is desired, it is preferable to use non-polarizable electrodes. Generally, the best way is to take lead electrodes, within a porous container, holding a soluble lead salt (acetate or nitrate). Sometimes ordinary lead electrodes are sufficient.

Practice has shown what precautionary measures are necessary, and when these are taken, readings are exact to one millivolt, even at the greatest depths (10,000 ft.). This accuracy is not unnecessary, as it is recognized that differences of potential of only a few millivolts may give interesting geological information.

Obviously, the presence of stray industrial currents may sometimes cause inconvenience. In general, natural telluric currents have only a small vertical component and do not give rise to any serious trouble. By employing two submerged electrodes placed close together, the effect of these disturbances is almost entirely eliminated, and even in the case of strong stray currents the local potentials caused by a permeable layer can be measured exactly.

(*e*) **Electrical Logs and Principles of their Interpretation.** Resistivity and permeability measurements are summarized in practice by two diagrams placed side by side, shown schematically in Fig. 3, which also gives the geological interpretation.

The logs are obtained by moving the measuring-device continuously throughout the drill-hole and recording the measurements by means of automatic apparatuses. The two logs are taken simultaneously during a single run, which saves time and ensures an exact correspondence between the two logs as to depth. Both the apparent resistivity, measured in ohms per cubic metre, and the spontaneous potentials, expressed in millivolts, are plotted as abscissae; the depths, which must be correct to a thousandth, or even a half-thousandth, are plotted as ordinates. For this, it is absolutely essential to use an electric cable that is exactly marked, and to take the measurements whilst raising the electrodes, that is to say whilst winding the cable on the winch. It is only by these means that the movements of the electrodes in the hole and the regular stretching of the cable, which is always subject to a certain elastic stretch, can be determined.

The geological interpretation of geophysical measurements is a complicated question. A single parameter, such as resistivity, is insufficient, since several completely different

Fig. 4. Photograph of heavy winch mounted on truck

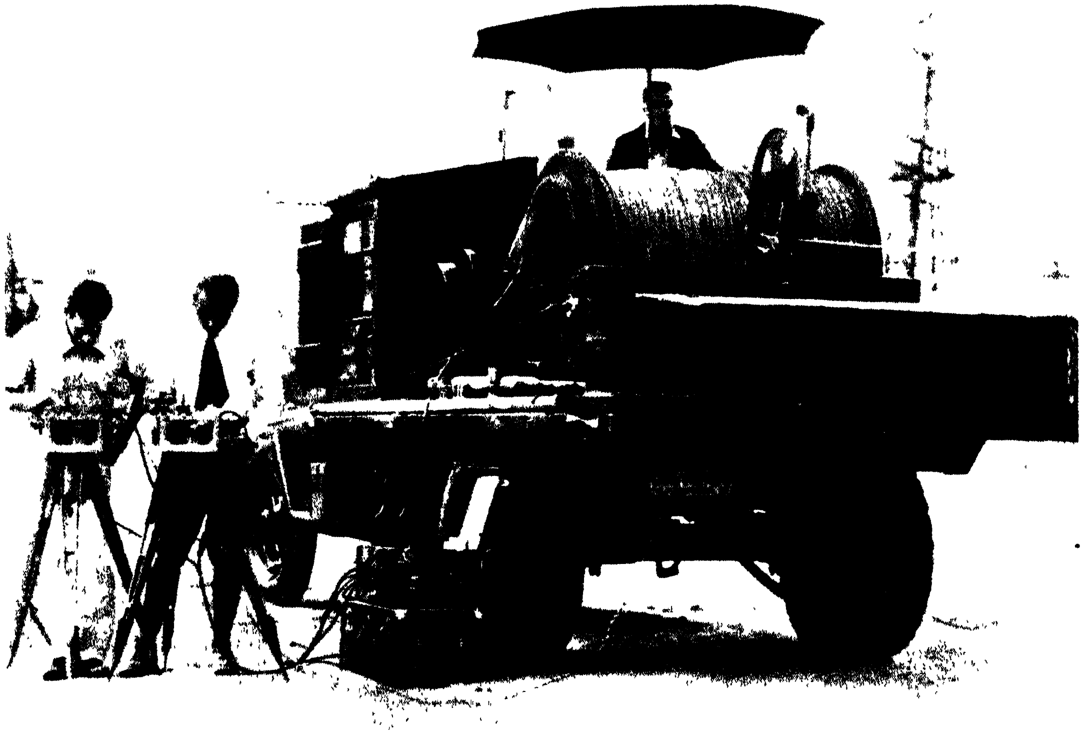

Fig. 5. Photograph of complete outfit in operation

rocks, such as sandstone, limestone, or an oil-bed, can have exactly the same resistivity. By adding a second parameter, such as permeability, the reliability of the diagnosis is greatly increased, and obviously the addition of a third parameter would be useful, assuming, of course, that it is quite independent of the first two. In practice, the task of interpretation is greatly assisted by a knowledge of the

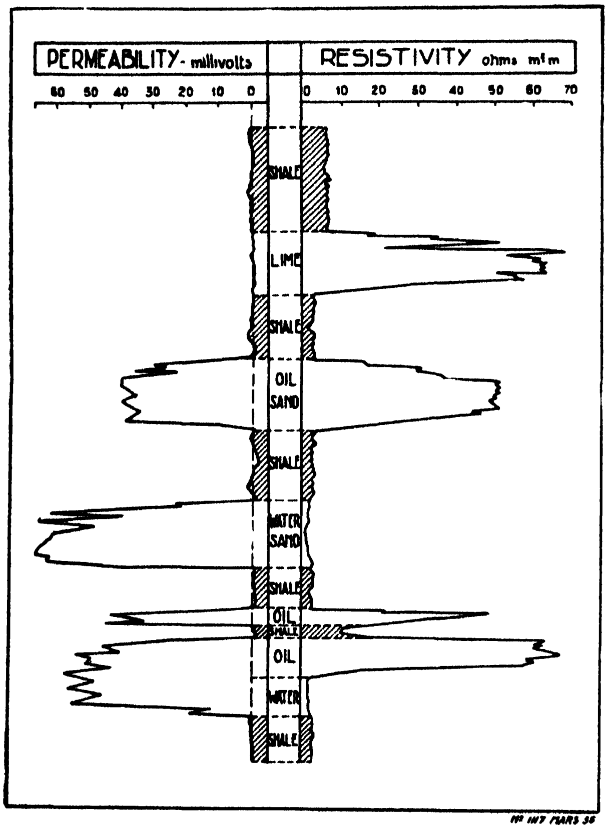

FIG. 3. Interpretation of Electrical Logs.

geology of the region under consideration. In holes in a well-known field, mistakes are usually insignificant. On the other hand, a geophysicist must not be blamed too much for mistaking a bed of coal for one of gypsum or limestone in an isolated wild-cat. A little common sense, and an estimation of the hardness of the bed from mechanical factors (such as the drilling progress in the bed), often enable the uncertainty to be cleared up.

Reading downwards, the following formations are apparent in Fig. 3:

(1) A shale, characterized by its low resistivity and its impermeability.
(2) A resistant (50 ohm metre) and impermeable limestone bed. A compact layer such as coal or gypsum would show up similarly.
(3) An oil sand, both permeable and resistant.
(4) A salt-water sand, permeable and conductive. A very sweet water sand could sometimes, but rarely, be mistaken for an oil sand (because of its possible high resistivity).
(5) At the bottom, a sand whose upper part is oil-bearing and whose lower part is water-bearing—quite a usual occurrence.

III. EQUIPMENT

The same instruments are used for resistivity and permeability measurements.

The three insulated conductors are twined together so as to form a single cable. This cable must possess both high mechanical strength (2, 4, or 8 tons, as the case may be) and excellent electrical insulation (several megohms per kilometre). This last quality is particularly difficult to secure, as the cable is immersed in muds which are often saline, hot, and at high pressure. The cable is kept taut by the weight of a plummet fixed at its lower end. This weight can vary from 25 up to 300 kg., and even more, when the viscosity and weight of the mud make it difficult to lower the device to the bottom of the hole. It is often necessary for the drillers to condition the hole carefully before starting an 'electric run' (either by using a reamer, or by circulating the mud for one or two hours after stopping drilling).

The upper part of the cable is wound on a winch, and its three conductors are connected to the three rings of a collector, which, in turn, are connected to the recording apparatus and to the source of current. For shallow wells, light winches (3,000 to 4,000 ft.) are available, worked by electricity and even by hand. In regions difficult of access, a winch, mounted on skids and driven by an oil engine, is used. In most cases, where it is possible to reach the wells by lorry, a strong and heavy winch is employed, capable of carrying more than 10,000 ft. of cable and of standing a strain of several tons. With this outfit the deepest wells can be surveyed (Fig. 4).

In the immediate vicinity of the winch, the cable passes through a measuring-device which shows continuously the length that has been unwound and which also actuates the unrolling of the paper on the recording-instrument. At the well-head the cable runs over a pulley to which is fixed a dynamometer indicating the tension.

The source of current is generally a dry-cell battery which produces either direct or alternating current by means of a commutator.

Potentials, whether direct or alternating, are measured preferably by a zero method with a specially adapted potentiometer. The recording is made on a paper unwinding at a speed proportional to that of the cable. In the semi-automatic apparatus in use at the present time, the operator constantly keeps the needle of the potentiometer at zero, by means of a handle controlling the tracing-pencil (Fig. 5). Entirely automatic apparatus will soon be available, and will eliminate all the tiring work for the operator, as well as possible errors. The tracing of the log can be made in a closed box, if it is wished to keep the results secret from the operators.

The simultaneous recording of the resistivity and permeability logs is made possible by the use of alternating current for the resistivity measurements. One of the potentiometers, only sensitive to alternating differences of potential, records the resistivity, whilst the other potentiometer, sensitive only to direct current, records the spontaneous potentials.

The speed of electrical coring depends largely on the requisite detail, and consequently on the depth scale that is adopted. This can vary from 1/50 for very accurate studies up to 1/1,000 for general investigation. With the semi-automatic apparatus the usual speed is about 1,000 ft. an hour, and it could be increased noticeably with a completely automatic apparatus. Including the setting-up and

the removal of the equipment, the total time for a run varies between two and six hours according to the depth, the amount of open hole, and the difficulties encountered whilst lowering.

IV. APPLICATION OF ELECTRICAL LOGS

(*a*) **Geological Correlations.** The first problem that electrical coring has to determine is that of correlation between neighbouring wells. It is obvious that any physical parameter of the formations can be used for this purpose, if only this parameter shows up a constant value for a given formation over a large enough area, and if the values for different formations are sufficiently distinguishable.

In present-day practice, correlations are made on the basis of two parameters, resistivity and permeability, each possessing its own particular advantages according to the special circumstances. The best key horizons or markers in an oil region are generally the clays, or shales, which, because of their sedimentation far from a shore-line, show maximum regularity of facies and of thickness over large areas. Both their resistivity and permeability are low and characteristic. Sands, which are formed near shore-lines, are much more sporadic, and apart from this, their electrical parameters vary with the nature of the fluid they contain (oil, gas, salt water, fresh water).

Palaeontological key horizons are obviously unobserved by electrical coring unless they correspond to some lithological change as well. On the other hand, there sometimes exist excellent electrical markers, resulting from a slight variation in the average composition of the rocks, which are difficult to recognize by simple examination of mechanical cores.

Correlation is very easy when simple and clear electrical markers are present. It is much more difficult in oil series consisting of numerous beds of shale and sand, especially

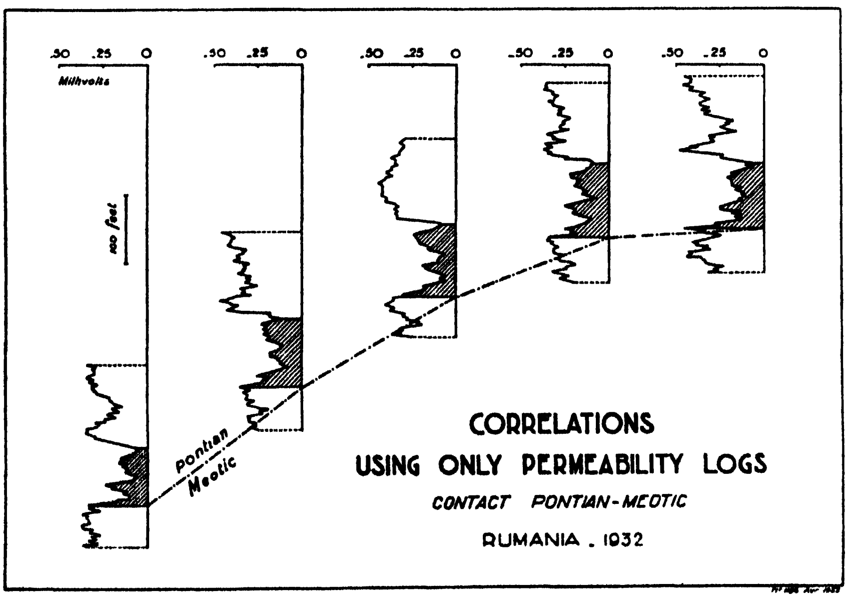

FIG. 8.

if the structures are steep and cut by many faults. It is precisely in such difficult cases that electrical coring renders the greatest service and gives a true notion of tectonics.

Electrical correlation between two wells is based essentially on the comparison of the form of their logs and on an endeavour to make them correspond as well as possible. The use of letters to indicate the different electrical markers is advisable. It has the advantage of avoiding risky geological assumptions. A few examples will make this clear.

Fig. 6 is taken from recent work in a tectonically complicated field in the Far East and is self-explanatory. There exists an alternation of sands (very permeable and very resistant) and shales (low permeability and low resistivity).

Fig. 7 is an example of the contact between the Dacic and Pontic series in three Roumanian fields. The Dacic is a zone comprising numerous sand-beds and giving rise to very irregular logs (it is to be noted that the resistivity is indicated on a logarithmic scale). Conversely, the Pontic is a very homogeneous marly formation (with low resistivity and slight permeability). Its appearance remains identical over a vast area, since the distance under consideration is about 25 miles.

Fig. 8 is an example of correlation by means of the permeability log only. It concerns the Pontic/Meotic contact in different wells of Gura-Ocnitzei and Gorgoteni (Roumania). This contact does not show up clearly on the resistivity log. On the contrary, very impermeable clays at the base of the Pontic give a very characteristic outline to the permeability logs.

Fig. 9 shows a section of the Grozny anticline—New Fields (U.S.S.R.), established according to the resistivity log.

(*b*) **Tectonic Studies.** Correlation work finally leads to the establishment of structural maps, which are drawn on one or several horizon beds or markers. These markers are located in each well according to the electrical log, as well as by mechanical coring. Likewise, as drilling proceeds, a 'normal' or composite well-log is made on the basis of the results of a careful study of the cores and the electrical logs of each well. Such a standard well-log shows the layers in their normal sequence, without any omission or repetition, and is taken as the basis of comparison for new wells. Electrical work, thus applied, very often leads to the discovery of faults and can explain anomalies encountered during exploitation. Formerly, such anomalies were often erroneously attributed to the lenticularity of the beds.

Fig. 10 gives a clear and simple example of a fault in a Venezuelan field. Well (1) is a typical hole, with two markers *A* and *B*, 450 ft. distant, as is usual. In well (2) the distance between these markers is only 110 ft. owing to the presence of a fault which cut out 340 ft.

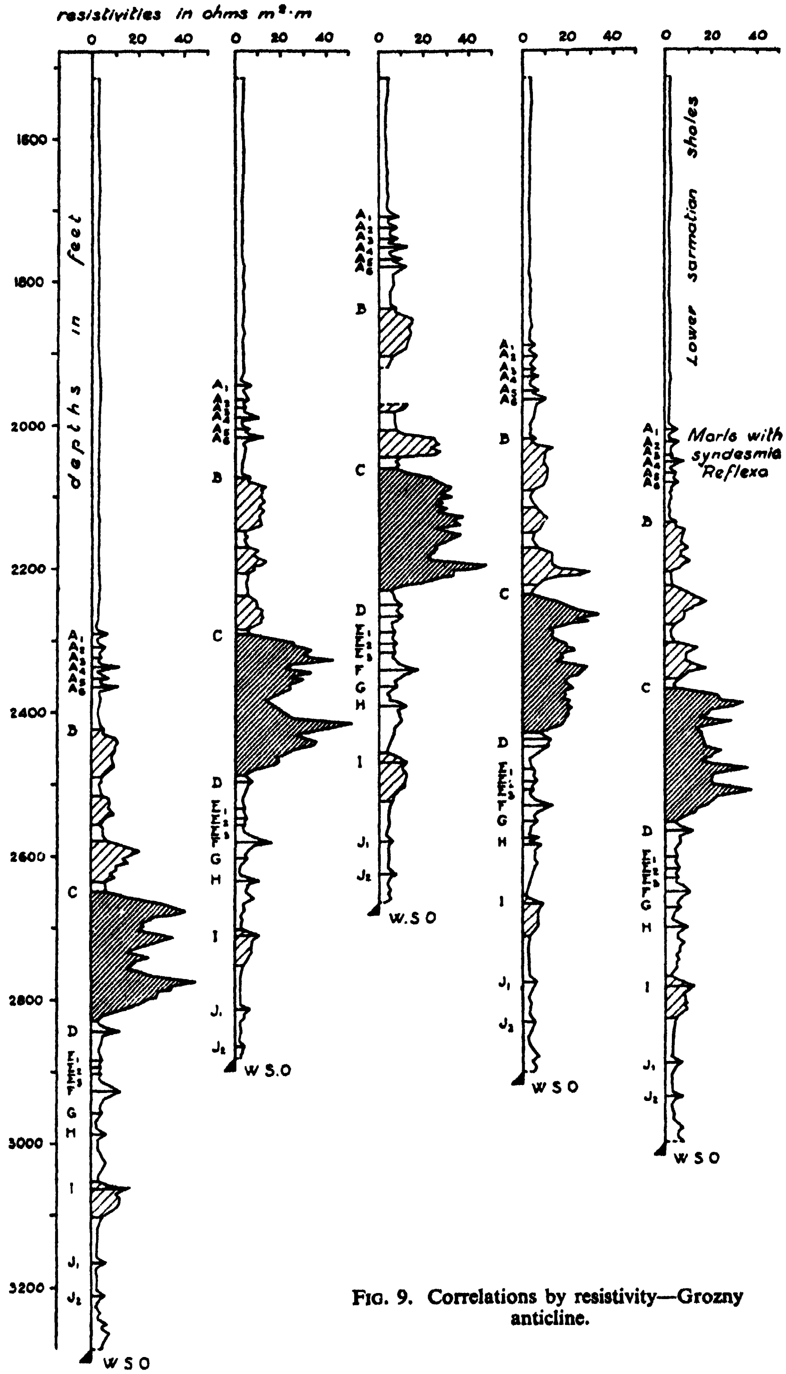

FIG. 9. Correlations by resistivity—Grozny anticline.

(*c*) **Detailed Study of an Oil Zone.** The study of an oil zone consists in determining exactly the positions of the oil, gas, and water sands, in order to set the water-shut-off at the right depth, to decide which sections are to be put on production, and finally whether any plugging back is necessary. Except in the case of work executed near already well-known wells, it is no longer merely a simple correlation that is needed, but a direct and absolute interpretation of the electrical measurements.

This is a difficult problem, and it must be admitted that in numerous cases an absolutely correct interpretation cannot yet be given. To begin with, the distinction between oil and gas is often rather doubtful. Then, some drilling-mud and particularly some of the water of the mud will always filter into an oil sand, and often conceal the usual high resistivity

of the oil, since the electrical measurement is only affected by the region close to the drill-hole, that is just where filtration is most important. This drawback is most serious with light oils. Beds of thick, oxidized, and viscous oil, on the contrary, show up very clearly on the logs, sometimes even in too marked a manner.

In spite of some technical imperfections this method

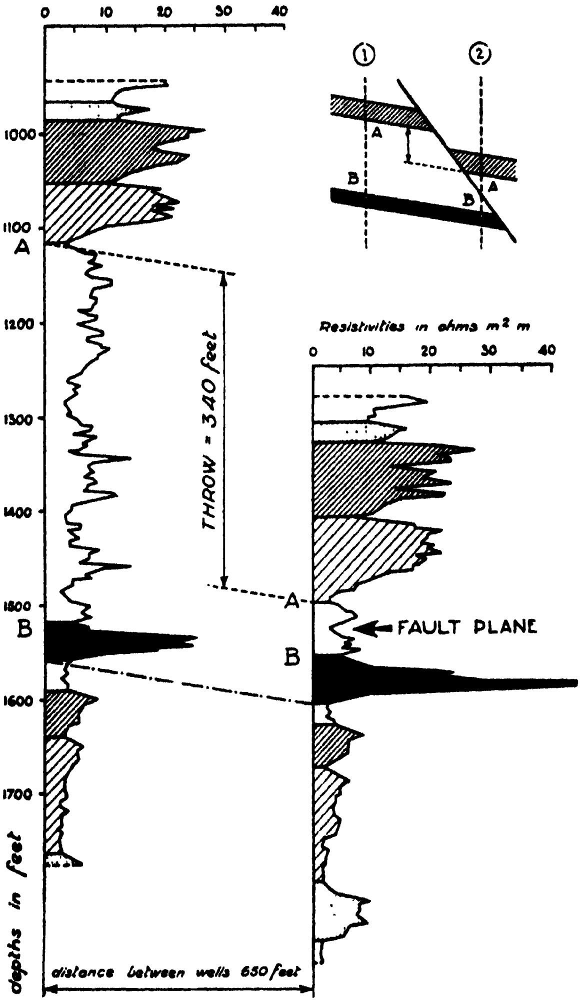

FIG. 10. Determination of a fault—Venezuela.

has already proved itself to be a very great help to this important branch of oil exploitation. In favourable cases, which are numerous, the interpretation is absolutely reliable. The position of the clays or shales, where the water-shut-off should be made, is always well defined electrically, since a mistake in the diagnosis of clays is almost impossible.

The example of Fig. 11 comes from Trinidad, and is quite recent. The electrical interpretation, which was verified when the well came into production, is shown on the figure. The two upper sands are partially water-bearing and are not exploited. The water-shut-off was thus made just above the lower oil sand, and the bottom of the hole was plugged back. Production was satisfactory, and the oil obtained was water-free.

(*d*) **Discovery of New Oil Sands.** It is common knowledge that pay sands are often missed by rotary drillers, and this for two reasons. Either a core was not taken or it was

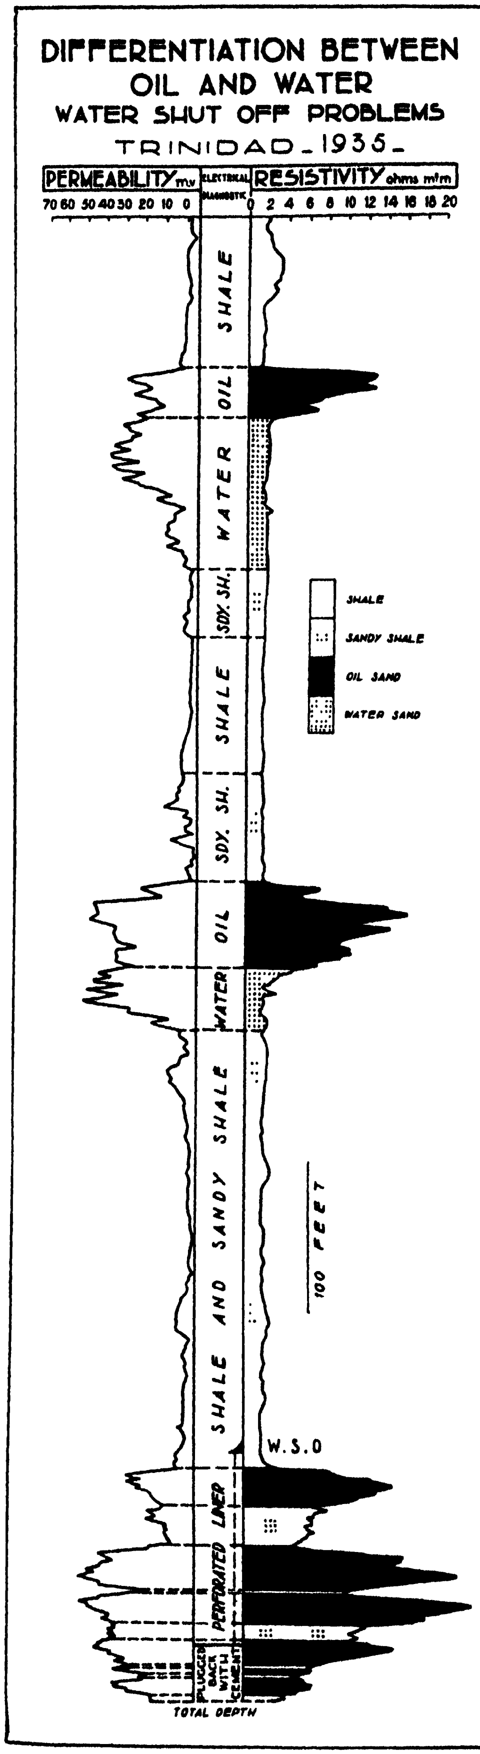

FIG. 11.

lost at the depth of the sand, or else the nature of the sand and oil were such that the core brought to the surface had completely lost its oil and appeared barren. The opposite can equally be true. The core, apparently rich in oil, belongs to a bed already invaded by water and unproductive from a practical standpoint.

To date, electrical coring must already be credited with the discovery of numerous otherwise unsuspected oil sands. Naturally, these sands are found mostly in the upper formations of the fields. If such a sand was once passed by during the exploration life of the field, the exploitation wells will continue to miss them, since they will be drilled

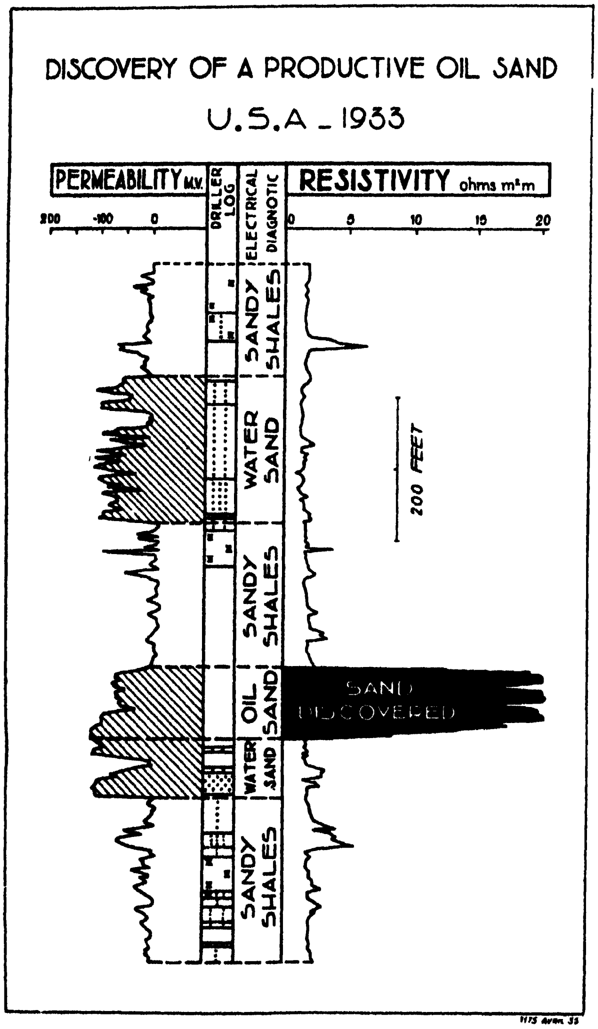

FIG. 12.

as rapidly as possible through what are believed to be unproductive horizons.

Fig. 12 is an example taken from the United States and Fig. 13 from Roumania. Thanks are due to Dr. Patriciu, Chief Geologist of the Credit Minier Company, who provided the data on the Viforata well. The two Meotic oil sands were passed by completely unnoticed, in spite of six cores having been attempted or taken in the neighbourhood, and even in one of the sands themselves.

(e) Relation between the Resistivity and the Productivity. Oil sands would show an infinite resistivity if the pores of the sands were entirely filled with pure oil. In reality, this resistivity is often not above a few ohms. This is due to the presence of films of water which, by capillarity, surround the grains of sand and establish a conductive network allowing the circulation of the electric current. It can easily be understood that, when the degree of oil impregnation and the pressure are high, the amount of capillary water is small and hence the resistivity is high.

Another factor must be mentioned in connexion with the above elementary principles. The logs give, as a general rule, the 'apparent resistivity', and no correction is made to determine the 'real' resistivity at a given distance from the hole. Therefore a low-pressure sand, more or less flooded by the water of the drilling-mud, will show up a low apparent resistivity. This electrical parameter therefore

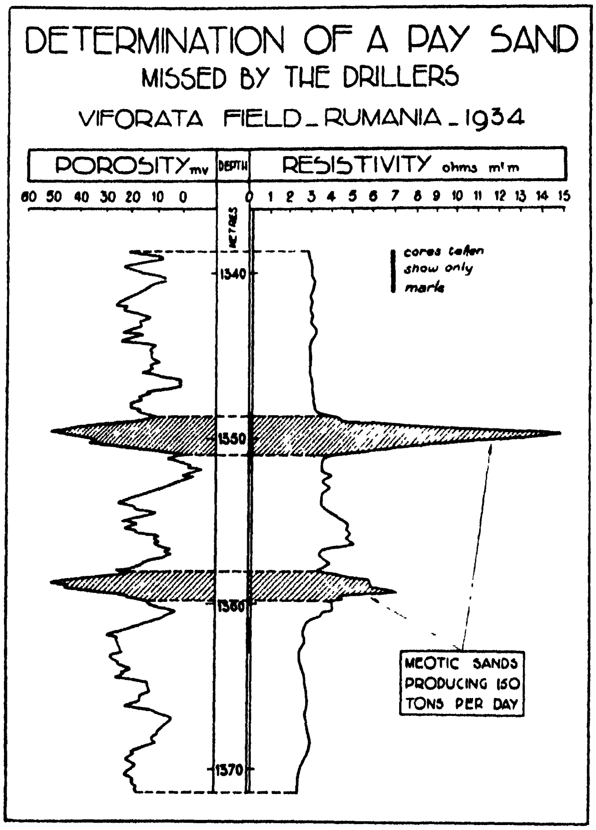

FIG. 13.

depends, to a certain extent, on the value of the pressure of the layers as opposed to the hydrostatic pressure of the mud, and a high rock-pressure is an indication of good productivity.

It should be clearly understood, therefore, on the basis of the above complex theory, that an absolute correspondence can never exist between resistivity and productivity. But, on the other hand, there is often a close relationship between these for a given layer in a certain field. The following examples show this clearly:

Fig. 14 shows five wells of a Venezuelan field. It is a good example of correlation, and it also shows how the resistivity of an oil sand decreases when moving from up-structure (well (*a*)) down the flanks into the edge-water (well (*e*)). The productivity follows a similar law.

Fig. 15 shows the log of five wells drilled in the Dacic of the Gorgoteni field (Roumania). First of all, it should be noticed that the Drader sand, which is figured shaded-in, shows up as very permeable and also very resistant when well saturated. These logs give the detail of the sand, and it can be studied easily foot by foot; the central clay streak

is clearly seen. Under each log is marked the corresponding initial daily production in tons. Reading these figures from left to right, it is seen that the decrease in production from 320 to 0 tons corresponds to a parallel decrease in the mean resistivity of the bed. Furthermore, the last well but one on the right appears to be really productive only at the base of the sand, and the very last one shows a permeable but non-resistant zone, which is a proof of sands without oil. often give very exact information as to the position of edge-water and as to its encroachment within the oil sands during their exploitation. This information is particularly useful in guiding the petroleum engineer in the case of several neighbouring but distinct sands, which may be exploited either together or separately, and in which the water-table does not necessarily rise in the same manner. The following example is given by Mr. Denissevitch (Azerbaidjan

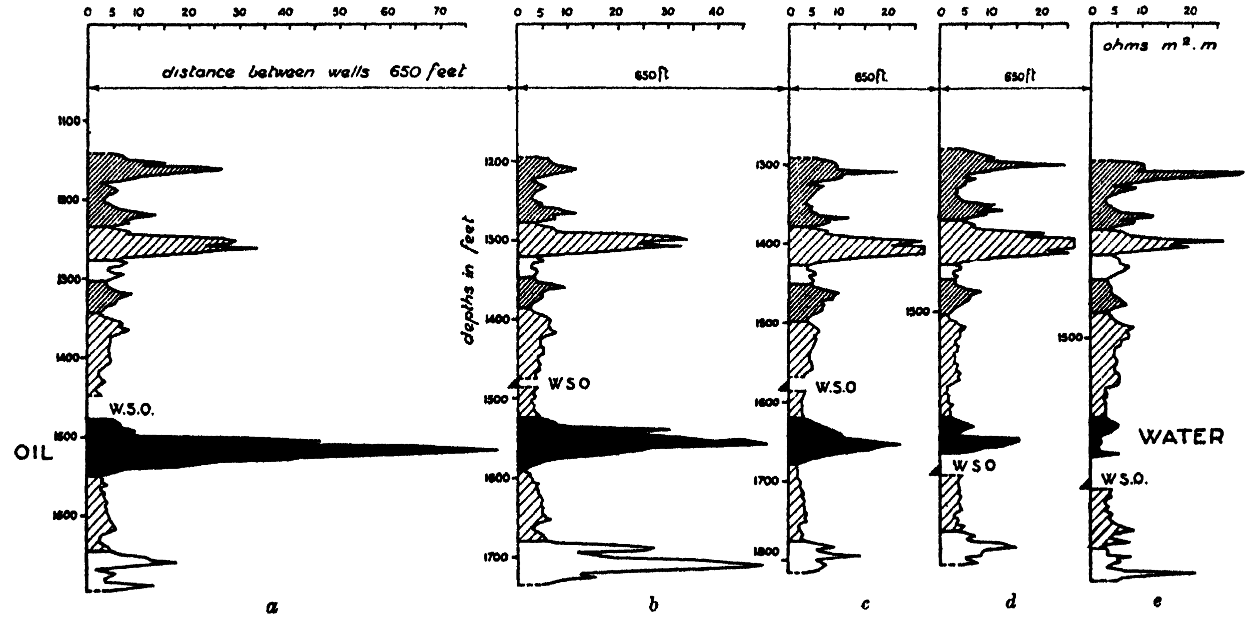

FIG. 14. Transition of a good producing sand into a water sand—Venezuela, 1930–1.

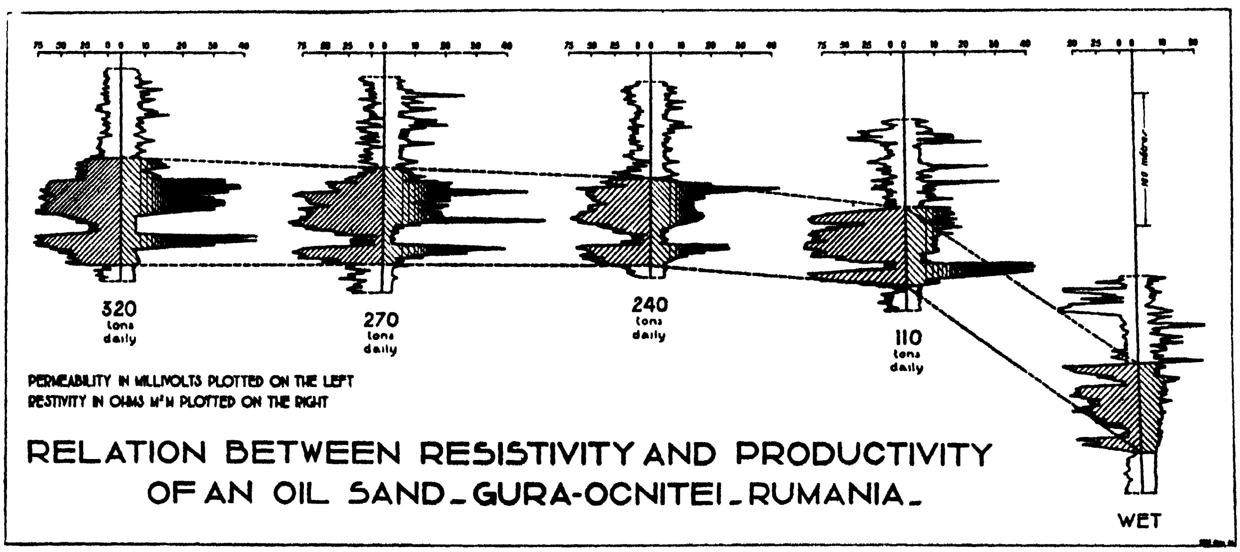

FIG. 15.

The parallelism between productivity and resistivity has been very widely used in the U.S.S.R. to draw horizon maps giving the value of the product of the thickness of the sand by its mean resistivity. Such a map is drawn in order to foresee the probable productivity of different wells exploiting the layer under consideration and to determine the spacing between the wells. It is in the form of a resistivity map with 'equi-resistivity' curves. These curves often cover the entire structure and define the position of the edge-water correctly.

(*f*) **Study of Edge-water.** Electrical resistivity diagrams

Petroleum Industry, November/December 1934). It concerns three layers called N.K.P. in the Sourakhany field at Baku. Fig. 16 shows a cross-section of the structure at successive periods of the life of the field; the resistivity logs of the sands are shown, together with their dates and the numbers of the wells.

Section (*a*) gives the assumed position of the water in September 1933, as well as the resistivity logs prior to this date. On the south-west flank the level of the water corresponds remarkably with the indication of the log of well 179. Section (*b*) shows the situation in February 1934. A new

well on the south-west (No. 668) shows that the two lower layers are flooded and that only the upper layer contains some oil at its top. Section (*c*) shows the situation in September 1934. On the south-west flank, the water encroaches regularly in the three layers. On the contrary, to the north-east a marked irregularity is to be noticed. The water has risen higher in the upper sand than in the other two (wells 571 and 724). Lower down, in well 719, the middle layer still contains oil, whereas the two others are flooded; it will therefore be difficult to recover this oil.

electromagnetic teleclinometer with an induction compass and a magnetic pendulum. This apparatus, which can only be used in the uncased part of a hole, has already been proved to be reliable by actual performance during several years [2].

3. Determination of the direction of formation-dips. This instrument is based on the ellipsoidal shape of the equipotential surfaces produced in anisotropic strata by electrical current flowing from a point electrode. This 'dip-meter' can be used at any depth [2].

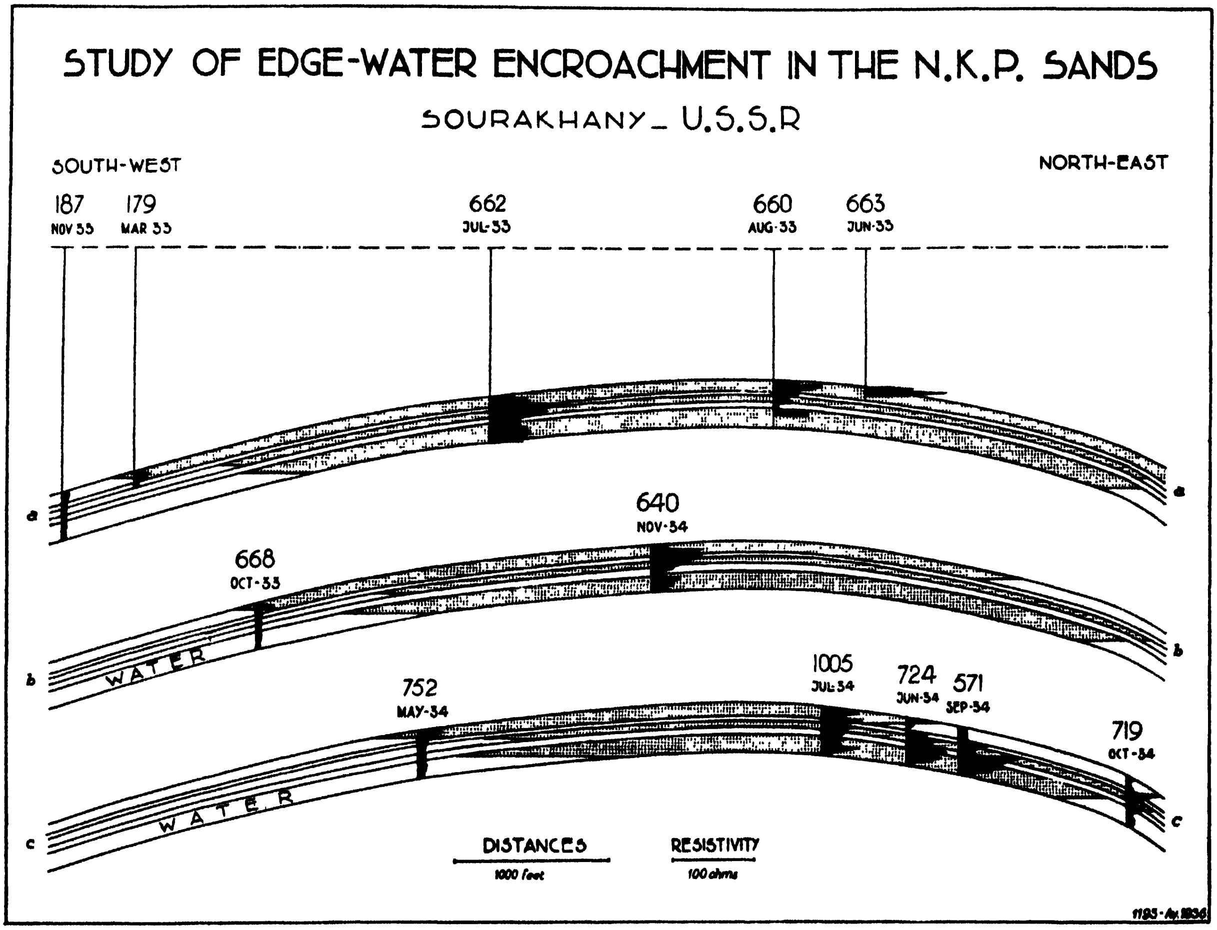

FIG. 16.

V. SUPPLEMENTARY OPERATIONS

Electrical coring operations (resistivity and permeability) can be completed by other geophysical measurements, using the same surface equipment (winch, cable, recording-potentiometer), but with special instruments lowered into the hole on the end of the cable. These supplementary operations cannot be fully described in the present article, and we shall discuss them only very briefly.

1. Continuous temperature logs inside a well. The electrical thermometer suspended at the end of the cable is of the resistance type. It is correct to a tenth of a degree centigrade and assumes the temperature of the surrounding mud or water quickly enough to allow a running speed of 15 cm. per second. These logs solve a number of problems, such as measurement of thermal conductivity of the different formations, location of water-flows, determination of the height of the cement behind the casing, &c.

2. Directional survey of crooked holes, by means of an

4. Many minor operations such as, location of the separation between oil and water in a well which is standing, search for pieces of metal lost in the walls of a hole, exact determination of the casing-shoe, perforation of the casing, &c.

VI. CONCLUSIONS

A summary of the principles of electrical coring and its major applications have been given. These methods may still be improved considerably as to many details, and for this purpose, further experiments are being made continually. It may, therefore, be hoped that electrical diagnosis will become more and more accurate and reliable, especially as to identification of the fluids absorbed by a permeable layer (oil, gas, or water). The adoption of drilling-muds specially suited for electrical processes (high resistivity, low viscosity, adequate colloidal properties) will undoubtedly improve matters considerably.

A few words may be added about the economic side of electrical coring. The process is very rapid, especially for the study of a deep open hole. It is also cheap, as the cost of an entire run corresponds to that of but a few metres drilled and a very few metres cored mechanically, this being particularly true for deep wells.

When electrical coring is introduced into a new oil region, it is necessary to compare it with the information already available from mechanical coring. In such a case it is undoubtedly an extra expense which, to the layman, may sometimes seem a useless luxury.

After this first stage and if, as is usually the case, geological conditions are favourable, it will be found that the results of electrical coring are at least as reliable as those of mechanical coring. When this occurs, the amount of mechanical coring is greatly reduced, and sometimes even abolished altogether (U.S.S.R.). This results in a great economy, and removes the drawbacks of mechanical coring (waste of time, poor recovery or total loss of cores, fishing jobs). The value of electrical coring is then unquestionable.

This economic aspect of the question, which it is easy to estimate in any given case, is not, however, the greatest advantage of electrical coring. The essential point is that, owing to the continuous logs, new facts are always available which may change the entire development of a field. These facts are: (1) The existence of electrical markers, invisible from cores, which enables structural maps in apparently homogeneous series to be drawn. (2) The recognition of previously unsuspected faults, and, in general, the correct and detailed interpretation of the tectonics of a field. (3) Above all, the discovery of new oil horizons, which had been unknown before. Experience has shown that such discoveries are frequent, and have an economic value much greater than the mere reduction of expenses due to the abolishing of mechanical coring.

It is obvious that electrical coring should be applied very prudently and progressively in a new region, as the mistakes of too hurried an interpretation can have serious consequences. The most important points to bear in mind are therefore: the quality of the measurements and the accuracy of the interpretation, that is to say, good equipment and experienced operators, even if such do cost a little more.

Except in limestone fields where few studies have as yet been made, it may be said that wherever electrical coring has been introduced, it has come to be used progressively in most of the rotary holes, and has thus become part of the routine of exploitation. Such has been the case for Venezuela, U.S.S.R., and Roumania. To-day this method is becoming more and more widely used in the U.S.A. The only exceptions to date are those fields whose geology is extremely simple, and those where the examination of cuttings (micro-fossils and characteristic lithological debris) enable one to follow up the stratigraphical horizons during drilling, with great ease.

GRAVITATIONAL METHODS OF PROSPECTING

By DONALD C. BARTON, Ph.D., M.Inst.P.T.

Geologist and Geophysicist, Humble Oil and Refining Co.

INTRODUCTION

THE possibility of the use of gravimetric surveys in the search for petroleum lies in the following circumstances:

1. In areas of unwarped, unfolded, unfaulted sediments the distribution of density tends to be constant horizontally, but to vary vertically, mostly in the direction of increase of density with depth.
2. Structural deformation raises or depresses rock of one density into a zone of another density.
3. Many of the resulting abnormalities in the subsurface distribution of density produce appreciable distortion of the gravitational field at the surface.
4. The appreciable anomalies can be mapped by instruments which are of high scientific precision and sensitivity, which can be used in rapid field surveys.
5. From the form of those anomalies, conclusions can be drawn in regard to the distribution of density in the subsurface.
6. Hence conclusions can be drawn in regard to the geologic structure of the area.
7. Many types of commercial oil deposits are found on types of structure which produce appreciable gravity anomalies.
8. The oilman, therefore, may indirectly hunt for commercial petroleum deposits by the petroleum geophysicist searching for the kind of gravitational anomalies which are produced by those structures on which deposits are likely to be found.

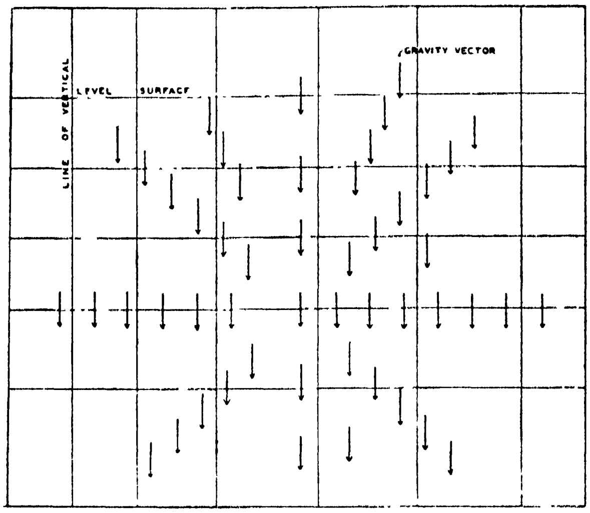

FIG. 1. Diagrammatic section through the gravitational field at the surface of a homogeneous earth with a flat surface. Vertical lines denote lines of the vertical, horizontal lines denote level surfaces; arrows indicate gravity vectors.

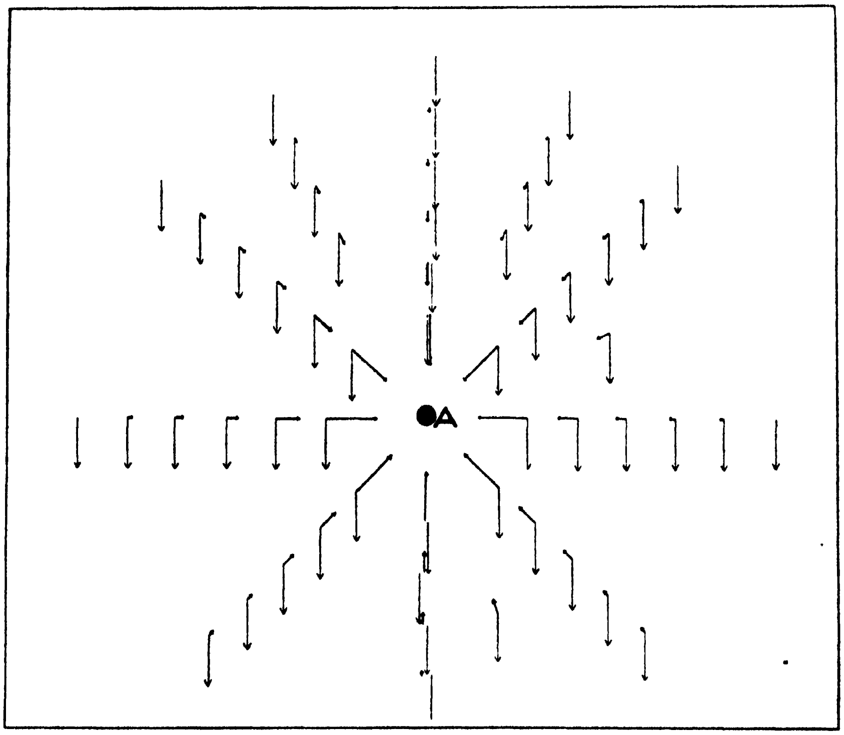

FIG. 2. A sketch of the field of Fig. 1 with a dense mass *A* added; diagonal arrows denote vectors of the gravitational attraction of *A*.

The petroleum geophysicist must first map the areal variations of the gravitational field at the surface. He must then consider the anomalies in his map, by analysis and quantitative calculations, by drawing on his geological knowledge and experience, and decide whether the indicated structures are likely to be in favour of the occurrence of commercial oil deposits.

MATHEMATICAL-PHYSICAL BASIS

A. Quantities Measured

Gravitational Field.

If the earth's crust were homogeneous, and if the earth's surface were perfectly flat, the lines of the vertical would be straight lines perpendicular to the earth's surface; and the level surfaces would be flat surfaces parallel to the earth's surface. (See Fig. 1.)

If a much denser body such as *A* in Fig. 2 is present in the otherwise homogeneous earth's crust of Fig. 1, it will set up its own gravitational field. Its attraction will be exerted radially towards itself, and the intensity of the attraction necessarily will vary according to Newton's law of the inverse square of the distance. The radial vector arrows of Fig. 2 represent the field gravitational attractions of the body *A*.

The actual total gravitational field will be the vectorial sum of the earth's gravitational field plus the field of body *A*. The vector of the actual gravity will be the sum of the vector of earth's gravity and the vector of the attraction by *A*. The resultant vectors are the ones shown in Fig. 3.

It should be remembered that the intensity of gravity at sea-level is slightly less than 980 gal.[1] (cm./sec.^{2}), and the intensity of very large structural anomalies is 0·050 gal. (cm./sec.^{2}). The ratio of gravity to the attraction of a body such as *A* in the earth's crust is distorted more than 20,000 times in Figs. 2, 3, and 4. The angular deviation of the resultant vector in Fig. 3 from the vector of earth's gravity actually is extremely minute.

The vector arrows of gravity are tangent to the lines of the vertical; and the latter, therefore, bend towards the body *A*.

The level surfaces necessarily, then, are tilted up and arch over the body.

If the density of *A* were less than normal, the vector arrows and the lines of the vertical would be deflected away from *A*, and the level surfaces would arch down above it.

Quantities used in Prospecting.

Three different components of the gravitational field of Fig. 3 are used in prospecting for oil: (1) the horizontal variation of the intensity of gravity; (2) the space rate of change of that horizontal variation of gravity; and (3) a quantity termed the differential curvature.

(1) Horizontal Variation of Gravity. If the gravitational field was wholly due to *A*, gravity would be represented by the radial vector arrows of Fig. 4 (and Fig. 3); but the direction of gravity in the composite system (field of attraction of *A* plus earth's gravitational field) will deviate only infinitesimally from the direction of the earth's gravity on account of the ratio 0·05 to 980 between the attraction of *A* and earth's gravity. The gravitational effect of *A* in contrast to its attractive effect, therefore, will be the vertical component of *A*'s attraction. Gravity at any point, therefore, will be the sum of the earth's gravity plus the vertical component of *A*'s attraction. The radial vectorial arrows and the accompanying heavy vertical component in Fig. 4 represent respectively (*a*) the gravitational attraction of body *A*, which is radially towards the body, and (*b*) the (anomalous) gravity of body *A*, which is the vertical component of its gravitational attraction. The curve of the variation of the anomalous gravity which is produced by body *A* is shown by the gravity profile in the middle part of Fig. 4. The anomalous gravity of the body *A* in any given level surface increases from zero at infinite horizontal distance to a maximum above the body. The form and amplitude of the gravity anomaly vary with the shape and the excess or deficiency of density of body *A* and its depth below the level surface

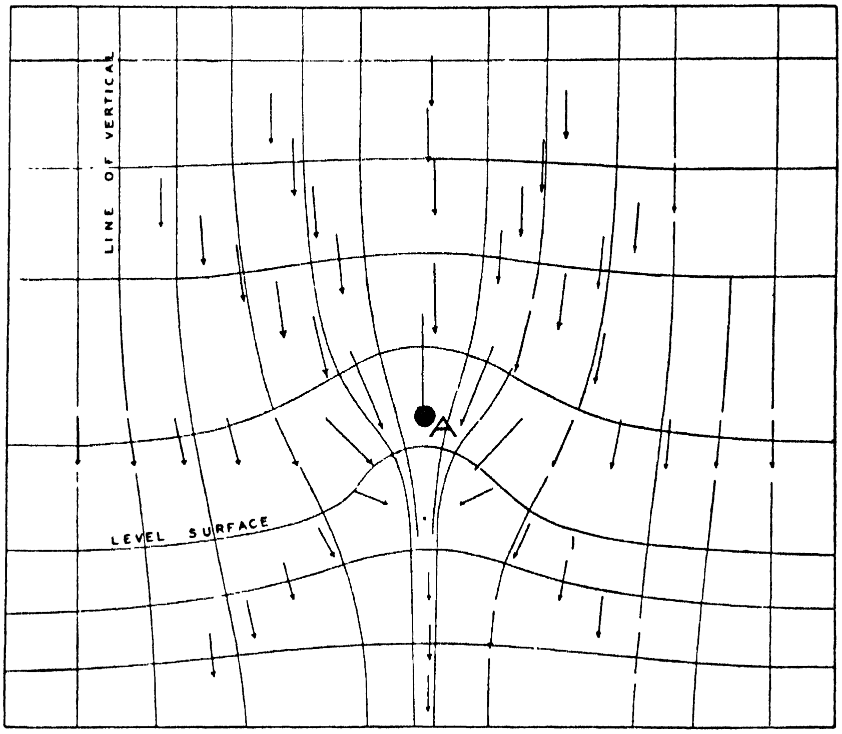

FIG. 3. The composite gravitational field. The arrows indicate the resultants of the two sets of vector arrows of Fig. 2. The warped vertical lines and a plane section of the level surfaces are also drawn.

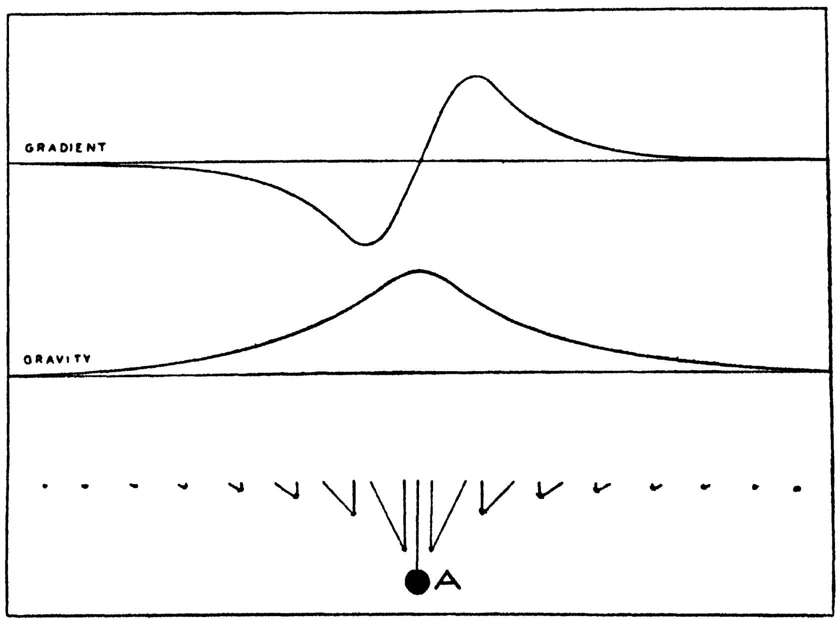

FIG. 4. Diagrams of the gravitational fields of Figs. 2 and 3. At the base is a line of vectors due to the attraction of the mass *A*; their vertical components are also drawn The curve in the middle shows the variations of those vertical components. The top curve plots the gradients of the middle curve and gives the space rate of change of the vertical components.

in which the value of gravity is observed, or to which it is referred.

The unit of measurement of the horizontal variation of gravity in prospecting is the milligal (0·001 cm./sec.^{2}) and tenth milligal, which are approximately the millionth and ten-millionth part of gravity at sea-level.

(2) **The Rate of the Horizontal Variation of Gravity or the Gradient.** The rate at which the gravity curve (Fig. 4) varies per horizontal centimetre is the gravity gradient (curve in upper part of Fig. 4) which is used in geophysical prospecting. It is the rate at which the vertical component of *A*'s attraction varies horizontally; it is the space rate at which gravity varies horizontally. There is also a corresponding vertical gradient, but the vertical gradient of *A*'s gravity is unimportant, and that of the earth's gravity is assumed to be constant, but a suitable correction is applied in surveys with the pendulum and gravimeter.

The unit of measurement of the gradient is 1×10^{-9} gal. per centimetre (cm./sec.^{2}/cm.), and is approximately the change of one-million-millionth of gravity at sea-level, per horizontal centimetre. It has been designated an 'Eötvös' unit, and is represented by the letter 'E'. The gradient is a vector, and is represented on maps by an arrow which flies in the direction of the maximum increase of gravity; its length is drawn to scale, most commonly 1 mm. equals 1 E.

(3) **Differential Curvature.**[2] The Eötvös curvature quantity is described by the following formula:

$$-g\left(\frac{1}{r_{\min}} - \frac{1}{r_{\max}}\right), \text{ and by an azimuth } \lambda, \quad (1)$$

in which g = intensity of gravity, $r_{\min}$ = minimum radius of curvature, and $r_{\max}$ = maximum radius of curvature of a level surface at the point of reference. The radius of curvature of an arc at any point is measured by the radius of the circle which fits the arc best at that point. The reciprocal of the radius of curvature decreases to zero as the curvature flattens to zero, and increases with the sharpness of curvature. The quantity $(1/r_{\min} - 1/r_{\max})$ is zero if there is no curvature of the level surface or if it is equal in all directions; this quantity increases as the curvature of the level surface increases in one direction and/or decreases (algebraically) in the perpendicular direction.

Geometrically, through the relation $(1/r_{\min} - 1/r_{\max})$ and the azimuth λ, the differential curvature gives the direction of greatest curvature (and necessarily the perpendicular direction of least curvature), and tells whether the curvature of the level surface in one principal direction is more than in the other major direction. It gives, however, no measure of the actual degree of curvature.

Any symmetrical differential warping of the level surface and the corresponding tilting of the vertical at each weight of a torsion balance gives gravity a small horizontal component at each weight, and thereby produces a torque which is proportional to the intensity of gravity as well as to the magnitude of the quantity $(1/r_{\min} - 1/r_{\max})$. The curvature quantity which the torsion balance measures, therefore, is

$$-g(1/r_{\min} - 1/r_{\max}).$$

The differential curvature is expressed in terms of a unit 1×10^{-12} cm.$^{-1}$. When this quantity is multiplied by g, the unit selected is (1×10^{-9} gal. per cm.) It must be remembered that the value of g is 980 gal. and for practical work this may be taken as 1,000, because the differential curvature $(1/r_{\min} - 1/r_{\max}$ is not observed with an accuracy of 2%.

On maps, the differential curvature is represented by a line whose direction is that of the axis of *algebraically* least curvature and whose length most commonly is drawn to the scale 1 mm. = 1 E (1×10^{-12} cm.$^{-1}$).

B. Measurement of the Three Quantities: Gradient, Differential Curvature, and Relative Gravity

I. Measurement by the Torsion Balance of the Gradient and the Differential Curvature.

Torsion Balance. The Eötvös torsion balance consists essentially (Fig. 5) of a carefully prepared and calibrated, very thin platinum-iridium (or tungsten) torsion wire (1),

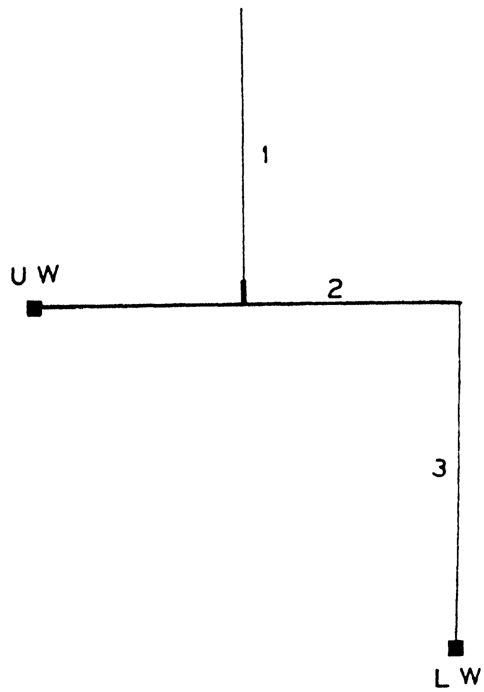

FIG. 5. Ideal sketch of the swinging system of an Eötvös torsion balance: (1) torsion wire; (2) aluminium beam, assumed to be of negligible weight; (3) lower suspension wire; *UW* and *LW*, upper and lower weights.

from which is suspended an aluminium bar of negligible weight (2). A gold or platinum weight (*UW*) is fastened to one end of the bar, and a similar weight (*LW*) is suspended by a fine wire (3) from the other end of the bar. A mirror is carried on the axial stem of the bar. Small horizontal rotation of the bar can be measured by the shift of the reflected image of scale against the vertical cross-hair in a telescope. The torsion wire resists rotation of the hanging system, and comes to rest when the resistance of the wire to torsion equals the torque affecting the swinging system. The torque necessary to rotate the swinging system per scale division is determined from the torsion coefficient of the torsion wire and from the dimensions of the instrument. If the swinging system is deflected by an unknown torque, its intensity can be determined by observation of the number of scale divisions and the multiplication of that number by the calibration constant for a scale division.

The deflection of the swinging system of an Eötvös torsion balance by the gravitational field depends upon the curvature of the level surfaces and of the lines of the vertical.

The relations of a torsion balance to the gravitational field in a very small section of space as in Fig. 3 are shown in a magnified form in Fig. 6. Within so small a region the level surfaces can be assumed to be parallel and to have a constant curvature; and similarly, the lines of the vertical may be assumed to be parallel and to have a constant curvature. The swinging system acts as a plumb-bob with its mass concentrated at the centre of gravity midway

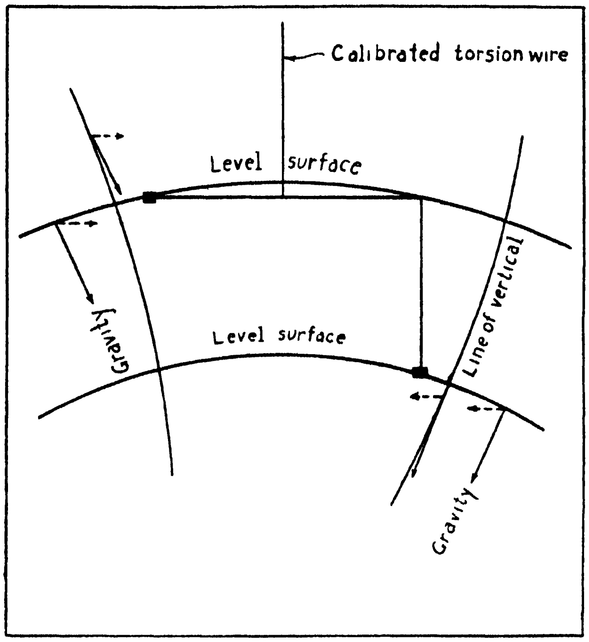

FIG. 6. The swinging system of a torsion balance in a very small space from the gravitational field of Fig. 3.

between the upper and lower weights, and comes to rest with the torsion wire in the straight line prolongation of vertical at that point. On account of the curvature of the level surfaces the directions of gravity at the two weights will no longer be parallel to the (vertical) axis of rotation of the swinging system, but will be warped symmetrically with reference to that axis. The curvature of the lines of the vertical produces similar warping symmetrically about the axis of rotation. The direction of gravity at each weight, therefore, is at an angle to that axis of rotation, and gravity has a horizontal component which produces a torque in the swinging system. Such horizontal components of gravity at the two weights in general do not lie in a radius of the swinging system of the torsion balance and, therefore, tend to rotate the swinging system. The intensity of the torque will be the resultant of two torques, the one a function of the curvature of the level surface, and the other a function of the curvature of the vertical.

Differential Curvature. The differential curvature is measured by the torsion balance as a function of the warping of the level surface.

The curvature of a level surface in the small space around a torsion balance is depicted in the block diagram of Fig. 7. The front face *ADFE* of the prism is assumed to be in the vertical plane of the maximum curvature, and the right face to be in the vertical plane of the minimum curvature of the level surface. The faces cut the level surface in the lines *h*, *k* of Fig. 7. One weight of the torsion balance is represented by *W*.

Gravity at *W* is directed diagonally downwards and in-

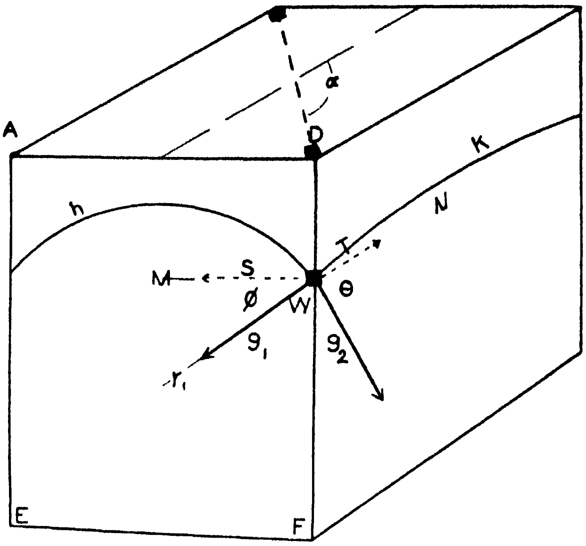

FIG. 7. Diagram representing a cube of space around a torsion balance and illustrating how warping of the level surfaces produces the Eötvös differential curvature effect.

wards at right angles to the level surface at *W*. The vector representing gravity will have a projection g_1 on the front face, and a projection g_2 on the right face. The vector g_1 has the horizontal component *S*, and g_2 the horizontal component *T*. If r_1 is the radius of curvature of *h* and r_2 of *k*, then[3] $\cos\phi = \dfrac{MW}{r_1}$, $\cos\theta = \dfrac{NW}{r_2}$, and $S = g_1\cos\phi = g_1\dfrac{MW}{r_1}$, and $T = g_2\cos\theta = g_2\dfrac{NW}{r_2}$. *MW* and *NW* are functions of the length (l) and azimuth α of the balance beam.

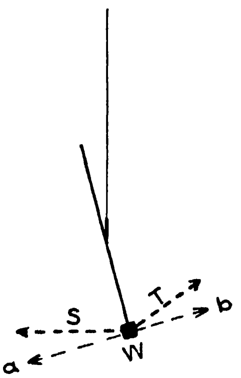

FIG. 8. Horizontal section through *W* of Fig. 7.

The force acting on the weight is a function of the difference between (*Wa*), the component of *S* perpendicular to the balance beam (Fig. 8), and (*Wb*), the component of *T* perpendicular to the balance beam, and, therefore, it is a function of gravity times the difference between the reciprocals of the maximum and minimum radii of curvature.

The value of the differential curvature is often denoted by the symbol *R* and its azimuth by λ (lambda). If the coordinates of reference are not parallel to the axes of curvature, the differential curvature has two components: U_Δ (less commonly U_{yy-xx}) which is used in place of its symbol[4] in the calculus $\left(\dfrac{\partial^2 U}{\partial y^2} - \dfrac{\partial^2 U}{\partial x^2}\right)$, and U_{xy} which is used in place of $\partial^2 U/\partial x \partial y$.

The relations between *R*, lambda, U_Δ, and U_{xy} are

$$R = \sqrt{(4U_{xy}^2 + U_\Delta^2)}, \qquad \lambda = \frac{-2U_{xy}}{U_\Delta}.$$

Gradient. The horizontal gradient of gravity is measured by the torsion balance as an effect of the curvature of the vertical.

Two vertical square centimetres, one above and one below the horizontal plane aa', through the centre of gravity of the swinging system of the torsion balance in Fig. 6, are represented in Fig. 9. Any line of gravity, V, necessarily is perpendicular to aa', but on account of its curvature makes an angle α, very close to 90 degrees, with bc and ed. If the value of gravity is g at a', it will be $(g+U_{xz})$ at c.

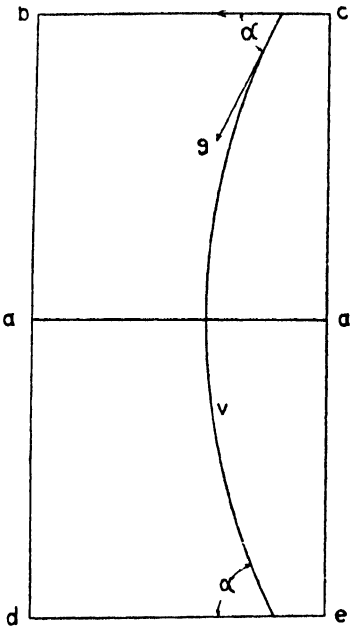

FIG. 9. This diagram represents two square centimetres, perpendicular to the plane of the level surface through the centre of gravity of the swing system of an Eötvös torsion balance; aa' is the plane of the level surface; V is a line of the vertical within the two squares; g is the vector of gravity at the intersection of V with bc.

The physical work of movement against gravity from one place to another, as, for example, from a to c, is independent of the route and will be the same via a' or b: i.e.

from a to b	g	from a' to c	$g+U_{xz}$
from b to c	$g\cos\alpha$	from a to a'	0

by addition, $g+g\cos\alpha = g+U_{xz}$

That is, the small horizontal component of gravity, $g\cos\alpha$, which is a function of the curvature of the vertical and which activates the torsion balance, is equal to the horizontal gradient of gravity U_{xz}.

The gradient is measured in its north-south and east-west components, which are known by the respective symbols U_{xz} and U_{yz}, contractions for the symbols $\partial^2U/\partial x\partial z$ and $\partial^2U/\partial y\partial z$ in the notation of the calculus. The gradient and its azimuth α are calculated from U_{xz} and U_{yz} by the formulae:

$$\text{gradient} = \sqrt{(U_{xz}^2+U_{yz}^2)} \quad \text{and} \quad \tan\alpha = \frac{U_{xz}}{U_{yz}}.$$

General Equation. The general equation which combines the effects of the differential curvature and the gradient on the Eötvös torsion balance can be shown by slightly longer consideration of those quantities to be

$$N-N_0 = \frac{K}{2}U_\Delta \sin 2\alpha + KU_{xy}\cos 2\alpha - MU_{xz}\sin\alpha + MU_{yz}\cos\alpha,$$

in which N = the scale reading, N_0 = zero-point scale reading (an unknown), K and M instrumental constants which depend on the torsion coefficient of the torsion wire, on the mass of the weights and on the horizontal and vertical distances between them; where α is the azimuth of the balance beam from north.

Five observations in different azimuths are necessary for the solution of the equation and the elimination of the five unknowns, N_0, U_Δ, U_{xy}, U_{xz}, U_{yz}. This is true if a single beam instrument is used, or if independent determination of those quantities by each of the two beams of the modern instruments is desired.

Six values of that equation by observations with the modern double-beam instrument in three positions (normally 120 degrees apart). This is sufficient for the solution of the six unknowns of the equation as applied to double-beam instruments. In such instruments the N_0 of the preceding equation is replaced by N_0' for beam I, and N'' for beam II.

Observations at azimuths of 0 and 180 degrees (or 90 and 270 degrees) will give the values of U_{xz} or U_{yz}.

Observations at azimuths of 0, 180, 90, and 270 degrees will give U_{xz}, U_{yz}, and U_Δ. Observations at azimuths of 45, 135, 225, and 315 degrees will evaluate U_{xy} and the two components of the gradient.

Field Observations. A site is chosen which preferably is plane within a radius of 5 metres from the instrument, and has a slope of less than 2 degrees. The station should not be near any hill or mountain with more than 5 degrees of elevation, or any valley exceeding 5 degrees of depression. Bedrock is better than alluvial fill for a site, which, if rough, should be smoothed artificially to a distance of 3, 4, or 5 metres.

The instrument is set up in an insulated portable shelter.

With the visual instruments, an observer has to read the instrument and turn it into the next position at stated intervals until he has a satisfactory series of readings.

With the automatic instruments, the observer sets the instrument for a stated number of readings at the correct intervals of time and azimuth, and then leaves it to make automatic photographic readings and to turn itself at the end of each interval, and he returns only after the end of the run. If the series of readings is unsatisfactory, a complete new run has to be made.

The time necessary for a complete observation at a station in a survey in which good accuracy is desired ranges from 5 hours for one of the large instruments, which takes 50 minutes to come to rest, to slightly over an hour for the shortest period instruments; and is slightly under 4 hours for the instruments in most common use. These figures envisage at least five readings in 120-degree positions, and a moderate but not extreme range of temperature.

Under the average conditions in the Gulf Coast of Texas and Louisiana, other than in the swamps, it is usual to complete observations at three or four stations each day. The rate depends, however, upon a considerable number of factors: the type of instrument and its condition, the conditions of terrain, the distance between stations, the precision desired in the observations and the policy of more stations per instrument, or of more stations per observer. In common practice, no difference exists between the rate of observation with visual instruments and that with automatic instruments.

In practical accuracy, no difference exists between the visual and the automatic instruments.

II. Measurement of Gravity.

Relative Gravity. The absolute value of gravity can be measured, but on account of the great difficulty of securing good accuracy, observations of it are made only at a few central geodetic observatories of the world. The geophysical prospector, however, is not interested in the absolute value of gravity, but in the local variations of its intensity, which are produced by such local subsurface irregularities of mass as body A in Fig. 2.

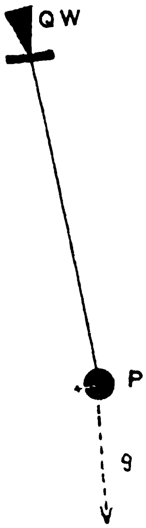

FIG. 10. Ideal sketch of a gravity pendulum: QW is the quartz knife-edge support; PB is the pendulum bob; g the vector of gravity.

Relative gravity, the value of gravity at any station in reference to the known or assumed value of gravity at some base station, is measured directly with fair ease and accuracy: (1) by the invariable pendulum; and (2) by static gravimeters of several different types; its value can also be calculated from the results of a series of torsion-balance observations between the stations.

By Pendulum. The rate of swing of a pendulum depends on the intensity of gravity and on the length, shape, and mass distribution of the pendulum (Fig. 10). The greater the value of gravity the more oscillations per minute by the pendulum, the faster is the rate of swing and the shorter is the period P of the swing. If a pendulum of constant length is swung at two different stations, the periods of swing at the two stations are inversely proportional to the square roots of the respective intensities of gravity, that is, for two stations a and b,

$$\frac{P_b}{P_a} = \sqrt{\frac{g_a}{g_b}};$$

and if x is any field station, and b is the base station,

$$g_x = P_b^2 \cdot g_b \cdot \frac{1}{P_x^2}.$$

Corrections have to be applied, for it is impossible to make the conditions under which the pendulums are swung exactly the same at all stations, and small changes in the temperature of the pendulum, in the air pressure within the pendulum case, &c., produce serious effects. Corrections, therefore, have to be applied for the effects of the differences of conditions.

The period of swing of the pendulum has to be determined with high precision, for an error of 0·00000005 sec. in the period corresponds to an error of one-tenth milligal in the determinations of the value of gravity.

The period of swing of the pendulum is determined by so-called 'coincidence' observations. In the standard method of observations by such institutions as the United States Coast and Geodetic Survey, the swing of a pendulum is compared with the beat of a chronometer. A coincidence determination consists of the observation and calculation of the times when the beat of the pendulum and that of the chronometer are coincident. In the interval between two coincidences a half-second pendulum makes one oscillation less (or more) than twice the number of seconds ticked off by the chronometer. The average value of the coincidence interval is determined by observing three or four coincidences when the pendulum is first started, and three or more at the end of the observation period. The chronometer has to be checked daily against wireless time signals from some such observatory as the United States Naval Observatory.

In precise pendulum surveys by oil companies, coincidence observations are taken between the oscillations of the pendulum at the base and those at the field station. The beats of the pendulum at the base station are sent out from a portable wireless sending station, are received at each field station and recorded photographically on the same strip of film as are the beats of the pendulums at the receiving stations. The coincidence interval, therefore, can be determined much more rapidly and accurately than in coincidence observations with chronometers.

A primary base station is chosen and all values of gravity in that general area are referred to it. But in surveys of local areas, a sub-base station may be chosen, or any station at which the value of relative gravity has already been established may be used as a temporary base station.

Less accurate pendulum surveys of the value of gravity at sea can be made with a special apparatus which was designed by Dr. F. A. Vening-Meinesz of the Dutch Geodetic Commission. The observations are made in a submarine. The apparatus is hung in a cradle in gimbals. Continuous photographic registration on the same film is made of all the oscillations of the several pendulums. From the interrelation of the oscillations of the different pendulums the effects of the unstable and moving foundation can be computed out, and the value of gravity can be determined with fair accuracy.

The accuracy of determinations of relative gravity with the pendulum is approximately as follows:

	Probable error in tenth milligal
Meinesz' determinations at sea . . .	± 30 to ± 50
Standard, Geodetic Survey determinations .	± 10
Best commercially purchasable pendulums .	± 5
Specially built or rebuilt company pendulums .	± 2 to ± 3

The rate of observation is one to four stations per day.

Observations of relative gravity with probable error[5] ± 5 tenth milligal or better is extremely difficult, and any one who attempts to attain and maintain observations with such accuracy will expect trouble.

Determinations of relative gravity with a probable error of ± 10 or even ± 5 tenth milligal are of value in geophysical prospecting only in broadly depicting large regional features or abnormally large local anomalies. The amplitude of the effects due to structural anomalies with which the petroleum geophysicist works is not as large as 50 tenth milligal, and may not be as large as 15 tenth milligal. Errors three times the probable error should be common according to theory. Determinations with a probable error of ± 5 tenth milligal, therefore, may have an error larger than the value in which the geophysicist is interested.

By Gravimeters. Several static gravimeters, of similar type, are in moderate commercial use. Most depend on the principle of the differential compression-extension of a spring by a constant mass under different intensities of gravity (Fig. 11). The greater the value of gravity, the more the supporting spring is compressed and the suspending spring extended. Slight vertical movement of the heavy mass is observed visually by an appropriate optical system. The instrument is calibrated in terms of scale divisions by determining the change of mass which is necessary to produce a vertical deflexion of one scale division. If the instrument is then read successively at two

different stations, the difference between the scale readings multiplied by the scale coefficient gives the value of relative gravity between the stations.

Observation with gravimeters is simple and speedy. The instruments can be permanently mounted in a truck, and 5 to 10 minutes suffices for the complete measurements at a station; but, unfortunately, gravimeters are erratic, and it may be necessary to repeat visits to stations in order to attain fair precision.

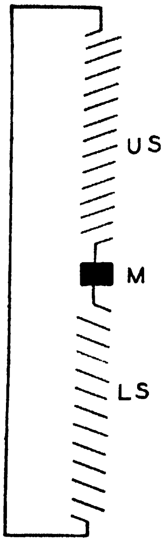

FIG. 11. A generalized, ideal sketch of some types of spring gravimeters; *US* and *LS* denote the upper and lower springs, *M* the heavy mass.

A probable error of ± 3 tenth milligal has been obtained in surveys with the gravimeter, but it is a question in the writer's mind whether any gravimeter maintains that accuracy at all times. Few gravimeters attain it at any time.

A gravimeter is as temperamental as an aneroid bariometer, or a magnetometer, and in many ways surveys with a gravimeter have to be handled similarly to those with the aneroid or magnetometer.

Several other types of gravimeters working on different principles are coming into use.

Torsion Balance. The variation of gravity between two places can be calculated if the gradient profile between them is known, for the gradient is the horizontal variation per centimetre, and, therefore, the distance in centimetres times the gradient gives the difference in gravity. If torsion-balance stations are close enough together, the gradient profile may be determined, and the value of relative gravity may be calculated for all points of the profile.

The variations of gravity are usually calculated and next lines of equal intensity, or isogams,[6] are drawn; for it is easier to interpret such a map than one covered with arrows or vectors. Stations are not close enough together to draw the curves with any precision, and the values calculated by different routes between two key stations often differ considerably, so that adjustments are unavoidable. Large-scale commercial surveys are frequently being extended, and new work must be blended with old. Such extension demands both experience and skill.

The accuracy of the determination of relative gravity in good torsion-balance surveys, in fair terrain, according to the writer's calculations, is of the general magnitude of $\pm 2{\cdot}5$ to $\pm 4{\cdot}8$ tenth milligal. per $\sqrt{\frac{d}{10}}$ km., where d is the distance in kilometres.

C. Extraneous Effects and the Reduction of Observations

Extraneous Effects. The crude values of the gradient, of the differential curvature, and of relative gravity which are determined by the instrument are not directly of use to the geophysicist. These include other effects of appreciable magnitude, in which the prospector is not interested. Values observed with the torsion balance are the sum of: the effect of irregularities of topography; the effect of soil and subsoil irregularities of density; the effects of structural irregularities of density of several different orders; the latitude effect. Values obtained with the pendulum or gravimeter are the sum of: the effect of elevation above sea-level; the effect of the shell of sediments between sea-level and the level of the station; the latitude effect; the effect of very large topographic features; and of structural irregularities of density of several different orders. By the application of the proper corrections the observed values can be reduced to those which are chiefly the composite effect of irregularities of density in the earth's crust.

Topographic Effect. The effect of topography on the gradient and differential curvature in general is of the same general magnitude as the structural effect. A plane slope of 1 degree over a radius of a thousand metres, for example, produces a gradient of 14 E.

Correction of the observed gradient and differential curvature for the effect of the topography, therefore, is a part of the routine of observation of every station. Levels are run as part of the routine, out to 20, 50, 100, or 200 metres from the instrument, according to the relief; and the correction is calculated by routine formulae. Correction for the topography beyond 200 metres is rarely attempted in commercial surveys, but can be made if a topographic map of the area is available.

The gradient effect of topography is at a maximum for excesses or deficiencies of mass within the zone 40 to 60 degrees below or above the horizontal plane through the instrument, and is zero for irregularities of topography in the same horizontal plane as the instrument, or in the vertical axis of the instrument. The effect of topography within ± 2 degrees of the horizontal plane of the instrument is negligible, and within ± 5 degrees is slight.

The differential curvature effect of topography is at a maximum in the horizontal plane and in the vertical axis of the instrument.

Too great topographic relief excludes the use of the torsion balance in most prospecting for oil, for the cost of obtaining sufficient topographic data and of making the calculations becomes prohibitive except for especially important surveys. The gravitational effects which are produced by rugged topography are in part the effects of subsoil irregularities of density, and therefore are not completely compensated by subtraction of the topographic effect. As the differential curvature is particularly sensitive, and the gradient particularly insensitive, to irregularities of mass in the horizontal plane of the instrument, the differential curvature is useless in mildly rugged topography in which the gradient is correctly found.

The gravity effect of the irregularities of topography is small; the mass of the close-in topographic irregularities, which so profoundly affect the gradient and the differential curvature, is so very small that the effect on relative gravity is negligible, and, furthermore, according to the law of its variation the gravity effect varies as the sine of the angle above or below the plane of the horizontal; and correction for topography is not made in the determinations of relative gravity in commercial surveys in regions of low or moderate relief. The geodesist who is interested in isostasy routinely makes a correction even for low or moderate topography. But the faint broad anomalies which regional topography might produce do not seriously distort the sharper and areally smaller structural anomalies. The calculation of the topographic correction is tedious. The petroleum geophysicist, therefore, normally neglects the very faint effect of the regional topography in areas of low or moderate relief.

Elevation Correction. The intensity of gravity decreases vertically upward at the rate of 3·08 tenth milligal. per metre. All determinations of gravity in geophysical prospecting, therefore, normally are reduced to the level of the base station of the particular survey.

The reduction is made by two different methods. In the 'Free Air' method the shell of space between the level of the station and the datum level is assumed to be composed wholly of air (i.e. 'Free Air') and to have no gravitational effect. In the Bouguer method, that shell of space is assumed to be composed of rock of some definite specific gravity, and allowance is made for its gravitational effect.

The 'Free Air' correction, therefore, is equal to $\frac{2h}{R} \times g$, in which h is the height of the place of measurement above the sea-level, and R the radius of the earth for the latitude under consideration. Since the influence of the latitude is very small, the quantity $2g/R$ (assuming the earth to be a sphere) is a constant term and can be taken as 0·0003086, according to Helmert, for almost every latitude. Hence the 'Free Air' correction is $+3{\cdot}08 \times h$ tenth milligal, where h is the difference of elevation in metres. The Bouguer correction includes the ratio of the density d of the assumed rock of definite specific gravity and the mean density of the earth:

$$3{\cdot}08 \times h \times \left(1 - \frac{3d}{22}\right)$$

$= 2{\cdot}05$ to $2{\cdot}15$ tenth milligal. per metre.

Reduction with allowance for isostatic compensation is made by many geodesists, but not by petroleum geophysicists.

No comparable reduction is necessary for the quantities measured by the Eötvös torsion balance. The 'Free Air' and Bouguer reductions compensate the vertical variation of gravity. The horizontal variation of gravity and of the curvature of the level surfaces, however, are the same for all level surfaces in the narrow vertical range of elevation within which it is practicable to make surveys with the torsion balance, except with reference to masses which are very close to the surface.

Latitude Correction. The intensity of gravity at sea-level increases from a minimum at the equator to a maximum at the poles according to the formula:

$$g_\phi = g_{\text{equator}}\,(1 + 0{\cdot}0053 \sin^2\phi - 0{\cdot}000007 \sin^2 2\phi).$$

The variations in latitudes between 0 and 30 degrees are: gravity, 7 tenth milligal. per kilometre; and gradient, 7 E. The latitude variation of gravity is produced because the earth is a rotating oblate spheroid flattened at the poles. The magnitude of that variation is of the same general order as that of the structural anomalies. Direct determinations of relative gravity in geophysical prospecting, therefore, are reduced to the latitude of the base station; and a normal correction is applied in the routine of the calculations of the gradient and differential curvature.

D. Mathematical Interpretation

The form, depth, and density of the subsurface body which is producing an observed anomaly can be determined within certain limits from the form and amplitude of the anomaly.

A unique solution cannot be obtained in practice. Certain limits in general can be set between which there exists a continuous series of possible solutions. Those limits are relatively close together if the depth to the body is approximately the same, or less than, the vertical thickness of the body. Those limits become progressively farther apart as the depth becomes greater than the vertical thickness of the body, and very little can be told about a body which lies at a depth great in comparison to its vertical thickness. The limits are closer together if the relative density relations are known, and yet closer if one or two points on the surface of the body are known.

Most structures of the petroliferous types resemble approximately some one of the following geometrically simple bodies: A, infinite steps; B, horizontal tabular prisms; C, triangular prisms, apices up; and D, triangular prisms, apices down (see Fig. 12).

A horizontal plate, infinite in all horizontal directions, produces an effect on the absolute value of gravity, but does not affect the relative gravity, the gradient, or the differential curvature. The presence of such an infinite horizontal plate, tangent to the top or bottom of one of the primary bodies of Fig. 12, therefore, does not affect relative gravity, the gradient, or the differential curvature. The correlative forms of Fig. 12, therefore, produce anomalies identical with those of the respectively corresponding primary forms.

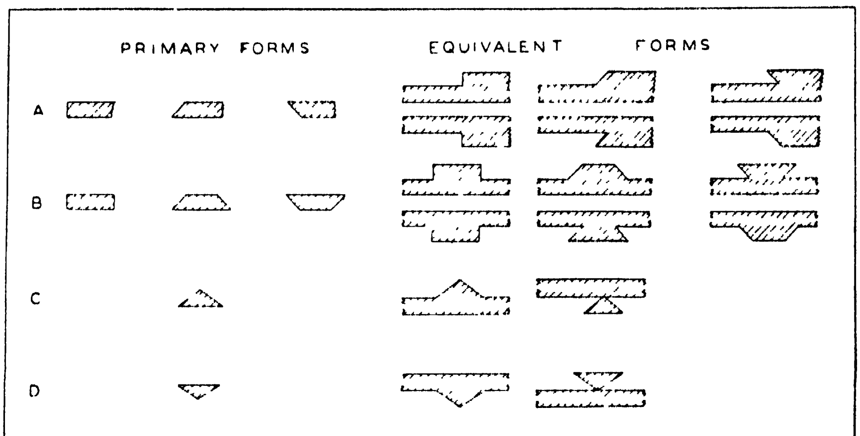

FIG. 12. Bodies of geometrically simple cross-section, which correspond to many common types of geologic structure.

Each one of the forms of Fig. 12 may be at shallow, medium, or great depth in comparison to the vertical dimension of the anomalous body.

The gradient, relative gravity, and differential curvature anomalies which are produced by such simple forms are shown in Fig. 13.

Change of the algebraic sign of the density of a body relative to its surroundings turns the anomaly upside down, but does not change its form.

Variation of the relative density of a body changes the amplitude but not the form of the corresponding anomaly; and by corresponding inverse change of the scale at which the gradient is plotted, the gradient profile can be held constant, although the relative density is changed.

The sign of the relative density of the causative body is shown by the sign of the anomaly. A gravity minimum is found over a body which is lighter, and a gravity

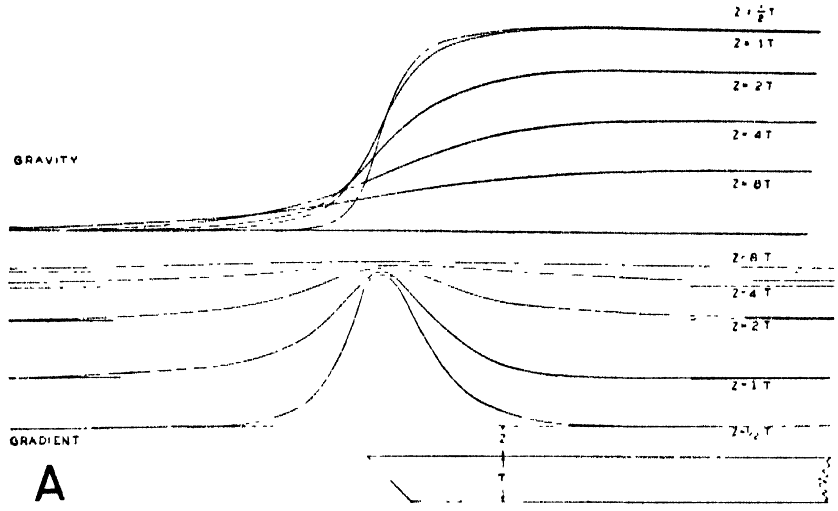

FIG. 13. Gradient, Gravity, and Differential Curvature anomalies of bodies of the types in Fig. 12.

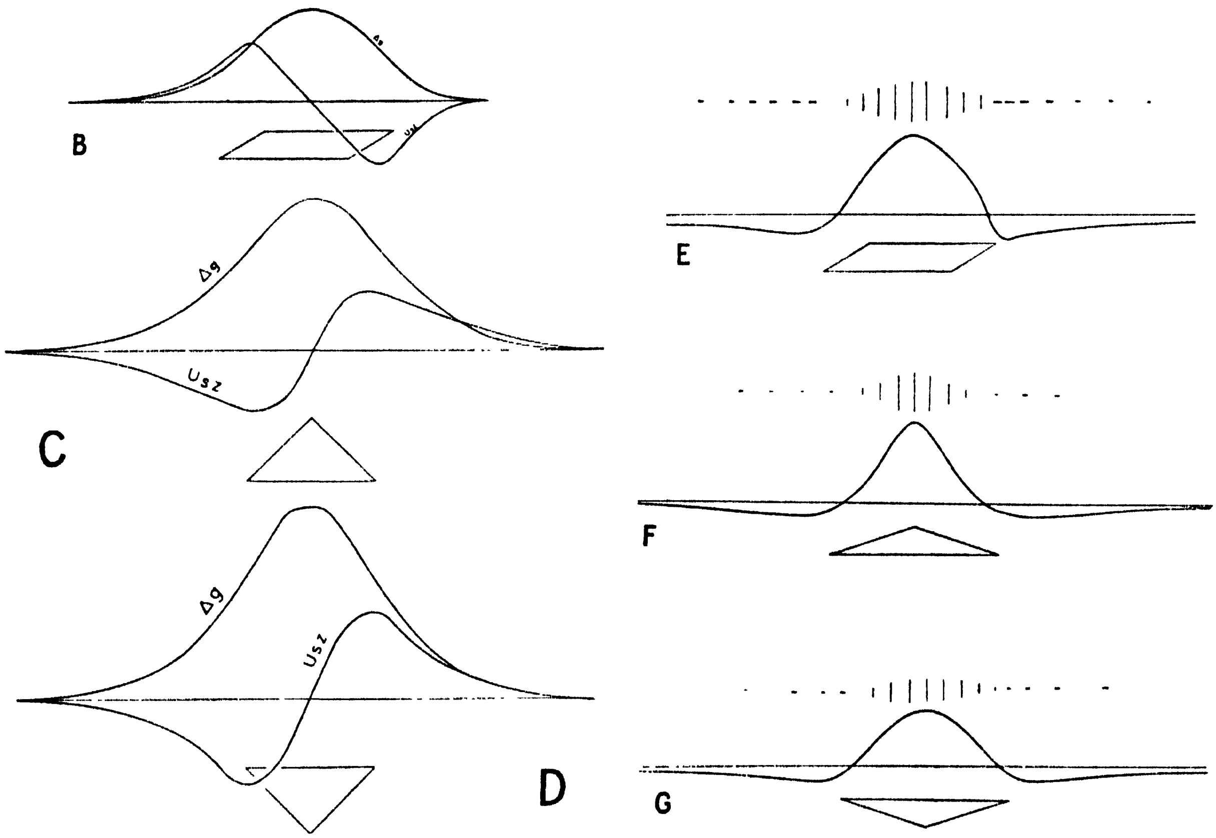
G. Map (above) and profile (below) of differential curvature for a prism of triangular cross-section, apex down.



maximum is found over a body which is heavier than the surrounding medium. The gradient seems, as it were, to be displaced from the relatively lighter mass towards the relatively heavier body. The differential curvature has the general pattern of —|— or —¦— over a finite body of positive relative density, and a pattern of |—| or ⊔ over one of negative relative density.

Primary Geometric Forms (Fig. 12). The magnitude of the relative density is not given definitely by the amplitude of the anomaly.

The approximate depth to the top of the body is given by the following two relations: (*a*) for fairly symmetrical anomalies of the type of *A*, Fig. 13, the distance on the ground between the two points at which the gradient is one-half of the maximum gradient is equal to twice the depth to the crest of the body; and (*b*) for anomalies of the type of *C* and *D*, Fig. 13, the horizontal distance between the two points of gradient maximum is equal to twice the depth to the crest of the body. For anomalies of the type of *B*, Fig. 13, rule (*b*) gives too great depth, and rule (*a*) must be used in connexion with either the right or left halves of the anomaly.

The form and dimensions of the causative body are indicated with varying degrees of vagueness by the form and dimensions of the anomaly. Bodies of type *A*, Fig. 12, are definitely distinguishable from those of types *B*, *C*, and

D by the difference in the respective types of anomalies. Bodies of type *B* are recognizable from those of types *C* and *D* unless the depth of the bodies is great in reference to the vertical thickness of the bodies. But it can be seen that the relative gravity anomaly does not show the difference as clearly as do the gradient and differential curvature anomalies.

Bodies of type *C*, Fig. 12, are recognizable from those of type *D* by the difference of the respective anomalies, if the depth to the bodies is slight, but the difference between the respective types of anomalies disappears if the depth to the bodies is moderate. The difference is much harder to distinguish in the relative gravity anomaly than in the gradient or differential curvature anomalies. The difference is much clearer if the vertical thickness of the body is very much less than the width. The difference between the anomalies of the subtypes of *A*, or of *B*, is recognizable, if the depth to the bodies is slight, or if the angle of slope of the inclined face is low and the depth to the bodies is moderate or slight. Asymmetry of the body is indicated by asymmetry of the anomaly, but the latter is necessarily the smaller. On the other hand, the area of the anomaly is greater than the area of the body to which it is due.

Isogams (the lines of equal intensity of gravity) have a seductive resemblance to structure contours. But, in general, isogams are convertible only indirectly into such contours. The relative gravity anomalies (Fig. 13) of the similar classes of bodies of Fig. 12 show the impossibility of simple conversion, and indeed the relation is indirect and complex. The three types of class *B*, Fig. 12, geologically represent a block fault, a broad anticline, and a broad syncline respectively; yet the difference between the general form of their respective anomalies is slight unless the bodies are close to the surface; and the anomaly may be either a maximum or a minimum depending on the relative density of the body. Simple transformation of the isogams of an asymmetric anomaly into structure contours, therefore, can lead to serious error in visualization of the structure. Approximate conversion of isogams into structure contours, however, is possible if the slope of the surface of the causative mass is only a few degrees, and if its width is large in reference to its depth.

Recognition of the presence of anomalous density is not possible under all conditions. These three quantities—relative gravity, the gradient, and differential curvature are not affected by—

(1) Infinite, plane, horizontal plates.
(2) Gently inclined plane plates, of great downward extension, in the zone where the thickness of the plate is less than 10 times its depth.
(3) Curved or warped plate-like bodies, approximately horizontal and of great extent, with the upper and lower surfaces parallel, except in areas where the depth to the top of the body is less than 3 times its thickness.
(4) Step-like bodies of type A, Fig. 12.
(5) Finite bodies of types B, C, D, Fig. 12, provided the depth of the body is greater than 10 times its thickness.

In the case of (4) and (5) observable anomalies would not be produced at half the depth-thickness ratios quoted if the relative density is small. For high relative density these ratios must be increased. Relative densities of 0·2–0·5 are regarded as normal; less than 0·1, very small; and more than 0·7, large.

Resolution of observed composite anomalies approximately into the constituent anomalies is an unfortunate necessity in all interpretation.

The form of an anomaly in which the geophysicist is interested is warped, distorted, and shifted by the interference effects of other anomalies; and satisfactory mathematical interpretation of the anomaly is possible only after the anomaly has been disentangled from the rest.

The anomalies of the surface irregularities and of the surface features commonly are smoothed out either by simple inspection and redrawing of the isogams or by several methods of 'averaging' of gradient, differential curvature, or relative gravity values at adjacent stations. 'Averaged' gravity pictures, however, should be used with care, and in general only in conjunction with the unsmoothed or unaveraged picture.

Resolution of a complex set of structural anomalies and a regional anomaly in general is impossible, for usually it is impossible to determine what the regional should be.

Resolution of a complex set of interfering salt-dome minima and a regional anomaly in the Gulf Coast in some cases is possible by elimination of the salt-dome minima. The latter have a small range of form and amplitude. By trial and error, various combinations of plausible salt-dome minima with their respective centres in various positions can be subtracted from the observed picture. There remains an approximation to the regional anomaly plus extraneous anomalies. The combination of least numerous positions of the minima is assumed to give the most probable distribution.

Quantitative calculation of the masses which approximately produce the observed anomaly are of high value, but are extremely tedious and are rarely made. From his general knowledge the geophysicist sketches a trial form of the bodies which presumably are producing the observed anomaly, assigns plausible relative densities, calculates the corresponding gradient, gravity, or differential curvature anomaly which would be produced, compares it with the observed anomaly, modifies his assumptions in regard to form and density of the masses, and by such trial and error calculations he finds the bodies whose calculated anomaly most closely fits the observations. The results of such calculations are qualitative to semi-quantitative rather than strictly quantitative. Calculations of the size, depth, and limit of the cap of Gulf Coast salt-domes for sulphur companies have been proved to have a high commercial accuracy, but in general the calculations give only certain limits to a series of mathematically possible structural situations, which would produce the observed effects. The limits in some cases may be close together, and in other cases far apart. But careful calculations always force the geophysicist to a sharper, more exact interpretation than that which he would be able to give from simple inspection or analysis of the data.

Quantitative calculation is not used as much in interpretation as it should be. The reasons are complex: the calculations are tedious; in oil work the exigences of the limitation of exploratory options or of competition in leasing will not wait on calculations which take many weeks; many geophysicists are not familiar with such calculations; and there is the psychological fact that in general in geophysics it is easier to get authorization for field men and equipment to acquire raw geophysical data than for office personnel to interpret the data. Quantitative calculations should become progressively more important in the interpretation of the future.

GEOLOGY OF GRAVITATIONAL PETROLEUM PROSPECTING

Geological Basis

The geological basis for the use of gravimetric surveys in prospecting for petroleum lies in the following relations between the accumulation of petroleum, structure, and the distribution of specific gravity in the subsurface:

(1) Specific gravity tends to be uniform horizontally, but to vary vertically in areas of horizontal, undeformed beds.

(2) Commercial accumulations of petroleum are generally found on geological structures, where there is deformation of the horizontally uniform distribution of specific gravity.

(3) Distributions of density, comparable in a complex way to the simple geometric bodies of Fig. 12, are produced by the formation of anticlines, synclines, upthrust or down-dropped fault blocks, grabens, and horsts, which affect the accumulation of petroleum.

A. Specific Gravity.

The specific gravity of common rock masses ranges from 1·0 to more than 3·0:

	Specific gravity
Diatomaceous shale, San Joaquin Valley, California	1·0
Soil and alluvium	1·5–2·0
Beaumont formation, Pleistocene sands and clays, Texas Louisiana Coast	1·8–2·1
Tertiary sands and clays, (*a*) at shallow depth	2·0–2·2
(*b*) at 7,000 ft. Gulf Coast of Texas and Louisiana	2·50 ± 0·03
Rock-salt	2·19 ± 0·03
Sandstones	2·2–2·6
Acid (massive) lava	2·4–2·6
Limestone	2·3–2·7
Granite, and other 'acid' rocks	2·6–2·9
Gneisses and schists	2·6–3·0
Anhydrite	2·8
Gabbro, basalt and other 'basic' rocks	2·7–3·0
Peridotites and allied rocks	3·0–3·3
Ferruginous rocks such as those of Lake Superior iron ore series and magnetic ore deposits such as those of the iron deposits of northern Sweden, and those of the sulphide Sudbury district in Ontario	3·0–5·0

Variation of Specific Gravity with Depth. Increase of specific gravity with increasing depth is the law of variation in a majority of petroleum areas (0·07 per thousand feet in the Gulf Coast down to a depth of 8,000 ft.). Sedimentary rocks other than anhydrite or massive limestone are lighter than the rock of the underlying crystalline basement. Thick stratigraphic sections of petroliferous sands, clays, and marls are lighter than underlying massive limestone or anhydrite series. Palaeozoic beds tend to be more consolidated, better cemented, and, therefore, heavier than post-Palaeozoic beds of similar lithologic character. Mesozoic beds, similarly, tend to be heavier than the comparable Tertiary beds. The specific gravity further tends to increase downwards in a thick section of sands, clays, and marls, for the older beds have been under more weight for a longer time and, therefore, are more compacted than the shallower, younger beds.

Decrease of specific gravity with depth is found, however, (1) if a massive salt series is present at considerable depth, (2) if a large thickness of diatomaceous shale is present at considerable depth, and (3) if a thick section of limestone, or if anhydrite, overlies a thick section of sands, shales, clays, marls, or other poorly consolidated beds.

Anticlines, the upthrown fault-blocks, horsts, buried 'granite' ridges, and all positive structures tend, therefore, to produce gravity maxima; and conversely, maxima in most cases tend to indicate the presence of positive structures.

Synclines, the down-thrown fault-blocks, graben, and all negative structures tend, therefore, to produce minima. Nevertheless salt-domes, ridges, the Lost Hills anticline (whose core is composed of diatomaceous shale) produce minima. And the synclinal thickening of the Hunton limestone at Seminole in Oklahoma produces a synclinal maximum.

Salt-domes. A salt-dome presents a large, clearly defined, sharp anomaly of specific gravity. A salt-dome in the Gulf Coast consists of the frustum of a cone of salt capped by a cylinder or thimble-like mass of limerock-anhydrite-gypsum and is intruded into 20,000 to 30,000 ft. of Tertiary and Cretaceous sands and clays. The diameter of the top of the salt core mostly is between 1 and 3 miles; the height of the salt core above its base is 3 to 6 miles; and the difference between the specific gravities of the salt and the surrounding beds ranges from 0 to +0·20 at the surface to −0·5 (estimated) at 20,000 ft. below the surface. The cap has a vertical thickness of 200 to 500 ft., but on a few domes of 900 to 1,000 ft. The difference between the respective specific gravities of the cap and the surrounding sediments is +0·5 to +0·7.

A characteristic shallow salt-dome in the Gulf Coast produces a composite anomaly which consists of a small maximum within a large minimum. The 'small' and 'large' refer simultaneously to area and to amplitude.

The cap, having a large positive relative density, produces a gravity maximum (Fig. 14). The cap lies relatively close to the surface; the maximum has a large value relative to that of extraneous regional variations of gravity and is not appreciably shifted by them; the maximum, therefore, lies directly above the top of the dome and is only slightly wider than the cap. The upper part of salt in domes close to the coast in Texas and Louisiana has a slight positive relative specific gravity in comparison to the surrounding Pleistocene and Recent sands and clays, and helps the cap in producing a gravity maximum. The diameters of the shallow dome maxima are approximately 1½ miles for average-sized domes, but range up to 4 miles for the larger domes. The amplitude of these maxima is of the general order of 0·6 milligal.

The lower half of the salt core of a shallow dome, on account of its negative relative specific gravity, produces a gravity minimum (South Liberty minimum, north-east corner of Fig. 15. As the depth to which the salt extends is great, the width of the minimum is correspondingly large and ranges from 8 to 15 miles. The amplitude of the minimum varies with the diameter of the salt core and with the downward flare of the flanks. The amplitude in the Gulf Coast is about 2·5 to 3·5 milligal, but may reach 7·0 milligal. Some shallow domes have no recognizable minimum, but calculations show that a cylindrical salt core slightly less than 1 mile in diameter may have a minimum of only 1·0 milligal; and an anomaly of 8 miles in diameter and of 1 milligal in amplitude is not recognizable in practice on account of the obscuring effects of the extraneous anomalies. The gradient on these salt-dome minima has the same general magnitude as the gradient of regional features, or of the resultant gradients of minima of adjacent domes. The centre of the minimum, therefore, may be shifted considerably by the combined effects of the other anomalies. The upper half of the salt core of salt-domes well back from the coast has a negative relative specific gravity, and, therefore, aids in producing the

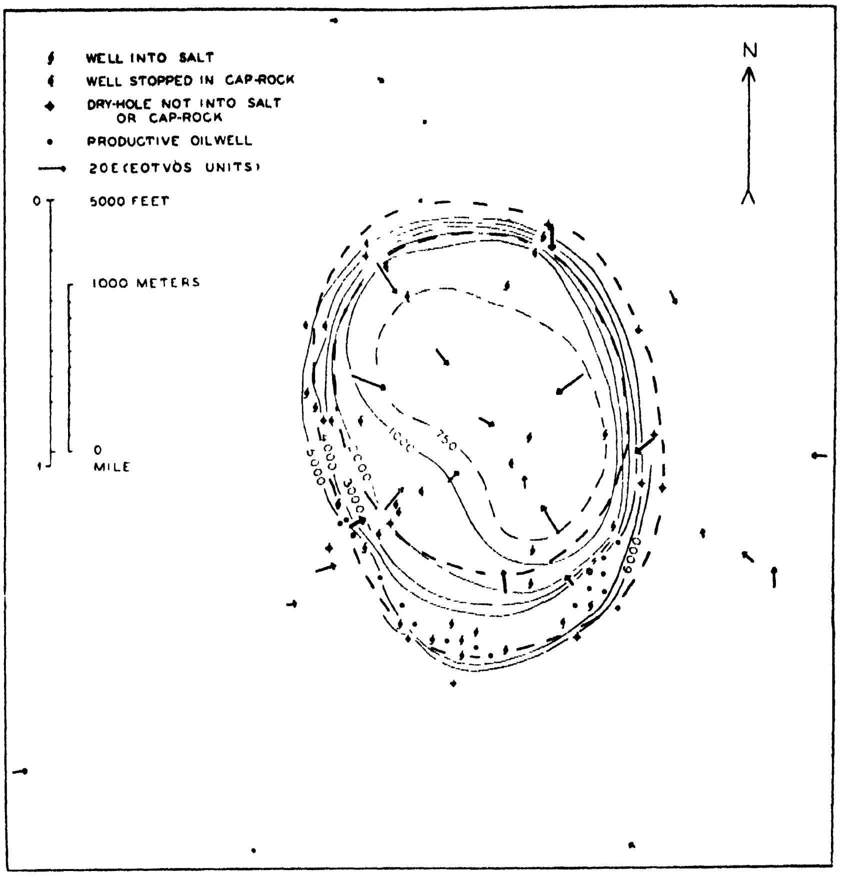


FIG. 14. GRAVITY MAXIMUM OF A SHALLOW SALT-DOME in the Gulf Coast, Nash Salt Dome, Brazoria, and Fort Bend Counties, Texas (after Barton, in *Geophysical Prospecting 1929*, A.I.M.E.).

Gradient arrows are superimposed on the structural contours on the top of the cap-salt.

Nash was the first salt-dome to be discovered by geophysics in the Gulf Coast. It was discovered on the basis of these gradient arrows. The two heavy dashed lines were the 500–900-ft. and 4,000–5,000-ft. contours on the cap-salt which were predicted by the writer in advance of drilling. The convergent gradient arrows well away from the dome are presumably more the effect of large minima to the west, north, and east than of the Nash Dome.

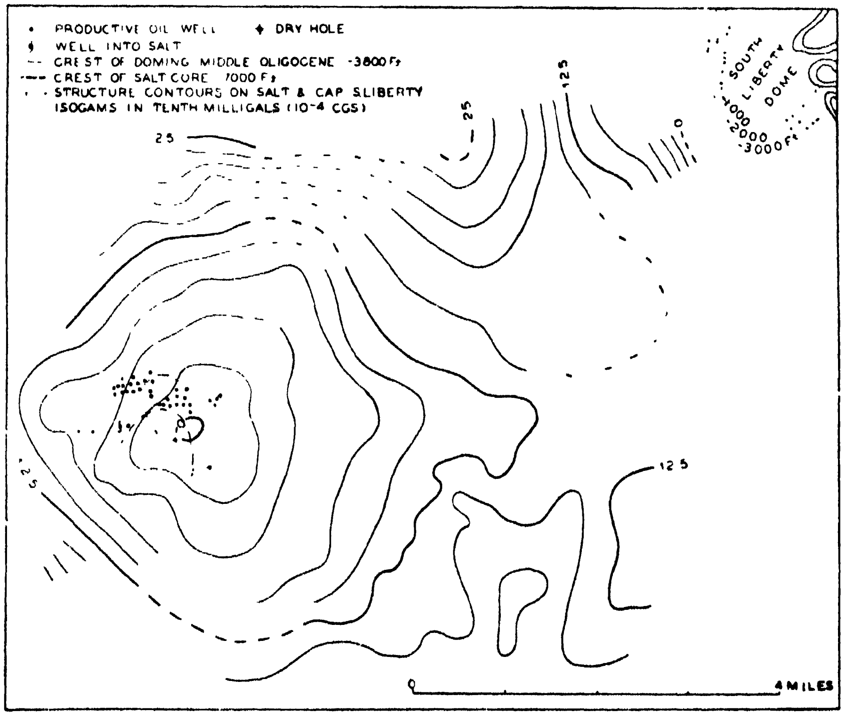

FIG. 15. ISOGAMS OF SALT-DOME MINIMA. (After Barton, in Bulletin, American Association Petroleum Geologists.)

This map shows the isogams due to:

(*a*) the minimum of a deep salt-dome, Esperson, the top of whose salt core lies at a depth of 7,000 ft.;

(*b*) part of the minimum around a shallow dome, South Liberty, Texas, the top of whose cap rises within 320 ft. of the surface; and

(*c*) the maximum ridge between the two minima.

The shift of centre of the minimum eastward from the crest of the dome is surmised to be due to asymmetry of the salt mass. Quantitative calculations suggest that the west flank of the dome is steeper than the east flank; the centre of the anomaly, therefore, should be slightly down the east flank.

The Esperson dome was discovered on the basis of this survey. These isogams are by the author. The original survey and interpretation were by Christian Iden, Union Exploration Company.

minimum. Most shallow domes show both the maximum and the minimum, but on some domes the one or the other is too faint to be observed.

A deep salt-dome is much the same gravitationally as the lower half of a shallow dome and, therefore, produces a similar minimum (Fig. 15). Even if a thick cap is present, the ratio of its thickness and volume to its depth would be so small that its effect on gravity at the surface would not be observable.

The anomalies of shallow salt-domes in east Texas and in north Germany do not show any maximum immediately above the dome, but are exclusively minima. The salt cores of those domes rise through a thick section of Cretaceous beds, which include much limestone, and through only a thin overlying section of Early Tertiary beds; the uppermost part of the salt core has, therefore, a negative relative specific gravity, while that of the salt as a whole is much larger than for the Gulf Coast domes, which also have the thicker caps. The amplitude of the minimum, therefore, is much greater than that which an identically similar dome in the Gulf Coast would have; the amplitude of the maximum effect of the cap-rock is smaller; and the minimum totally obscures that faint effect. But, on the other hand, the doming of the limestone produces a maximum effect which tends to counteract the minimum of the salt.

The greatest success in the use of the gravitational methods of prospecting for petroleum has been in connexion with salt-domes.

B. Regional Framework of an Area.

Regional gravity surveys give a valuable, although not complete, picture of the geology and structure of an area.

The regional gravity anomalies predominantly are the effect of major warping of the basement. The effective difference in specific gravity lies between the thick sedimentary cover of sands, weak sandstones, clays, shales, marls, salt, and subordinate limestone and anhydrite, and the underlying basement. The latter may be either the crystalline basement of igneous and metamorphic rocks or a series of limestones, well-consolidated sandstones, or highly compacted shales, which lie on the crystalline basement.

But such anomalies may also be produced either by heavy batholithic masses within the basement, or by lateral changes in a thick prism of sediments. An example of the former is given presumably by the Crosbyton maximum, Crosby and Garza Counties, (west) Texas. The circular anomaly has a width of 50 miles. The gravity anomaly has an amplitude of 70 milligal, and the magnetic anomaly of Z has an amplitude of 2,500 gammas. The vertical dimension of the extra heavy mass is 4 miles or more, according to some calculations by the writer. Normal beds at usual depths were found by a well which was drilled to a depth of 5,000 ft. on the crest of the anomaly. According to the writer's present interpretation, this anomaly must be produced by an ultra-basic, perhaps peridotitic igneous mass within the basement.

Examples of the effect of large lateral lithologic changes are given by the great limestone reef of the south-west central Permian basin of west Texas and south-eastern New Mexico. The changes are from relatively light beds to massive limestone through a vertical stratigraphic section many thousand feet thick. A large gravity maximum comparable to that of a buried mountain range is thereby produced.

The regional framework of central southern Oklahoma and adjacent Texas is depicted in good agreement with and beyond the geologic data by the regional gravity map of Fig. 16. The Wichita Mountains, the Arbuckle Mountains, and the Nocona-Muenster buried mountain ridge, like such structural masses in general, are represented by maxima, and the intervening deep sedimentary basin is seen as a broad minimum. The Nocona-Muenster ridge is shown to be the south-eastern continuation of the Wichita Mountain

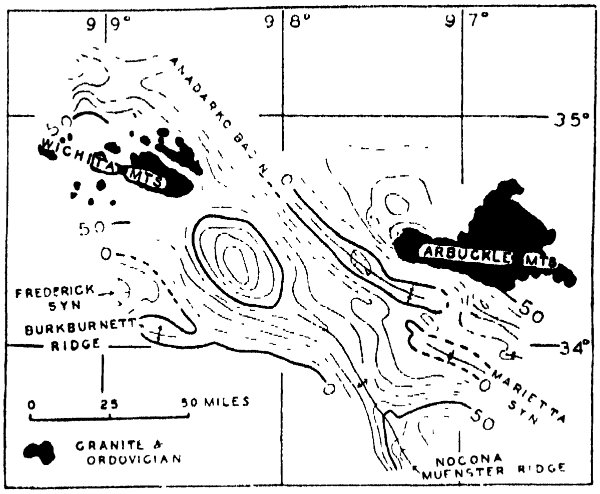

FIG. 16. REGIONAL SURVEY. Isogam map of Central Southern Oklahoma and adjacent Texas (mostly after Van Weelden, *Proc. Intern. Petroleum Congress*, London, 1933).

system, although geological confirmation of the connexion is not yet available. The Criner Hills, a sharp local uplift, which brings Ordovician to the surface through the Pennsylvanian and Permian beds, produces the maximum which lies between the *échelon* overlap of the Marietta and the Anadarko(-Ardmore) minima. Healdton and Hewitt, sharp structures which bring Ordovician limestone within reach of the drill in those oilfields, produce the nose of maximum between the Anadarko minimum and the vague north-west extension of the Marietta minimum. The Burkburnett buried 'granite' (crystalline) ridge and the Frederick syncline to the north-west are represented respectively by a maximum and a minimum.

C. Anticlinal Maxima and Elimination of Regional Effects.

Anticlines frequently produce maxima, and a corresponding anomaly in the differential curvature, provided the specific gravity of the beds increases downwards.

Anomalies of such type are shown by the Fort Collins anticline in Colorado (Fig. 17). That structure is a sharp fold in a thick section of Cretaceous shales and weak sandstones. The structure contours of Fig. 17 were mapped at the surface, on the Hygiene sandstone member of the Pierre shale (Upper Cretaceous) as the datum horizon.

The gradient arrows sharply define a maximum coincident with the anticline.

The differential curvature anomaly of the anticline is masked by a regional anomaly and can be recognized only after elimination of the regional effect. A crude study of such elimination is made in Fig. 17*B*. The profiles of U_{Δ} and U_{xy} are plotted for a transverse line across the anticline. The dashed diagonal line in each graph represents the assumed variation of the regional effect. The deviation of

each observed value from the corresponding value of the dashed line is assumed to be the effect of the local structure. The data are not extensive enough for a reliable study of the elimination of a regional anomaly, but the resulting residual values of the differential curvature which are plotted in Fig. 17*C* are essentially those which the structure at the Fort Collins anticline should produce. The differential curvature lines over the crest of the anticline should be at a maximum, and should be parallel to the longitudinal axis of the anticline; and a synclinal trough, such as that between the west flank of the anticline and the regional eastward dip, should produce differential curvature lines at right angles to the longitudinal axis of the trough.

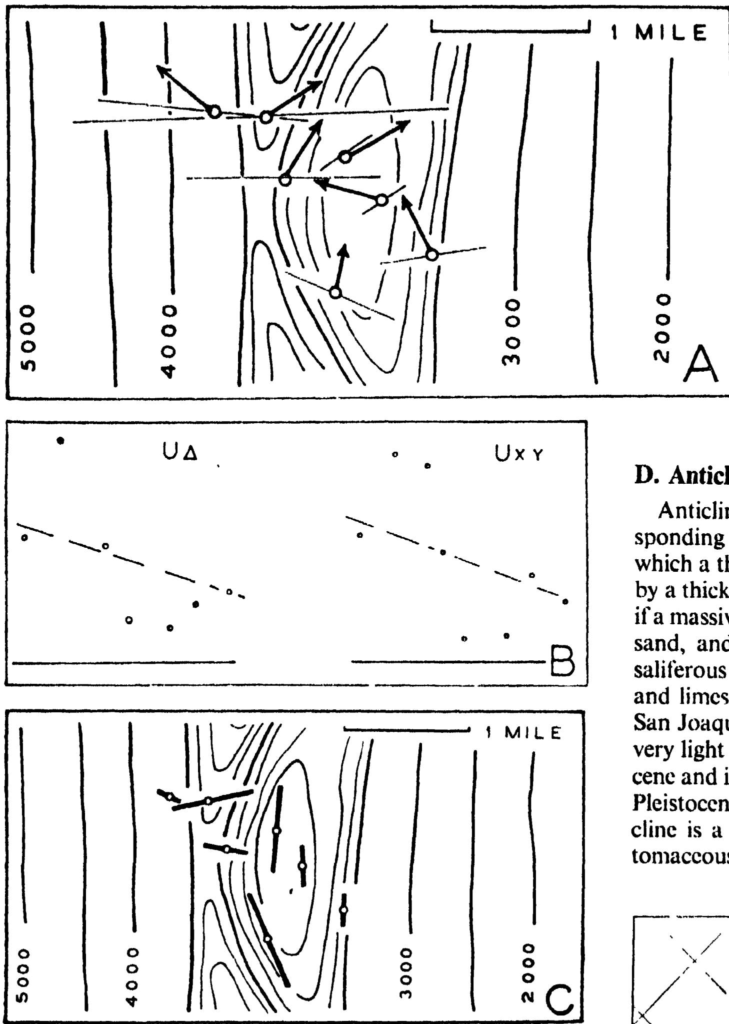

FIG. 17. AN ANTICLINAL MAXIMUM. Fort Collins anticline, Larimer County, Colorado (*A* after J. H. Wilson, *Colorado School of Mines Magazine*, **17**, Oct. 1928).

A. Gradient arrows and differential curvature lines superimposed on structure contours (after U.S. Geological Survey) on Hygiene sandstone of Pierre Shale (Upper Cretaceous).

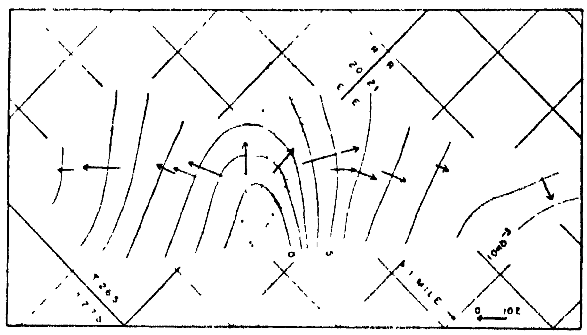
B. A study of the elimination of the regional anomaly in the differential curvature.

C. Residual differential curvature lines (from the analysis in *B*) superimposed on the structure contour map.

D. Anticlinal Minima.

Anticlines will produce gravity minima, and the corresponding type of differential curvature anomaly, in areas in which a thick section of relatively heavy beds is underlain by a thick section of lighter beds. Such a situation obtains: if a massive limestone section overlies a thick section of clay, sand, and weak sandstone; if a thick section of salt, or saliferous beds, underlie a section of sand, clay, sandstone, and limestone. In the south-western part (Fig. 18) of the San Joaquin Valley of California, 3,000 ft. more or less of very light diatomaceous shale is present in the Upper Miocene and is overlain by many thousand feet of Pliocene and Pleistocene sands, clays, and gravels. The Lost Hills anticline is a very sharp, possibly diapiric, fold of that diatomaceous shale up to shallow depth below the surface.

A



B

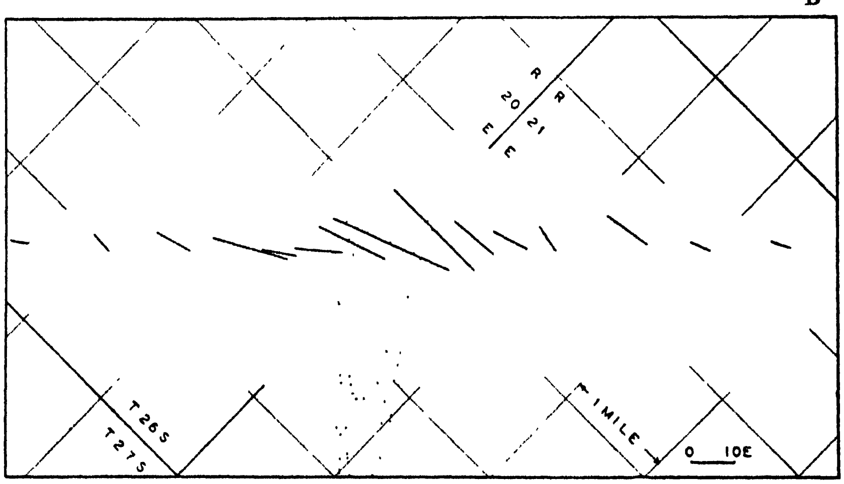


FIG. 18. ANTICLINAL MINIMUM. Lost Hills anticline, San Joaquin Valley, California (survey by, and released through the courtesy of, Paul E. Getty, Inc.).

A. Gradient arrow-isogam map; structure contours drawn on shallow oil sand; isogam interval 1 milligal.; structure-contour interval, 100 ft.

B. Differential curvature lines superimposed on the same structure contours.

The gravity anomaly of the Lost Hills anticline, therefore, is a minimum, and the differential curvature is perpendicular to the longitudinal axis of the anticline instead of parallel as in the case of the anticlinal maximum. The sharpness of the gradient, gravity, and differential curvature anomalies over the crest of the anticline show that the anomaly is anticlinal and not synclinal, even if the drilling data were not available.

E. 'Buried' Ridges.

'Buried' ridges such as the Muenster 'granite' ridge of northern Texas produce maxima (Figs. 16 and 19). The Muenster ridge consists of a core of granite, gneiss, schist, and Ellenburger (Ordovician) limestone rising into a cover of Carboniferous and Cretaceous shales, sandstones, and limestones. The anomaly in large part is the effect of the contrast in specific gravity between the core of basement rocks and the overlying relatively less dense beds. If the burying beds are predominantly limestone, the difference in specific gravity between the rocks of the cover and those of the core of the ridge may be too small to produce an observable anomaly.

F. Faults.

Faults produce observable anomalies, but these are often narrow and faint and may be difficult to distinguish from the anomalies of surficial irregularities.

An observable anomaly will be produced by the part of the fault which lies very close to the surface, and the anomaly will be very narrow.

In order to map narrow anomalies, the interval between stations on a profile must be 50, 100, 150 ft., and adjacent profiles should not be many hundreds of feet apart. Such mapping in petroleum geophysics is unprofitable except under exceptional circumstances.

The mapping of faults is, however, sometimes practicable.

The Luling fault is of such a type. The anomaly (Fig. 20) is produced by the large contrast in specific gravity between the abutting masses of the upthrown block of Edwards limestone (Georgetown and Buda limestones, not differentiated in Fig. 20) and the downthrown block of Taylor marls and clays (Del Rio clay not shown in Fig. 20) and Austin chalk. These abutting, contrasting masses lie at a depth of 2,000 ft. The difference of specific gravity across the fault above and below that zone is very small. An observable anomaly, approximately 4,000 ft. wide, therefore, is produced by that one zone of contrasting density and lies immediately above the trace of the fault in that zone. A second narrow observable gradient and gravity anomaly should be produced along the surface trace of the fault. But the net of stations on this survey was not sufficient to map this. The differential curvature rather commonly, as in Fig. 20, shows greater effect from the shallower part of the fault.

RETROSPECT

A. Geological Interpretation versus Geological Probability

Interpretation of the geophysical data in general should be guided by the known geology and geological probabilities of the particular area.

The exceptional case not uncommonly arises, however, in which a geophysical survey indicates the presence of some radically unorthodox geological feature which is contrary to well-accepted concepts of the geology and geological probabilities of the area. The south-eastward regional gradient of the survey across the Luling fault presents such an exceptional case (Fig. 20).

The Luling Field lies south-east of the Llano-Burnett uplift of pre-Cambrian granites and metamorphics. The dip of the beds at the surface, east to south of the uplift, is eastward into the east Texas geosyncline and south-eastward to southward into the Gulf of Mexico, past the area of the Luling Field. According to former surmise, the surface of the pre-Cambrian rock dipped in the same way. The regional gravity gradient, therefore, should have been towards the Llano-Burnett uplift up the slope of that basement surface.

The reverse regional gradient, south-westward down that supposed slope of the basement surface, is present in the Luling area. Its significance was not understood at the time of this survey (1925). The physical-mathematical significance was clear, but all of the geophysically plausible interpretations seemed contrary to fairly well-established geology.

A Palaeozoic trough, perhaps comparable to the Appalachian trough, was shown by subsequent deep drilling into the Palaeozoics to lie between the Luling area and the Llano-Burnett uplift. The gravity surveys in the Luling area were mapping the east side of that trough. But at the time of the surveys the geologist would have regarded the interpretation by the geophysicist of the presence of such a trough as geologically improbable. The gravity surveys which were available to the author at the time were inadequate for interpretation of the regional anomaly, but were adequate to indicate the presence of some feature contrary to the accepted geological picture of the subsurface.

The geophysicist in general must be extremely cautious in making interpretations contrary to well-accepted geological concepts of what is possible or probable. But the geologist frequently has formed his concepts of the subsurface from inadequate and partially inaccurate data, and individual geologists may form concepts by erroneous reasoning. The geophysicist, therefore, should not hesitate cautiously to make geologically unorthodox interpretations, if careful reconsideration of his geophysical data force him to them, and if re-examination of the geological data and reasoning does not definitely preclude his interpretation.

B. Limitations of the Gravitational Methods

The gravitational method is useless unless effective variation of specific gravity with depth is present. A 'buried' granite ridge mantled with limestone cannot be detected, unless the upper surface of the limestone series is warped over the 'ridge'. Fair-sized structures in a thick series of relatively homogeneous beds may not produce observable or definite anomalies, particularly if the basement is deep and is not considerably deformed. A great many productive structures do not produce observable gravitational anomalies. A synclinal maximum may be indistinguishable from an anticlinal maximum. An observed salt-dome minimum may not indicate whether the salt or the super-salt doming of the sediments comes within reach of the drill. A batholithic mass within the basement may not be distinguishable from deformation of the surface of the basement. The effects of sharp lateral changes may obscure or mask the structural anomalies. The interference of the anomalies from the deep basement with those of shallower

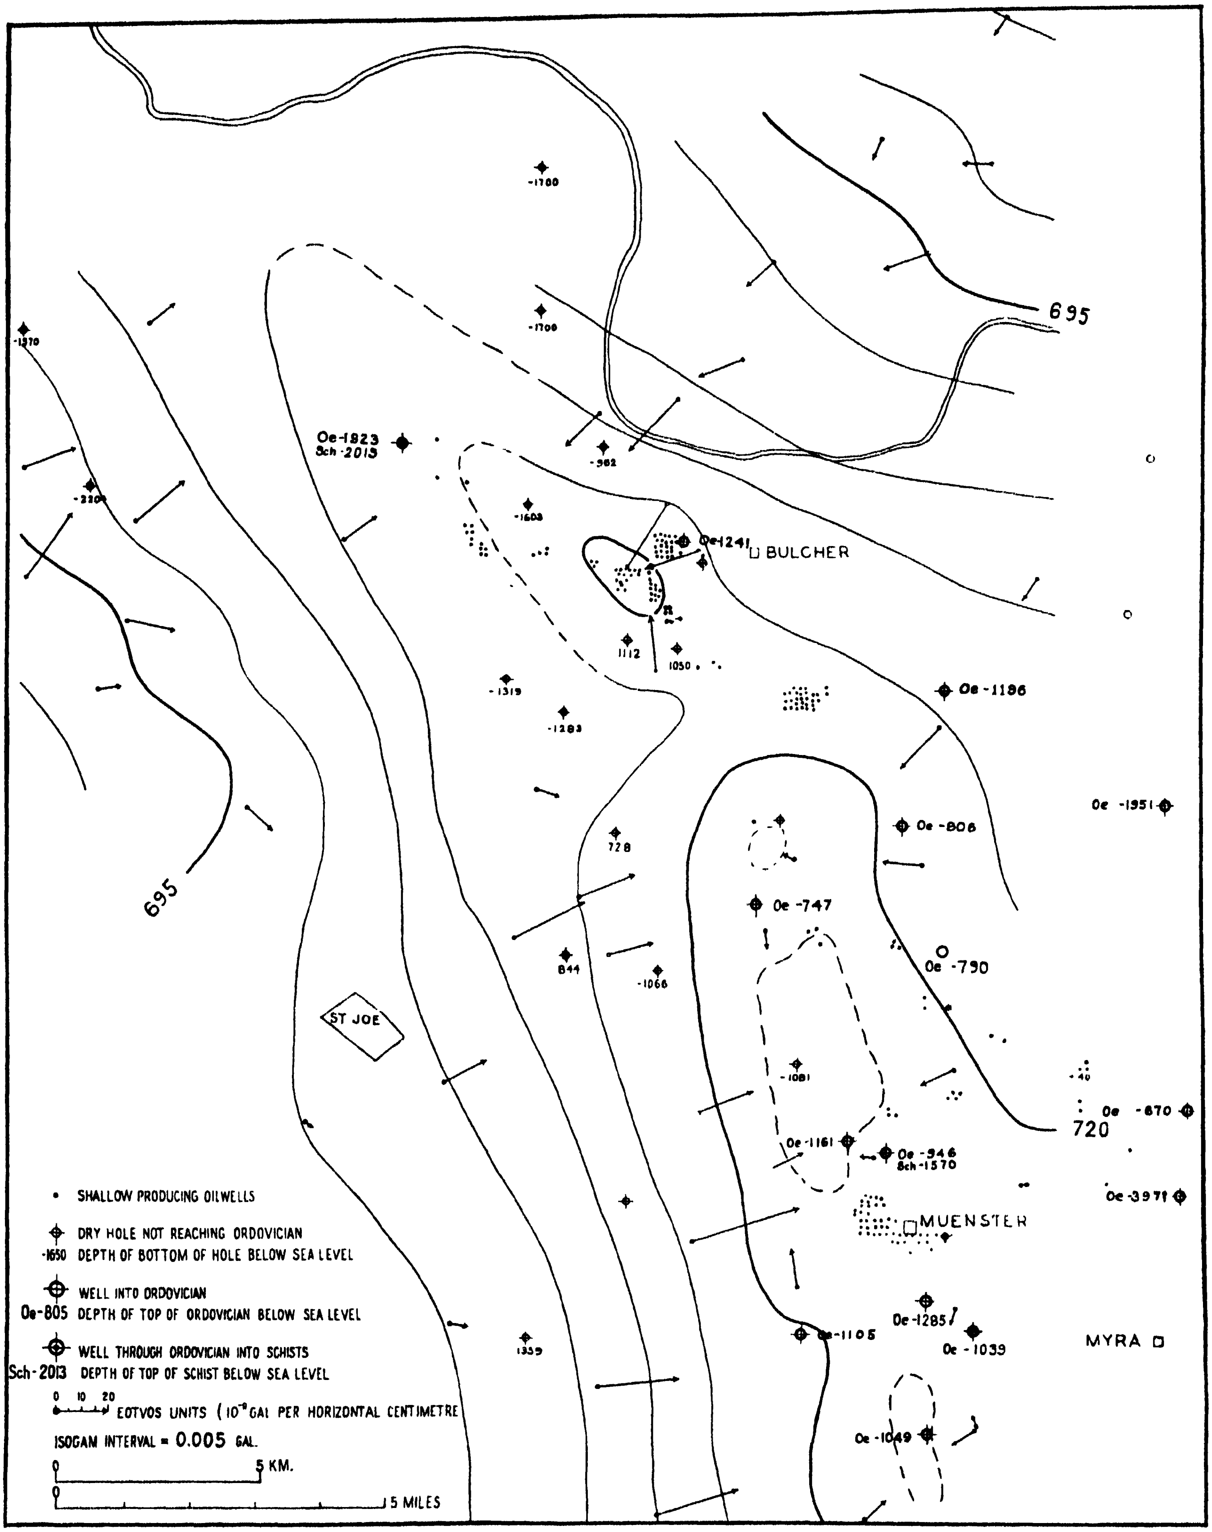

FIG. 19. 'BURIED' CRYSTALLINE-LIMESTONE RIDGE. Isogam-gradient arrow map of the Muenster 'Granite' Ridge, Cooke and Montague Counties, Texas (after Barton, *Geophysical Prospecting 1929*, American Institute of Mining and Metallurgical Engineers). This map covers a small part of the area of the map of Fig. 16.

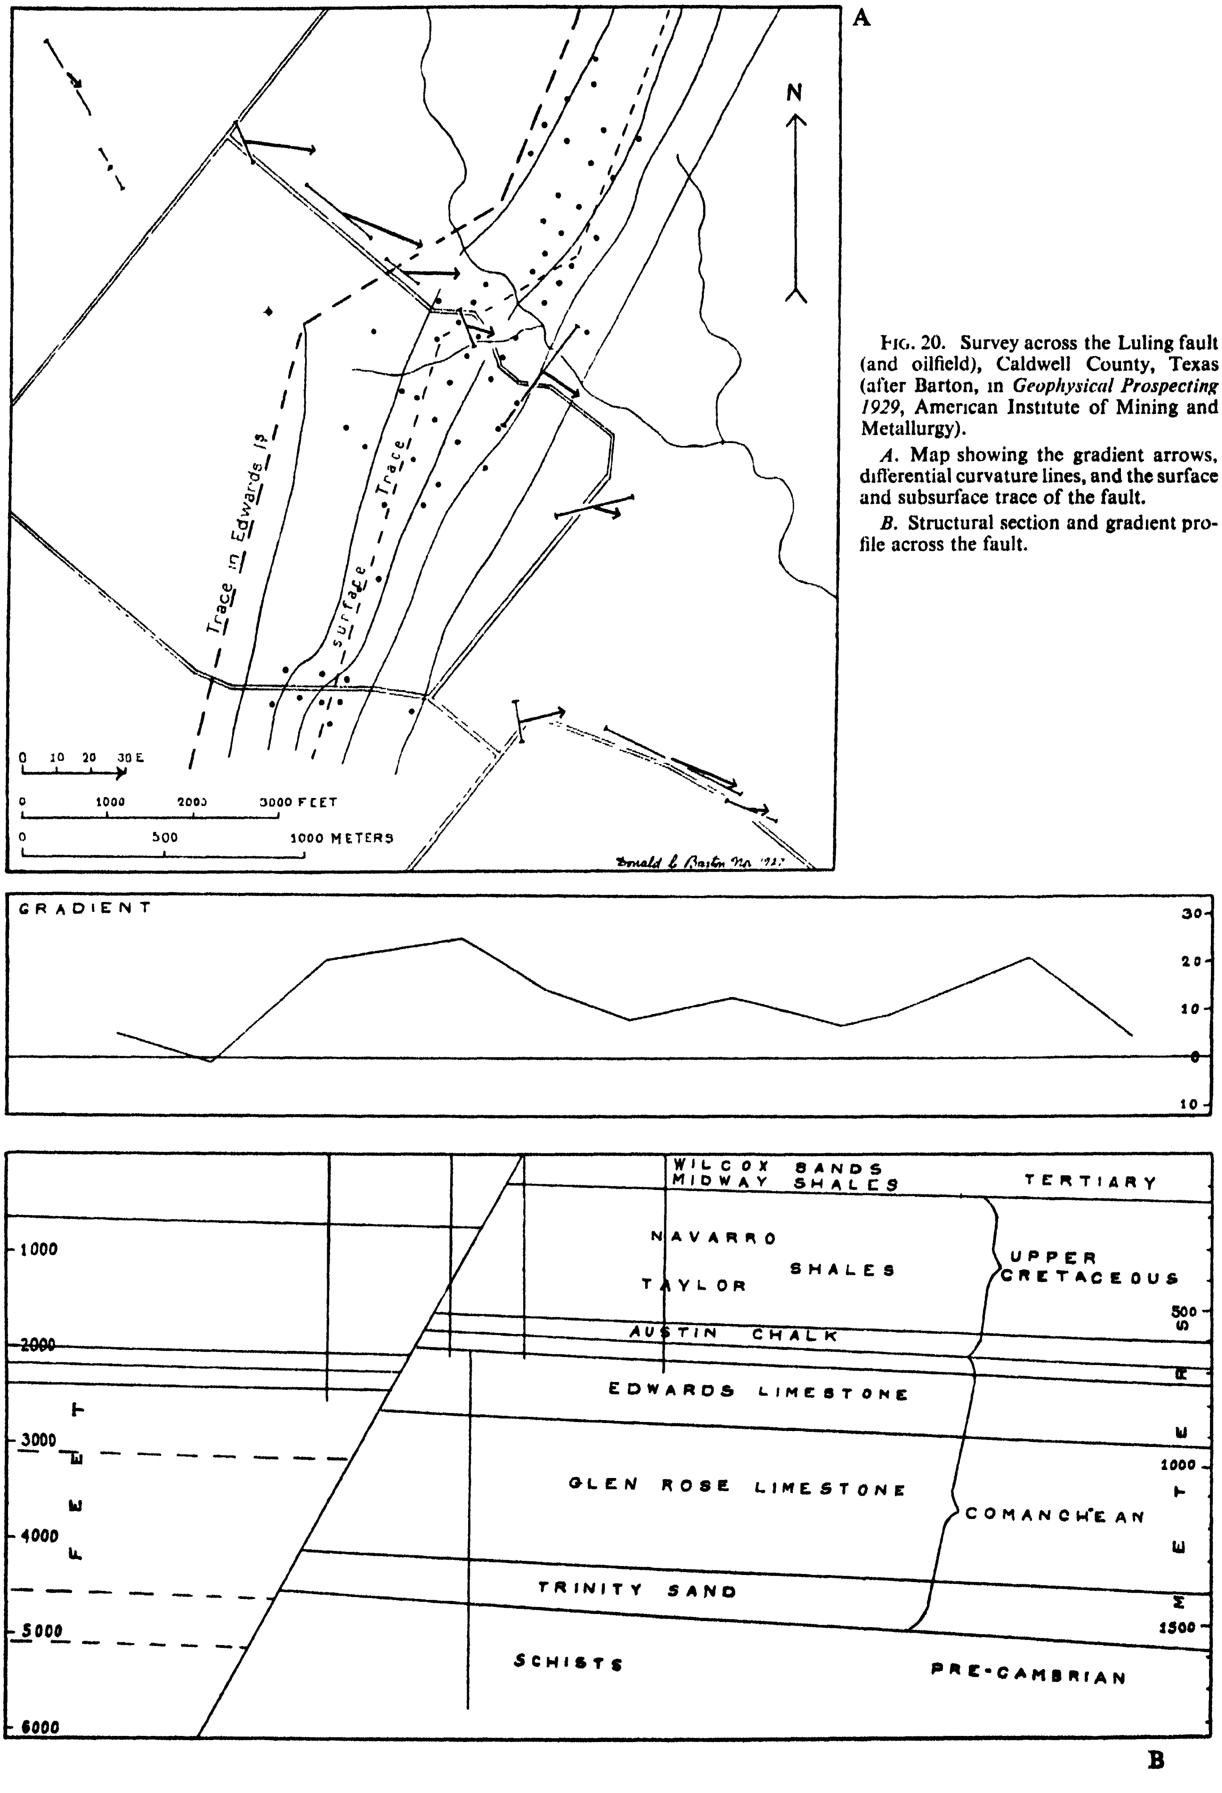

FIG. 20. Survey across the Luling fault (and oilfield), Caldwell County, Texas (after Barton, in *Geophysical Prospecting 1929*, American Institute of Mining and Metallurgy).

A. Map showing the gradient arrows, differential curvature lines, and the surface and subsurface trace of the fault.

B. Structural section and gradient profile across the fault.

structures, and the interference between anomalies of adjacent vertically elongated structures, may produce a complicated gravity picture and the analysis in such cases is never wholly satisfactory.

Surveys over a large area are necessary for proper interpretation of most local structural anomalies. If a good geologist were placed in an area about whose geology he knew nothing, if he could get no information from the literature or from other geologists, and if he were confined within the area of a local structure, he would hesitate about making much interpretation of the structure and its oil potentialities. The geophysicist is subject to a parallel but more rigid limitation.

Surveys with the torsion balance are slow. Unless an army of torsion balances is thrown into an area, quick completion of the survey of a considerable area is impossible.

The effective use of the torsion-balance in surveys is severely limited by the terrain. Rugged topography prevents such surveys, except under exceptional circumstances. Observations with the torsion balance are impossible over deep water, and are taken with difficulty in open shallow water. Heterogeneous alluvial deposits, irregular weathering of bed-rock, small-scale irregularities of the surface of the bed-rock buried under slight or moderate cover of soil or alluvium, irregular alluvial cut and fill, some glacial deposits, produce much irregularity in the gradient and differential curvature, which can be overcome, if at all, only by multiplication of stations.

Differential curvature cannot be determined by pendulum or gravimeter and this is a serious objection to the use of these instruments on a survey. Many are not competent to handle the interpretation of the differential curvature; it is more sensitive to irregularities of topography, and correction for such effects is not as successful as the gradient. The differential curvature, therefore, is neglected by many geophysicists. It is of very great value in the interpretation of many surveys, and in some it may be of more use than the gradient.

The scarcity of really first-class interpreters is a serious limitation to the use of the methods. Interpretation is not so simple as it is believed to be by most physicists and geologists. The technique of interpretation has a very considerable content, only a little of which is known to most of the men who are actually engaged in such work. A thorough training in the mathematics and technique of interpretation, with wide practical experience of gravitational surveys which have been checked against known geology, besides sound training and experience in geology are all necessary for really first-class interpretation, but unfortunately are possessed by few men.

Nevertheless, gravitational methods in petroleum geophysics have not been precluded by all these limitations. Good commercial success has been obtained with the gravitational methods in prospecting for petroleum. In the Gulf Coast of Texas and Louisiana the largest geophysically discovered oilfield, Thompson (Rabbs Ridge), Fort Bend County, Texas; two of the next largest geophysically discovered oilfields, Sugarland and Tomball, Fort Bend and Harris Counties respectively, in Texas; several large oilfields: Manvel, Brazoria County, Texas; Dickinson, Galveston County, Texas; Roanoke, Jefferson Davis Parish, Louisiana; several less good oil-fields: Esperson, Liberty County, Texas; Hankamer, Chambers County, Texas; and the smaller oilfields: Nash, Fort Bend and Brazoria Counties, Texas; Cleveland, Liberty County, Texas; and Mykawa, Harris County, Texas, were discovered by gravitational surveys and, with the exception of Cleveland, torsion-balance surveys. The ratio of barrels of oil discovered, to dollars spent is surmised to be greater for the torsion balance than for the seismic method. The torsion balance was of good use in the early days of the Hendricks field, Winkler County, Texas, in the future extension of the field. The torsion balance aided the magnetometer in the discovery of the very large Hobbs oilfield, Lea County, New Mexico.

In spite of their serious limitations, the gravitational methods have won a permanent place in petroleum geophysics.

NOTES

[1] A galileo is a unit of acceleration, that is, one centimetre per second per second. Hence the gal.

[2] Also Horizontal Directive Tendency (H.D.T.), and sometimes 'R' lines or values, from Baron Eötvös's term *Richtkraft*.

[3] Several steps are necessarily omitted; MW and NW are directed lengths depending on the dimensions and orientation of the balance. The theory is given in full in *Applied Geophysics* by Eve and Keys (Camb. Univ. Press), pp. 185–203; 2nd edition, 1933.

[4] In the mathematical theory U denotes the *gravitational potential* whose space rate of change in any direction gives the component of the force on unit mass in that direction.

[5] The 'probable error' by definition is the error such that errors numerically larger or smaller are equally probable.

[6] A dyne force acting on a gram mass produces an acceleration of 1 cm./sec.^{2}, here called a gal. One thousandth of this has been termed by some a gamma. Horizontal lines of equal vertical intensity of gravitational attraction have been called *isogams*. This word may have originated with magnetic surveys.

THE REFRACTION METHOD OF SEISMIC PROSPECTING

By J. H. JONES, Ph.D., D.Sc.
Chief Geophysicist, Anglo-Iranian Oil Company

I. History of the Method

ABOUT the middle of the nineteenth century Robert Mallet made perhaps the first attempt to investigate the transit velocities in rocks of elastic waves due to artificial earthquakes.

In these experiments, carried out in Ireland and North Wales, Mallet determined the velocities of earthquake (or seismic) waves passing through various rocks. The values that he found ranged from 825 ft. per sec. through sandstone to 1,665 ft. per sec. for granite. These velocities are of course much lower than the compressional and distortional wave velocities in these rocks, and probably represent the velocities of surface waves. Later, velocity determinations were made by Pfaff in Germany (1873), by Abbot in America (1878), and by Milne in Japan (1888).

A paper on 'Wave Propagation and Earthquakes' by Schmidt appeared in 1888. In this paper Schmidt considered the possibility of the velocity of the wave increasing with depth, and suggested that the variation with depth might be obtained from time-distance graphs of artificial earthquakes.

Further determinations of velocities were made by Fouque and Levy in 1899, and by Hecker in 1897–1900. The latter investigator observed that the main wave was preceded by small disturbances which appeared to travel with higher velocity. He suggested that the small forerunning waves were of the compressional type and that they would not, in general, travel direct from the focus to the observation point, but would follow another path determined by the ratio of elasticity and density at different depths within the earth.

In 1901 an article suggesting a new practical application of seismometers was written by A. Belar. In this article Belar suggested that seismometers could be used to obtain useful information regarding subsurface conditions in connexion with the construction of tunnels along the Tauern Railroad.

During the close of the nineteenth, and the beginning of the twentieth, century the science of seismology was put on a quantitative basis by the classical researches of Milne and his collaborators in Japan, and of Wiechert and his pupils in Germany. Subsequent investigations have been based on the foundations laid by these seismologists. Wiechert, in particular, showed how the physical properties of the earth's crust could be studied with the aid of time-distance graphs of natural earthquakes. His investigations led him to believe that there were surfaces at which the velocity changed abruptly; these abrupt changes were indicated by singularities in the time curves, brought about by a sudden change in the slope.

A very definite suggestion appears to have been made by von dem Borne in 1908 for applying the principles established by Wiechert to the smaller-scale problem of investigating the geological structure of the outermost layers of the earth's crust. It was some years later, however, before the actual practical application to this important problem was made by Mintrop, who realized the possibilities of the method in economic geology. Mintrop applied for patents on his refraction method in Germany in 1919. The method was introduced into the United States late in 1923.

Some years before the development of the refraction method by Mintrop, the suggestion had been put forward by A. Mohorovičić that the initial disturbance recorded at stations close to the epicentre was caused by a wave which had travelled along an indirect path.

A mathematical treatment dealing with the formations of the indirect wave was made by Jeffreys in a paper to the Cambridge Philosophical Society in 1925. Jeffreys considered the problem of the compressional wave in two horizontal layers. His analysis shows that an explosion in the upper medium produces, in addition to the direct surface and reflected waves, an indirect wave which appears to have travelled along the interface with the velocity of sound in the lower medium. It is found that the variation of amplitude with distance from the focus is in reasonable accordance with seismological observations and that the time of travel is that along a path determined by the law of refraction. The theoretical aspects of the problem have also been considered by Morris Muskat in a paper 'The Theory of Refraction Shooting', *Physics*, **4**, Jan. 1933.

II. The Mintrop Method

The method invented by Mintrop to determine the depth of a covered horizontal layer is described in a patent application filed in December 1919 in Germany, and in the United States in December 1920 [6]. In this application Mintrop briefly considers the two-layer problem, and shows how the depth of the lower layer can be calculated from the time-distance curve.

A disturbance is set up in the ground by the explosion of a charge of dynamite at or near the surface, and the movement of the ground is recorded with portable seismographs at different points along a linear traverse. The time of the first pulse is determined at each observation point along the line, and a graph is constructed showing how the time varies with distance from the point of explosion. At the nearer points the first wave-pulse will have travelled along, or close to, the surface, and the slope of the first part of the time curve will be a measure of the velocity of the elastic wave in the upper medium. At greater distances the indirect wave-pulse will arrive first, and the slope of the time curve will now be a measure of the velocity of the elastic wave travelling in the lower medium. At some intermediate point the direct wave-pulse arrives simultaneously with the indirect one, and because the slopes are different on either side of this point there will be a discontinuity in the time curve.

The depth of the lower layer is calculated with the aid of a formula involving the distance of the point of discontinuity from the origin and the value of the slopes of the two branches of the time curve.

Fig. 1 shows the assumed path of the indirect wave. The ray *OA* falls on the surface *AB* at an angle θ with the normal. This angle is the critical angle of refraction and is given by the usual relation $\sin\theta = v_1/v_2$. The disturbance travels along the surface *AB* of the lower layer, and

secondary disturbances travel across the upper layer along paths BC, B_1C_1, &c., again making the same angle θ with the normal to AB. When OC is sufficiently large, the path $OABC$ becomes the shortest time path between O and C.

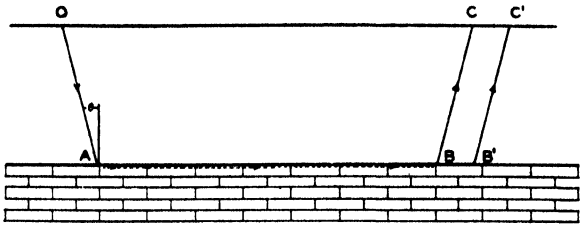

FIG. 1

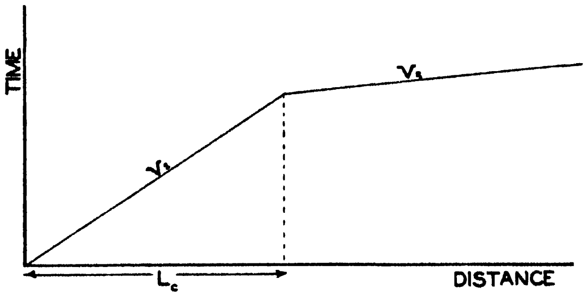

FIG. 2

Fig. 2 shows the type of linear traverse time curve. It can be shown that the depth H of the surface of the lower layer can be obtained from the two velocities v_1 and v_2 and the distance of the discontinuity (L_c), by the relation

$$H = \frac{L_c}{2}\sqrt{\left(\frac{v_2-v_1}{v_2+v_1}\right)} \tag{1}$$

(Equate L_c/v_1 and $2H/v_1 \cos\theta + (L_c - 2H\tan\theta)/v_2$. This means that the direct shock arrives at the same time as the long-path shock). Again, it is easy to show that the time along the indirect path at a point on the surface distant L from O is given by

$$t = \frac{L}{v_2} + \frac{2H\cot\theta}{v_2}. \tag{2}$$

The relation (2) is often used to determine the depth H.

Apparent Velocity.

The slope v_2 of the time curve in Fig. 2 will be a measure of the velocity of the elastic wave in the lower layer only when this layer is horizontal.

When the layer is inclined it is necessary to determine the slope of the time curve when the direction of travel is reversed; the arithmetic mean of the two slopes gives a close approximation to the true velocity when the angle of inclination is small.

Thus if the inclination of the layer to the horizontal is ϕ, v_2 is the true velocity in the layer, θ is the critical angle, the slope of the time curve when the wave is travelling up-dip is given by

$$v_2' = \frac{v_2\sin\theta}{\sin(\theta-\phi)}, \tag{3}$$

and down-dip by

$$v_2'' = \frac{v_2\sin\theta}{\sin(\theta+\phi)}. \tag{4}$$

The true velocity v_2 and the dip ϕ can be determined from these two equations when the angle θ is known.

For small values of ϕ,

$$v_2' = v_2(1+\phi\cot\theta),$$
$$v_2'' = v_2(1-\phi\cot\theta),$$

so that

$$v_2 = \frac{v_2'+v_2''}{2}. \tag{5}$$

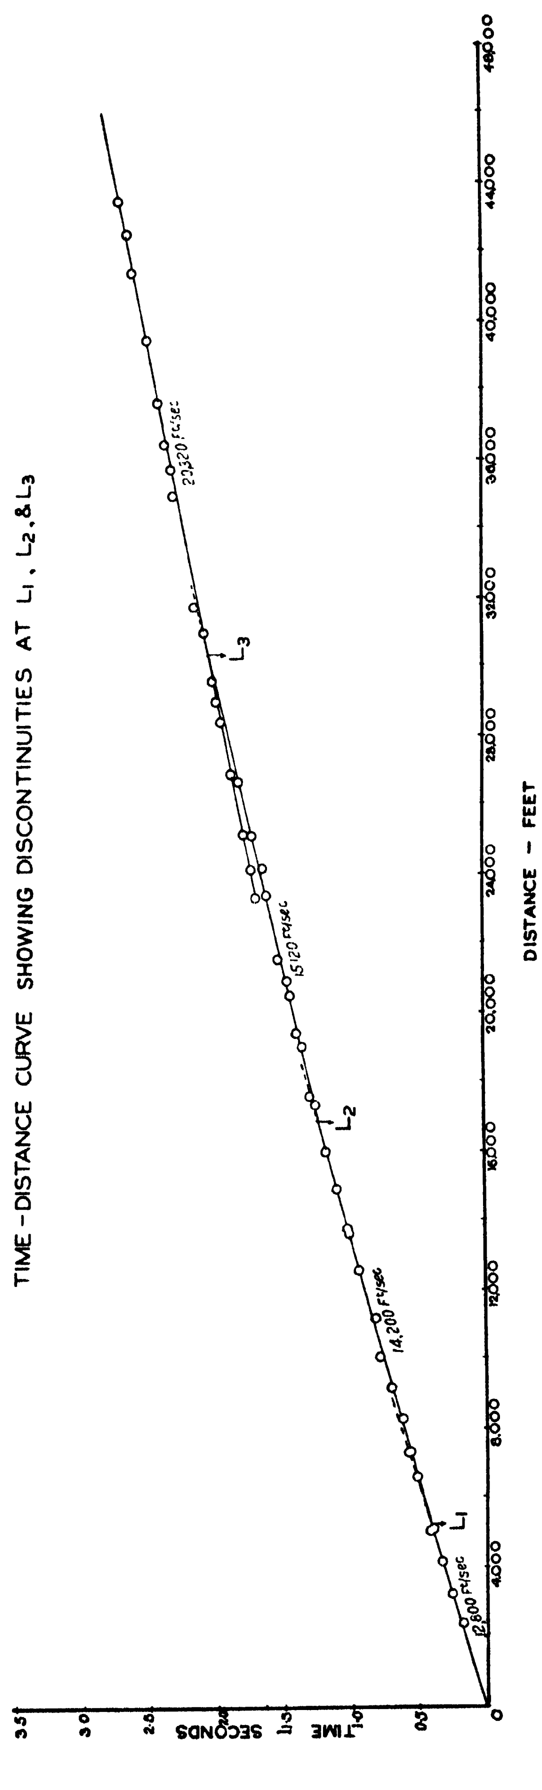

FIG. 3.

The Problem of Multiple Layers.

In practice there may be more than one discontinuity on the time curve indicating the presence of two or more layers overlying the solid layer under investigation. If the boundaries of the layers are assumed to be parallel, simple formulae can be deduced for calculating the depths from the time curve [3, 1932].

An example of a time-distance curve showing three discontinuities is shown in Fig. 3.

A set of seismograms showing the indirect wave-disturbance preceding that of the direct wave is given in Fig. 4. The onsets of the two disturbances are indicated on the seismograms by the arrows at *a* and *b*.

These seismograms were recorded in south-west Iran with the Jones Microid Seismograph; the natural period of the instrument was close on 0·8 sec. [5, 1933]. The average value of the velocity in the overburden was approximately 9,500 ft. per sec., and the value in the lower layer was about 15,500 ft. per sec. The average depth of the lower layer was 1,100 ft.

III. Recent Developments

The linear profile method invented by Mintrop is not suitable for large-scale exploration work, and other methods have been devised for this purpose.

There are two methods which have proved extremely useful and deserve special mention. These are the fan method developed in the Gulf Coast area for the search of salt-domes, and the arc method developed for reconnaissance work in the oilfields of Iran.

The Fan Method.

A good example of this method of exploration is given in an article by E. E. Rosaire and O. C. Lester, Jr., in the *Bulletin of the American Association of Petroleum Geologists*, **16**, no. 12, Dec. 1932. The article is titled 'Seismological Discovery and Partial Detail of Vermilion Bay Salt Dome, Louisiana'. The detectors are spread out fan shaped at different distances from the explosion point. A network of these fans is arranged to cover the area which is to be explored.

Fig. 5, taken from Messrs. Rosaire and Lester's paper, shows the network of fans in the survey of Vermilion Bay. The time of the first arrival is recorded at each observation point. All the times are plotted on one time-distance chart. Normal paths give times which lie approximately on a straight line, or on a smooth curve showing slight curvature. Abnormally short-time paths are indicated by large deviations from the mean line. Often these deviations amount to many tenths of seconds, and are unmistakable indications of the presence of salt-domes. The Vermilion Bay refraction fan time-distance curve is shown in Fig. 6.

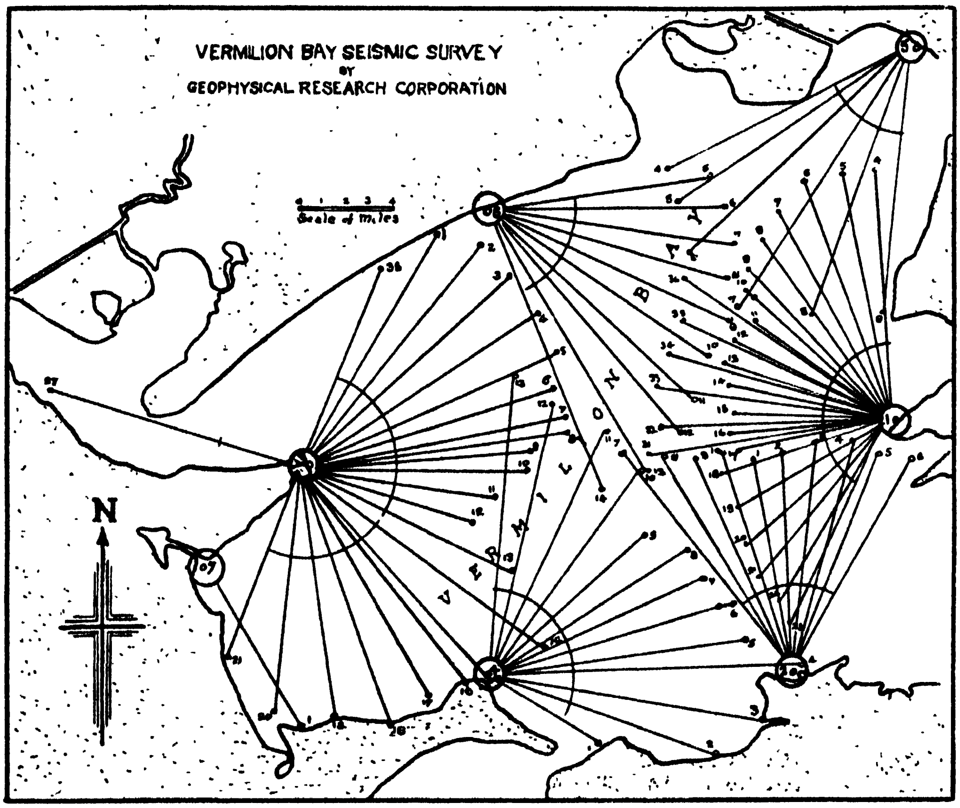

FIG. 5.

The points marked with crosses represent abnormally short-time paths and indicate the presence of a salt-dome between the particular explosion point and the corresponding observation stations.

The next step consists in detailed examination of the particular area defined by the reconnaissance fans, so that the top and the flanks of the dome can be accurately located. For this purpose the Mintrop linear traverse method is used.

The Arc Method.

This method was developed by the writer in connexion with an extension survey of the Haft Kel oilfield in Iran at the end of 1930.

A full account of the method is given in the *Proceedings*

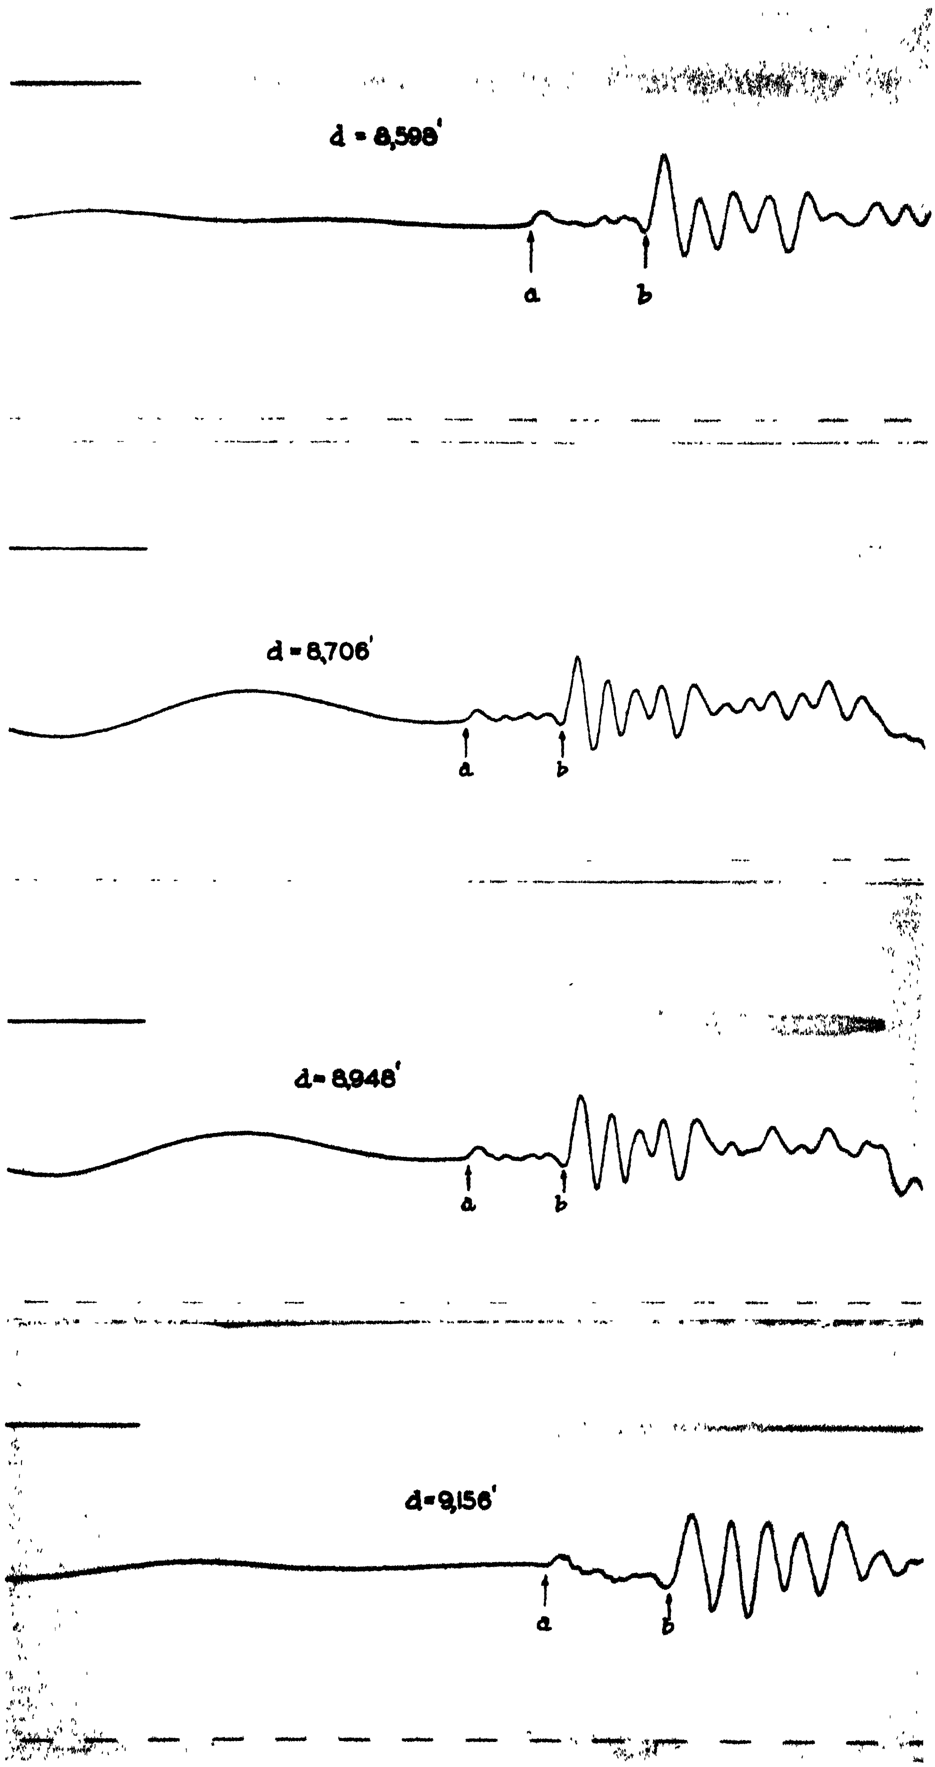

Fig. 4

of the World Petroleum Congress, London, 1933 [4]. In this method the detectors are arranged on the ground at approximately equal intervals on an arc of a circle of large radius. The length of the radius is governed by the depth and the velocity ratio. The charge of gelignite is fired at the centre of the circle and the times of first arrival observed at each detector station.

It is clear from (6) that the time will be a minimum at the point where H is least. This is immediately over the axis of the anticline; from this point the time will increase continuously down either flank of the structure.

Fig. 7 shows an arc-time curve, together with the corresponding profile determined from well data in the Haft Kel oilfield in south-west Iran.

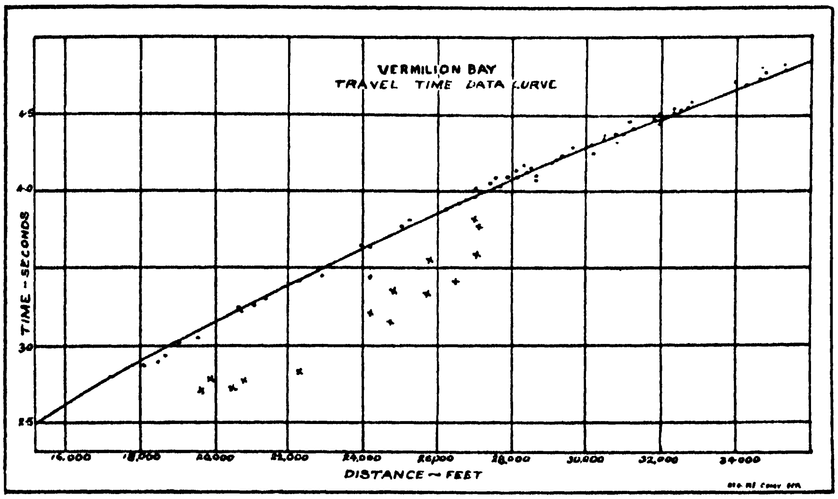

FIG. 6.

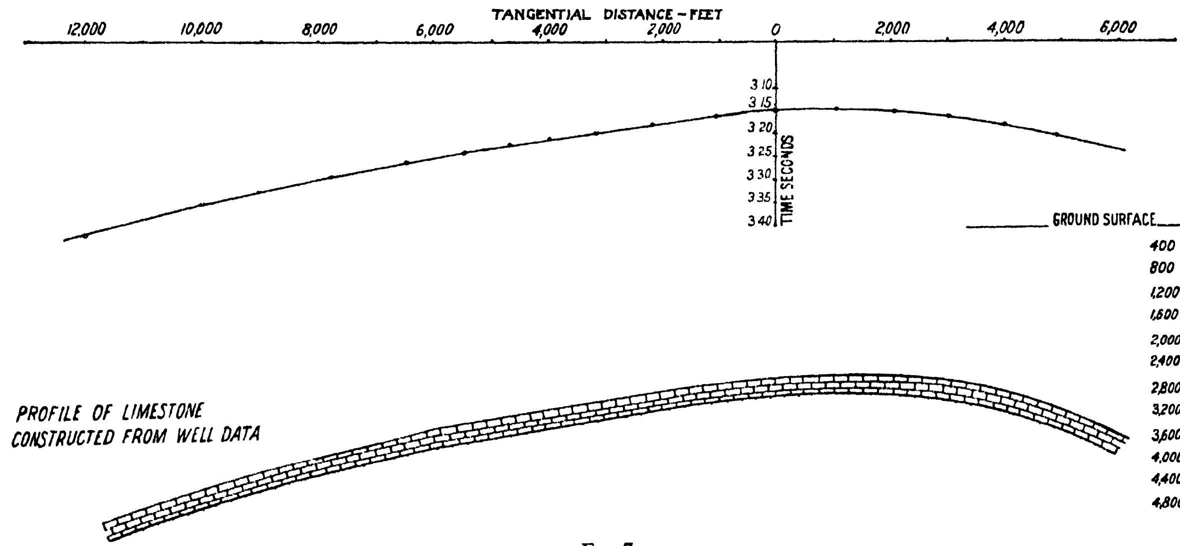

FIG. 7.

It can be shown that, to a first approximation, the travel time at any point on the arc can be expressed in the form

$$t = a+\frac{b}{v_L}+cH, \tag{6}$$

where b = the radius of the arc,

v_L = velocity in the solid layer,

a = quantity depending on the normal depth at the shot point and the average value of the elastic wave velocity through the overburden,

c = a quantity depending on the average value of the elastic wave velocity through the overburden.

Isochron Contour Maps.

For the purpose of detailed mapping with this method a number of arcs are surveyed at two- or three-mile intervals. These arcs are then linked together by linear traverses and all times are reduced to a common datum point.

It is necessary to know the value of the velocity v_L very accurately, and several determinations have to be made on linear traverses of suitable lengths.

The expression (6) can be put in the form

$$t' = t-\frac{b}{v_L} = a+cH. \tag{7}$$

The right-hand side of this equation depends only on the depths at the transmitting and receiving points, and on

the average values of the elastic wave velocities through the overburden [2, 1935].

To reduce the time t' in (7) to another datum point it is only necessary to change the value of the constant a. Thus if an arc with shot point O_1 intersects a line with shot point O_2 at a point P, we can reduce the times on the line to refer to the shot point of the arc.

We have for the arc

$$t'_{P_1} = t_{P_1} - \frac{O_1 P}{v_L} = a_1 + cH, \tag{7 a}$$

and for the line

$$t'_{P_2} = t_{P_2} - \frac{O_2 P}{v_L} = a_2 + cH. \tag{7 b}$$

To reduce the t' times on the line to refer to the shot point of the arc it is necessary to change a_2 in (7 b) to a_1. This is effected by adding the amount $(t'_{P_1} - t'_{P_2})$ to all values of t' on the line. In a similar manner times on other lines and arcs can be reduced to refer to O_1. Having reduced all times to the common datum point O_1, it is a simple matter to construct the isochron map of the underground structure.

The time at any point on the map will be related to the normal depth at that point by $t' = a_1 + cH$.

The vertical depth contour map can be constructed from the isochron map by a simple geometrical method when the values of the two constants a_1 and c are known.

IV. Values of Compressional Wave Velocities in Various Rocks

The following group of values for the compressional wave velocities are given by Salfeld [1, 1928].

1. 600 to 800 metres per sec.; rubble, gravel, sand loess.
2. 1,800 metres per sec.; clay, clayey sandstone.
3. 2,200 to 2,400 metres per sec.; slightly calcareous marl, siliceous sandstone, slightly calcareous sandstone.
4. 3,200 to 3,800 metres per sec.; calcareous marl, calcareous sandstone, hard clay slate.
5. 5,000 to 6,200 metres per sec.; limestone, dolomite, gypsum, anhydrite, salt, metamorphic rocks, massive rocks.

The following values have been determined in England and Iran by the Geophysical Staff of the Anglo-Iranian Oil Company:

Clay	about	5,000 ft. per sec.
Chalk	,,	10,000 ,, ,,
Calcareous sandstone	,,	11,000 ,, ,,
Gypsum	,,	13,500–14,000 ft. per sec.
Anhydrite	,,	14,500–15,000 ,, ,,
Salt	,,	15,500–16,000 ,, ,,
Limestone	,,	17,500–20,000 ,, ,,

REFLECTION METHOD OF EXPLORING SUBSURFACE GEOLOGY

By BURTON McCOLLUM, B.Sc.
Geophysicist

General

THE utilization of seismic waves in mapping subsurface strata depends on physical phenomena closely akin to those observed in that branch of optics dealing with reflected light. In general, if an elastic wave travelling in any medium encounters changes in elasticity or density, or both, within the medium through which the wave travels, phenomena of reflection, refraction, and sometimes diffraction occur. The paths of such waves resemble those of light and of sound.

As the name suggests, seismic exploration by the reflection method is concerned only with that part of the wave energy which is reflected or turned back at the contact surfaces between subterranean formations possessing different physical properties.

The elastic waves utilized in subsurface exploration are commonly called 'sound' or 'seismic' waves. The waves are caused by a charge of high explosive fired a few feet beneath the earth's surface.

The simple theory of the reflection method is best illustrated by the well-known echo method of submarine sounding. This is illustrated in Fig. 1. Here a sound wave, usually of audible frequency, is transmitted from one part of a ship's hull, downward through the water, and reflected back, as indicated by the arrows, to a receiving device in another part of the hull.

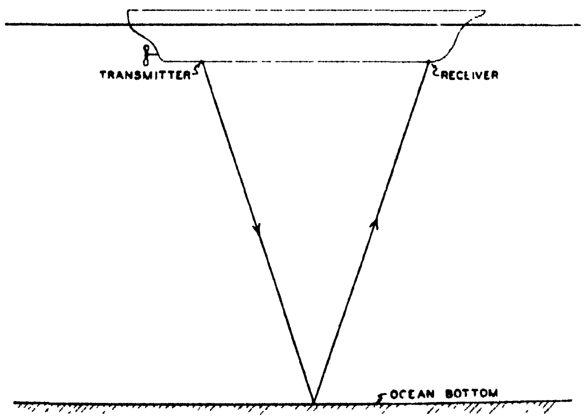

FIG. 1. Depth-finding by reflected sound.

In one embodiment of this method the total time of travel of the reflected waves, from transmitter to ocean bottom and back to the receiver, is measured. The velocity of sound in water being known, the depth of the reflecting boundary, which, in this case, is the bottom of the ocean, is readily calculable. This method has reached a high degree of development and, at the present time, direct reading instruments are available which give a continuous indication of the depth of the water while the ship is in motion.

No such ideal result has been accomplished in determining the depth of subterranean reflecting boundaries, due to basic differences between the conditions under which the operations have to be carried out in the two cases. In the early attempts at subterranean exploration work it was natural to seek to apply the principles that were then being successfully used in submarine sounding. Experience showed, however, that these were totally inapplicable, and it became necessary to develop an entirely new and radically different technique before success in subterranean exploration was achieved. The fundamental differences between the problem of ocean-depth sounding and that of subterranean exploration may here be set forth briefly as an aid in visualizing the problems involved in developing methods and equipment for commercial exploration work by the reflection method.

In submarine soundings we are dealing exclusively with water as a medium for transmitting the wave energy. Water is a highly elastic medium and transmits wave energy with very little absorption. Also, the velocity of sound in water is nearly uniform, and such variations as occur can readily be calculated from easily obtainable data. Furthermore, water being entirely lacking in rigidity transmits only simple compression waves, and in ocean soundings only a single reflecting boundary is involved. These ideal conditions greatly simplify the problem incident to ocean sounding and make possible the present remarkable speed and accuracy of the method. This simplicity led to false hopes and wasted effort in the early experimental attempts to apply the method to subterranean exploration.

In subterranean work the following conditions are encountered which do not occur in marine work:

1. The earth is a non-homogeneous medium, and the velocity of elastic waves passing through it varies from place to place both vertically and horizontally.
2. Transmission characteristics of most sedimentary formations are relatively poor, in consequence of which enormously greater energy radiation from the source is required.
3. Under most conditions the character of reflecting boundaries is such as to give a much lower coefficient of reflection than is obtained from the bottom of the ocean, so that it becomes necessary to work with very small amounts of reflected energy.
4. The earth possesses the characteristics of a solid in that it manifests a certain degree of rigidity; in consequence of this, both compression waves and transverse waves are generated at the source, while in water only compression waves are generated. Transverse waves travel at a lower velocity than compression waves, and hence there arises a disturbing factor in the reception and identification of reflected waves in subterranean work. Further, when either one of these types of waves impinges upon the boundary surface between two strata having different physical properties, each in turn is resolved into two components, one being of the compression type and the other the transverse type, and a certain amount of energy of each type is reflected back towards the surface, further complicating the problem of reception and identification of the individual reflected events.

5. A further condition of considerable importance in subterranean work grows out of the condition illustrated in Fig. 2, which represents a more or less typical section of sedimentary deposits. Here, a relatively thin layer, *a*, not infrequently called by geologists the weathered layer, rests upon a relatively more compact deposit, *b*. Because

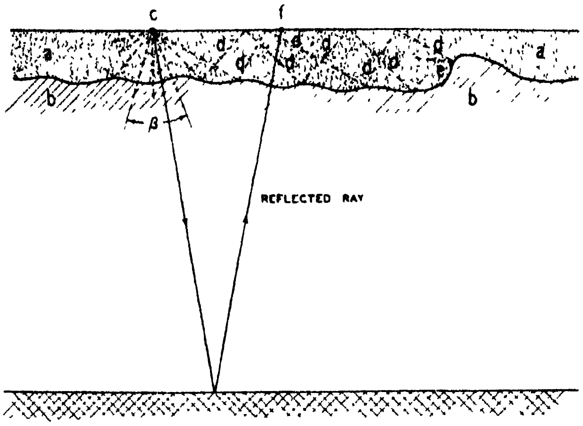

FIG. 2. The main reflection from the lower layer tends to be obscured by multiple reflections from the base of the weathered layer.

of its more consolidated nature, and due also partly to the greater pressure to which the formation *b* has been subjected over a long period of time, the velocity of sound in medium *b* will usually be much greater than that in medium *a*. If now a source of sound be located at a point *c*, and radiates therefrom in all directions, it will be seen that for the most part this radiant energy strikes the boundary surface between *a* and *b* at rather oblique angles. It is a well-known fact that when an elastic wave is travelling in any medium and impinges obliquely beyond a certain critical angle on a boundary surface of an adjoining medium of much higher propagation velocity, total reflection occurs. Since under practically all conditions the velocity of sound in medium *b* may be several times that in medium *a*, all of the energy radiated outside of a relatively small angle β will be totally reflected back towards the surface as shown by the arrows, *d*, *d*. These waves, on reaching the surface, are again reflected downward at an angle and, in general, reflected again and again, as shown by the zigzag lines. In consequence of this phenomenon the greater part of the energy radiating from the source is confined to the surface layer, and is ultimately dissipated therein. This phenomenon is analogous to the confinement of a light beam within a bent quartz rod, and is due to total reflection at the boundary surfaces between the quartz and the surrounding air in which the velocity of light is much higher than in quartz. Further, due to the variable character of medium *a*, numerous reflections, more or less horizontally directed, occur as at *e*. Any detector of sound waves, *f*, that may be set in the surface of the ground, will be actuated by these relatively violent disturbances for a long period after the sound emanates from the source. These disturbances are superimposed on relatively feeble reflected waves coming from the deeper horizons and so render their reception and identification difficult.

6. Under many conditions the source of sound embedded in the ground generates an air wave as well as an earth wave, and this air wave, radiating in all directions from the source, is frequently a disturbing influence on the seismogram.

7. Finally there exists the so-called Rayleigh wave, which is a surface phenomenon. It often has much energy and travels with low velocity, often not over 200 to 300 metres per sec. It is often a source of interference with the relatively feeble reflected waves under observation.

In consequence of the above, the methods and equipment that have been found so remarkably effective in ocean sounding prove to be of no value whatever when applied to the study of subterranean formations.

The successful development of the reflection method depends on means that have been devised for successfully minimizing the various undesirable radiation components above described. Three measures of prime importance which have contributed to this result are:

1. The use of relatively short shooting distances, that is, small angles of incidence and reflection, which greatly minimizes disturbances that would otherwise result from splitting up of the reflected wave into components embracing a large percentage of their energy in transverse waves, and also avoiding the relatively high dissipation of energy that takes place when these reflected waves travel at an oblique angle across stratified deposits.

2. The use of deeply planted explosives, or shots, which places the source down below the greater portion of the very low velocity surface formation, thereby avoiding, in a large degree, the effects of total reflection above described.

3. The development of effective filtering devices which give the equipment a high degree of selectivity to the reflected waves.

Experience shows that reflection seismograms are better if the shooting distance is kept below about 1,000 metres, but at less distance there is little difference, except when working quite shallow horizons, in which case still further shortening of the shooting distance is helpful. The relative intensities of the several surface waves, and the velocities at which they travel, vary so much from place to place that it is not possible to adopt any general rule as to the shooting distances that will give maximum freedom from undesired effects; this can only be determined by trial records in any particular locality, after which the optimum distance for that locality can be adopted for subsequent shooting. In commercial practice to-day, probably more than 90% of the shooting is done at distances between 0 and 1,000 metres.

Typical Field Procedure

A schematic arrangement of apparatus for reflection shooting is shown in Fig. 3. Here, *I* is the first shotpoint where a suitable charge of explosive is fired at a predetermined time; *a* is the communication line used both for

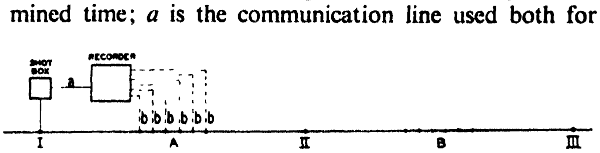

FIG. 3.

signalling between recorder station and the shot-firing station, and for transmitting the shot signal to the recorder. The lines *b*, *b* connect the recorder to the sound detectors, at station A, where there are usually 6 of these detectors in a set. The distance between the shotpoint and the centre of the detector group will usually be less than 1,000 metres, while the span embracing the group of detectors will usually range from 50 to 300 metres.

The usual procedure is to lay out a line of shot stations 1,000 metres apart, for example, and make set-ups of the

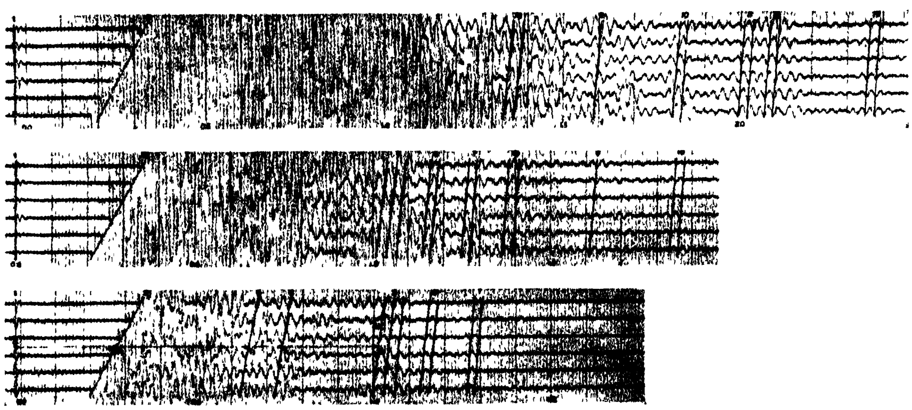

FIG. 7

detector group midway between the shotpoints. Each detector set-up is shot from the two nearest shotpoints in opposite directions in order to permit more accurate interpretation of the data as will be described later. On each set-up it is customary to shoot several times from the same shot hole, small charges being used for obtaining reflected waves from shallow horizons and heavier ones from the deeper horizons. As a rule from 3 to 5 shots are required to embrace all horizons down to about 5,000 metres. When shooting from shot station I has been completed, the shooter moves to shot station II on the other side of the detector set-up, and the same set-up is shot from the opposite direction. The shooter then remains at station II while the detector set-up is moved to station B, and so on. This procedure has two important advantages, viz., it yields two depth determinations for each shot station, and each detector station is shot from opposite directions, an important consideration, as will later appear.

The depth of the shot holes is of prime importance in securing satisfactory reflection results. In most areas the usual practice at present is to drill the shot holes to depths ranging from 15 to 30 metres, although in some cases, particularly where it is necessary to get the shot below deep surface sands or other low-velocity beds, still deeper holes are used. This is essential for reducing effects of surface travelling waves discussed above. In many cases, particularly where the holes are drilled in sand, it is necessary to case the holes before shooting, and some companies make it a standard practice to case all holes to ensure that they will stand up throughout the shooting operations. For the most part, $2\frac{1}{2}$ to 3 in. casing is used. The shots are stemmed with water in order that the same hole may be shot as many times as desired.

The amount of explosive charge required will vary greatly in different places, and to some extent from point to point along any line. Sometimes a single percussion cap will suffice and the charge required may range upward to several kilograms of explosives. Rarely will more than 4 or 5 kg. of explosive be required.

The operator in charge, guided by immediately preceding experience, will first use a charge of about the mean size required at the preceding adjacent shotpoints. The resulting seismogram is immediately developed and used as a guide in determining the subsequent charge for that shotpoint to give information over the desired range of depth with a minimum number of shots.

At each station along the line the seismograms give information which can be used for determining the depth and position of the points of reflection on various horizons. Such points of reflection are usually, although not always, somewhere below a region between the shot station and detector station.

In some cases, where greater accuracy or detail is considered of sufficient importance, there is an interchange of shot and detector stations. In this procedure the first series of shots will be taken as described above, then the relative position of the shot station and detector station is interchanged and a similar series of shots taken. The advantage of this is that the points of reflection in both cases are coincident, permitting somewhat greater theoretical accuracy than is obtainable from the procedure first described. This is a slower and more expensive procedure, however, and, in the opinion of the writer, the extra expense is not warranted, except in special cases, as when detailing important areas characterized by difficult subsurface conditions.

Automotive Equipment

A complete set of transportation units required for the seismograph party is shown in Fig. 4. This embraces a portable drilling rig, usually of the rotary type; a tank wagon to service the drilling rig; a recorder truck to transport the recording and amplifying equipment; a tank wagon to serve as a shooter's truck and to provide water for stemming the shots; a surveyor's car and one or two additional passenger cars for transporting personnel of the party.

Organization and Personnel

The personnel required for a representative seismograph party will vary somewhat according to conditions and individual views as to what constitutes the most efficient organization. For the most part, a representative party may be considered as made up of the following personnel:

- Geophysicist.
- Assistant geophysicist.
- Party chief.
- Instrument operator.
- Shooter.
- Two shooter's assistants.
- Surveyor.
- Two surveyor's assistants.
- Chief wireman.
- One or more assistant wiremen.
- Driller.
- Two driller's assistants.

The chain of responsibility in a typical seismograph party is shown in the organization chart in Fig. 5.

Instruments and Apparatus for making Reflection Seismograph Surveys

A typical instrument set-up for making reflection seismograph surveys is shown in principle in Fig. 6. A photographic recorder, generally embracing 5 or 6 galvanometer elements, is used. The elements may be of either the Einthoven or d'Arsonval type. The time scale is placed on the seismogram by means of a light shutter consisting of a rotating slotted disk, driven at a constant speed by a small synchronous motor, operated from a tuning fork. The slots in this disk are usually adapted to give a time line on the film every 0·01 sec., and it is the usual practice to have every tenth slot wider than the others to give a relatively heavy line every 0·1 sec. to facilitate the scaling of time on the seismogram. Means equivalent to the 'shot-kick' transformer are provided whereby the instant of firing the shot is recorded on one or all of the traces on the seismogram. In its simplest embodiment this shot-kick mechanism is coupled to the telephone circuit used for communication between the shot and recorder stations.

At the present time it is usual to determine the time of firing the charge, not from the time of firing the cap, as was formerly done, but by looping an electrical circuit around the charge and recording on the film the instant of the breaking of this circuit. This arrangement is provided in the hook-up shown in Fig. 6, as will readily be seen by tracing out the wiring diagram. This eliminates any error due to time lag in the cap.

Sound detectors are connected with the recording unit through independent lines passing through the filter and amplifying unit, both of which are preferably combined in a single unit for compactness and efficiency.

Electrical Seismograph

The electrical seismograph unit described above has virtually replaced the older mechanical type of seismograph for reflection work. One of the reasons for this is the greater adaptability of the electric type to filtration, this principle being of vital importance in suppressing the horizontally travelling waves so that the relatively feeble reflected waves will stand out with sufficient clearness on the seismogram.

Experience has shown that most of the energy of reflected events is carried on wave-lengths corresponding to frequencies varying between about 40 and 60 cycles per sec., whereas most of the horizontally travelling energy is usually carried on longer wave-lengths. By adjusting the filter to pass only a narrow band of frequencies between about 40 and 60 cycles, the horizontally travelling waves can generally be suppressed to a sufficient degree for practical purposes.

Interpretation of Seismograms

We shall now examine the procedure to be followed in analysing and interpreting the seismograms obtained as above described. Fig. 7 may be regarded as typical of seismograph records obtainable throughout most of the Texas-Louisiana Gulf Coast area. These seismograms were taken on a shooting distance of 450 metres with detector spacing of 50 metres. The following outstanding events will be noted:

First, we observe the shot-kick which is recorded on all of the traces at 1; next we encounter a large burst of energy at 2, which is produced by the series of more or less direct travelling waves between shot and detector stations, including surface and compression waves and other components as described above. Succeeding these waves are a series of more or less distinct events, 3, 4, 5, &c., occurring on the seismogram. These are reflected waves coming from horizons at successively greater depths. Their definite identification as reflected waves, rather than horizontally travelling waves, is made from the fact that they line up across the film at a very small angle as compared to the large angle characterizing the direct travelling waves.

As a basis for interpreting these records in terms of subsurface geology, we derive from them certain time data as follows:

1. The time, T_2, elapsing between the shot-kick 1 and the first main event 2 on the seismogram.
2. The various over-all times elapsing between the shot-kick and the several reflected events on the seismogram. These will subsequently be referred to as T_3, T_4, T_5, &c.
3. The interval time, this being the difference in time between the arrival of a particular reflected event at the detector station nearest the shot and the arrival of the same event at the station farthest from the shot, as illustrated on event 5 of Fig. 7. These interval times will be referred to as t_3, t_4, t_5, &c.

In reflection work the times to the first or main events on the seismogram are useful only in making corrections for the surface or weathered layer, but the over-all time, T, from the shot to reflected waves, and interval time, t, are basic to the interpretation of reflection records.

We are now ready to proceed with the analysis and interpretation of the above data.

The essence of the analytical problem is shown in Fig. 8. Here a shotpoint is located at A and a group of detectors is spread uniformly between the positions F and G, thereby giving a total detector span equal to the distance b, with the centre at C. The distance from the shotpoint to the centre of the detector group is a. A reflected wave arrives at point C, after reflection from point B, on a reflecting bed which, in general, is inclined to the horizontal at some

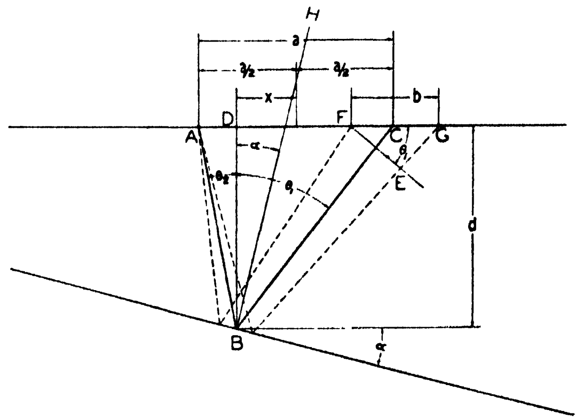

FIG. 8.

angle α. The line BD is a vertical line passing through the point of reflection, B, and the angle DBC, designated as θ_1, is called the angle of emergence. The angle θ_2 is the corresponding angle when shotpoint and detector stations are interchanged. The line BH is drawn through B, normal to the reflecting surface. It will be evident, on inspection of the diagram, that the angle GFE is also equal to the angle θ_1, where FE is at right angles to BC.

We are now concerned with the following quantities:

1. *Quantities known from the line survey.* These comprise the distance, a, between the shot station and the centre of the detector set-up, and b, the over-all span of the detector group.
2. *The mean velocity*, V, of sound in the earth section overlying the reflecting boundary. This value must be known from prior experience in the area under exploration, or it must be derived from special procedure to be described later.
3. *Quantities obtainable from the seismograms.* These embrace T, which is the over-all travel time of the reflected wave from A to C via the reflection-point B, and t, which is the difference in time of arrival of the reflected wave at the nearest and farthest detectors at F and G respectively.

The above are the known values of the working equations. The unknown values, with which we are ultimately concerned, are:

α, the angle of dip of the reflecting bed;
x, the horizontal displacement of the reflection-point B, with reference to the centre of the set-up;
d, the depth in a vertical direction of the point of reflection B.

As an intermediate step in arriving at these latter values we must, however, evaluate θ_1 and θ_2.

It will be observed that in stating the premises of the problem we have assumed that the reflecting layer below shotpoint and detector set-up extends with a constant dip, while, in general, in reconnaissance work this will not be the case. It can, nevertheless, be shown that the dip of the

reflecting bed, below the shooting line, will be given by the data obtained with a degree of accuracy satisfactory for practical purposes.

Again referring to Fig. 8, we observe that at the instant at which any particular wave arrives at the nearest detector, F, the line $\overline{FE}$ constitutes a portion of the wave front of the reflected wave. It is here assumed that this segment of the wave front is a straight line; also, it is assumed that the travel paths $\overline{AB}$ and $\overline{BC}$ are essentially rectilinear, and that b is small compared with d. No errors of consequence occur when these assumptions are made. The following relationships will be obvious:

$$\sin\theta_1 = \frac{\overline{EG}}{\overline{FG}}$$

$$\overline{FG} = b \quad \text{and} \quad \overline{EG} = Vt'.$$

$$\therefore \sin\theta_1 = \frac{Vt'}{b}.$$

Since V and b are known, it is necessary only to determine the value of t' in order to derive the value of θ_1. This is done by firing a shot at point A, and receiving the reflection from B on the detector group extending from F to G. From the record thus obtained, the difference in time of the arrival at the station G and station F gives the desired value of t'. In the general case it is necessary to interchange the positions of the shot and detector set-up, the shotpoint now being placed at C and the detector set-up having its centre at A. Another record is then taken with the shot fired at C and the difference in time, t'', is taken from the record as the time between the arrival of the reflected wave at the farthest and nearest detector. The geometry of this interchanged set-up will be identical in principle with that shown in Fig. 8, so that it is not necessary to draw a separate figure to illustrate it.

(*a*) **Calculation of Angle of Dip of Reflecting Horizon.** Proceeding now with the analysis of the data it will be seen from Fig. 8 that the following relationships hold:

$$\left.\begin{aligned}\sin\theta_1 &= \frac{Vt'}{b}\\ \sin\theta_2 &= \frac{Vt''}{b}\end{aligned}\right\} \tag{1}$$

These values are fundamental to all subsequent calculations. It will also be observed from geometrical considerations that

$$\theta_1 - \alpha = \theta_2 + \alpha.$$

$$\therefore 2\alpha = \theta_1 - \theta_2$$

$$\alpha = \frac{\theta_1 - \theta_2}{2}. \tag{2}$$

Since θ_1 and θ_2 are both derivable from equations (1), the angle of dip, α, of the reflecting boundary is calculated from equation (2). If α comes out positive, the reflecting horizon is dipping in the direction from shotpoint to detector station, and if negative, the direction of dip is opposite.

In deriving the above formulae we have assumed that the position of the shotpoint and detector group are interchanged for determining both t' and t''. Theoretically this would be the correct procedure, since in this case the points of reflection of the waves are the same for deriving both t' and t''. However, in practice it is usually sufficiently accurate and more economical to follow the procedure described on page 388. This presumes that the direction and magnitude of the dip are substantially the same at two adjacent reflection points several hundred metres apart. The data obtained from the seismograms will show definitely whether or not this is the case, and if not, the more accurate method of interchange of shot and detector may then be used.

(*b*) **Calculation of Position of Point of Reflection.** The length x is the horizontal distance from the reflection point to the midpoint between shot and centre of the detector group. From simple geometrical considerations we observe:

$$\tan\theta_1 = \frac{\tfrac{1}{2}a + x}{d}$$

$$\tan\theta_2 = \frac{\tfrac{1}{2}a - x}{d}.$$

$$\therefore \frac{\tfrac{1}{2}a + x}{\tfrac{1}{2}a - x} = \frac{\tan\theta_1}{\tan\theta_2} = r.$$

$$\therefore x = \tfrac{1}{2}a \cdot \frac{r-1}{r+1}. \tag{3}$$

values of θ_1 and θ_2 are derived from equations (1) ve, and thus the value of r, the ratio of the tangents, me known; hence equation (3) permits the calculation . If x comes out positive the shift of the reflection t is towards the shotpoint; if negative, the shift is rds the detector set-up.

) **Calculation of Depth of Reflection Point.** From Fig. 8 ll be seen that the total distance travelled by the wave shotpoint A to a detector at C via B is

$$L = \overline{AB} + \overline{BC} = d\sec\theta_2 + d\sec\theta_1 = VT.$$

$$\therefore d = \frac{VT}{\sec\theta_1 + \sec\theta_2}. \tag{4}$$

The value of V is known and T is taken from the seismogram, while θ_1 and θ_2 are obtained from equations (1) above, whence d is calculated from equation (4).

From the above it is evident that each shot-set-up combination is productive of both depth and dip determinations. Repeat the procedure at intervals along a surveyed line and the local variations of these quantities are found within the area explored. Two independent methods are available for evaluating these data for the purpose of obtaining the structural picture; namely, the 'Dip Method' and the 'Correlation Method'.

Dip Method. If we calculate the dip of the reflecting bed from equation (2) we can usually assume, with a fair degree of accuracy, that this value of dip persists over a considerable distance on either side of the point of reflection. If, for example, we make dip determinations at 500-metre intervals and assume that the measured dip persists for 250 metres on each side of the point of measurement, we can calculate the total change in elevation of the strata between adjacent reflecting points without regard to any direct correlation between reflecting beds at those stations. If it be true in any case that no reflecting beds persist from one point of measurement to the next, then this is the only method available for constructing the profile. In this case the dip of the reflecting bed for any particular reflected wave is determined as described above. A point is then spotted, as at A in Fig. 9, at the appropriate position along the line, and at a slant depth corresponding to the over-all time, T, for that particular reflected wave. Then a line is drawn through this point parallel to the calculated dip of the reflecting stratum at the point. A similar procedure is next followed for all other points on the diagram. It frequently develops that most of the reflected waves have come from local and discontinuous strata interbedded in

fortuitous fashion and related only by a general parallelism at any particular vertical section. From this observed parallelism we can draw a 'virtual profile', substantially paralleling the dip indicators, and this virtual horizon will give a fairly accurate picture of the subsurface structure, although it does not refer to a specific formation. Fig. 9 is a typical profile of Texas-Louisiana Gulf Coast formations derived by the dip method.

The relative merits of the correlation and dip methods have been a subject of considerable discussion, and at times sharp differences of opinion have developed as to the applicability of one or the other in certain areas. It is the view of the writer that all such discussions and opinions are of academic interest only. The records taken by the usual modes of field procedure give the main data for both methods of interpretation, and since each interpretation will, in most cases, lend increased support and certainty to the other, there is no warrant for deliberately discarding one or the other. If, as sometimes occurs, the interpretations by the two methods are definitely in conflict, we are then confronted with a case in which more field work is required to resolve the uncertainty. If, on the other hand, as is usually the case, the interpretations by the two methods are in substantial agreement, the geophysicist can then present his findings with greater confidence than if only one method is used. Since the cost of making the interpretations is but a fraction of the total cost of the seismograph operations, it appears that the small additional expense of the double check on the accuracy fully warrants the use of all information available from any set of seismograms.

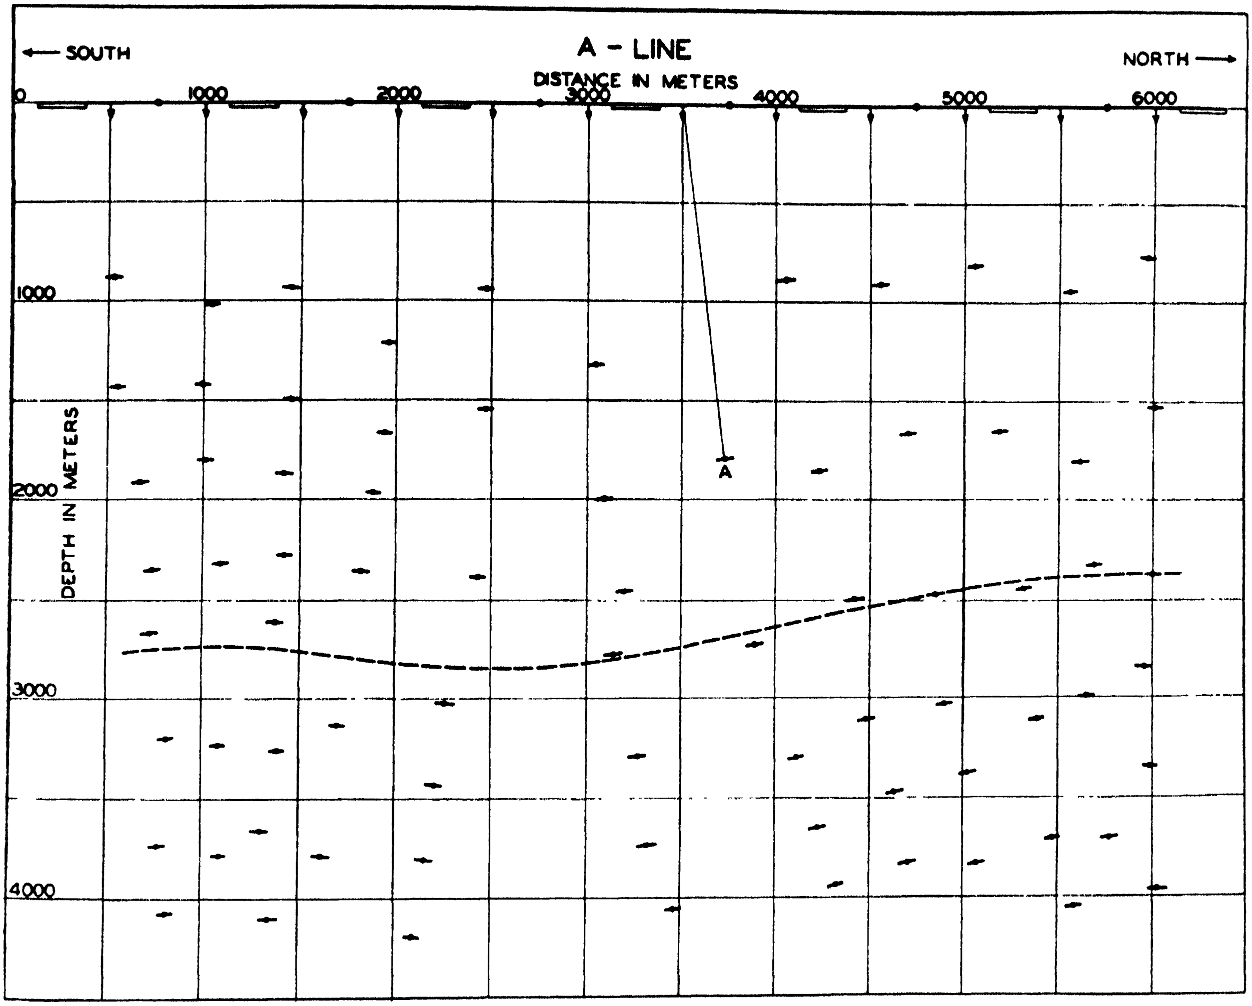

FIG. 9.

Correlation Method. In this method the depth of any particular reflecting stratum is calculated for any one point of observation by using equation (4). We then endeavour to identify the reflected wave from this same stratum on the seismogram taken at the next and succeeding stations on the line and calculate the depth at those stations. If we can definitely identify the corresponding waves, this method permits the ready and accurate profiling of the section. In certain cases, especially where there exist hard limestone horizons separated by relatively thick beds of shale or other soft formations, this can be done with virtual precision. Under such favourable conditions, little, if any, attention need be given to dip determinations. This procedure is known as the correlation method. In many cases, however, the identification of the corresponding reflected waves on successive set-ups is not immediately obvious, and in such cases the dips of the several strata are of great aid in making such identification.

of more or less regional extent. On account of the large number of reflecting strata, they have been first plotted as time strata; the total over-all time, T, from shots to reflected waves being shown on the left. At the top of the chart the direction and approximate magnitude of the dips as determined by the dip method are shown by the arrows. These dips will be seen to offer material aid, in many cases, where otherwise the correlation of the time strata might be obscure. On certain of the more definite horizons it is usual to convert the time strata into actual depth profiles by applying equation (4). The depth scale for this conversion is shown at the right-hand side of the chart.

Velocity Determination

Since the velocity of elastic waves in the earth varies greatly from region to region and also varies with depth in any particular area, the accurate determination of this velocity is of considerable importance. Two methods are available for this. The most direct and satisfactory method is to place a sound detector down in a deep well and measure the velocity from the surface down to a series of different depths. It is desirable to place the shot at some distance from the well, preferably at about half the usual distance between shotpoints and detectors in reflection shooting. This has the double advantage of taking account of the effect on the velocity of the waves travelling at an oblique angle with the formations as it actually does in most reflection shooting, and it also corrects automatically, for the effect of curvature of path due to change of velocity, with depth. It is important also to shoot on opposite sides of the well to avoid error due to deviation of the well from the vertical. This method gives very precise data on the velocity for the region contiguous to the well.

In many areas, however, no wells are available, and in such cases it is necessary to use another method for determining the velocity. A method available for this purpose is illustrated by Fig. 11. A shot is fired at the point A and

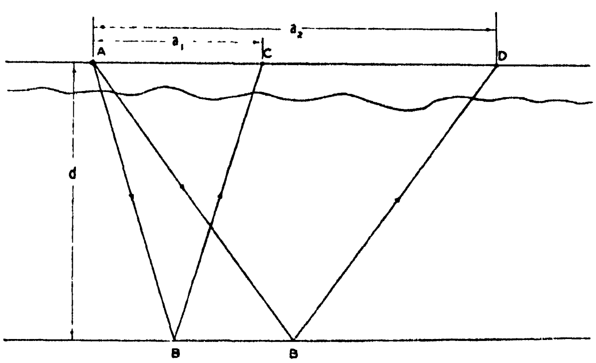

FIG. 11.

reflected events from the bed B–B are recorded at detector stations C and D. Here a_1 is the horizontal distance from A to C, and a_2 that from A to D, and d the depth of the reflecting bed. Further, if T_1 and T_2 are respectively the over-all times of travel of the reflected waves from A to C and A to D, and if V is the mean velocity, we have the following simple relationship:

$$V^2T_1^2 = 4d^2+a_1^2, \qquad V^2T_2^2 = 4d^2+a_2^2.$$

$$\therefore\ V^2(T_2^2-T_1^2) = a_2^2-a_1^2.$$

$$\therefore\ V = \sqrt{\left(\frac{a_2^2-a_1^2}{T_2^2-T_1^2}\right)}. \qquad (5)$$

This method, while theoretically very simple, leaves much to be desired from the standpoint of accuracy unless great precautions are taken. It will be seen that the denominator contains the difference between the squares of two quantities not greatly different in magnitude. A small error in measuring either of these quantities is therefore greatly magnified in the calculated value of V. In general, the greater the spacing of the two detector stations the greater will be the accuracy of velocity measurements. Obviously, in applying this method it is essential that the reflections take place from the same depth in both cases. This combination is often difficult to achieve and will be discussed later.

Further, small variations in the thickness of low velocity surface beds at C and D will, if not carefully corrected for, introduce large errors into the calculated value of V. Also in some areas, as in the Gulf Coast, if the points C and D are separated by a considerable distance, doubt may exist as to whether the reflected waves chosen come from the same bed. The following procedure has been found to minimize the difficulties mentioned and give results sufficiently accurate for practical purposes.

First a preliminary profile is run, about 2 km. in length, preferably about parallel to the geological strike so as to secure not only a nearly level horizon, but also to give greater assurance of nearly uniform velocity throughout the line. Depth determinations are made at sufficiently frequent intervals to eliminate doubt as to the continuity of the reflecting strata. If the strata are found to be continuous and virtually level, a reflection set-up is made with two detectors from 1 to $1\frac{1}{2}$ km. apart. A seismogram is then taken with the shot 100 or 200 metres from the nearest detector. The shot and detector stations are then interchanged and another seismogram taken. The mean values of the over-all times, T_1 and T_2, are then substituted in equation (5) and the velocity calculated. If the work is done with care, values of sufficient accuracy for most practical purposes can be thus obtained. Of course, a number of reflecting beds can be used on the same set-up so that the values of V at a number of depths can be obtained.

Corrections for Surface Irregularities

In many cases one of the chief sources of error in reflection seismograph work lies in the formations near the surface which comprise what is usually called the weathered layer.

This is shown in principle in Fig. 12. It will be seen that there is not only topographic relief on the surface, but the depth of the so-called weathered layer may vary greatly from point to point. It is a well-established fact that the velocity of sound in this weathered layer is very low in comparison with the velocity of the more compact shales

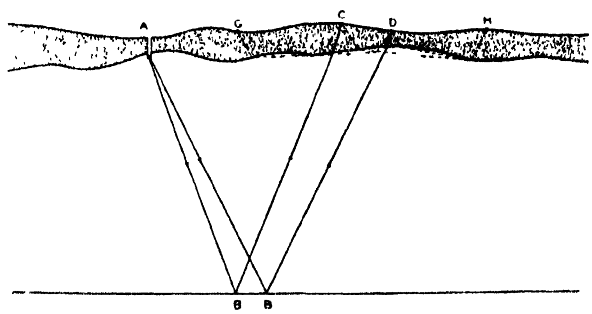

FIG. 12.

and clays immediately underlying it. Many instances have been found in which sound velocity near the surface has ranged between 200 and 500 metres per sec., whereas at depths below 100 metres or so the velocity will be between 1,000 and 2,000 metres per sec. It is obvious, therefore, that variations in the thickness and velocity of the weathered layer from point to point will introduce large variations in the travel time of reflected waves quite independent of the depth of the reflecting surfaces. Furthermore, local irregularities in the depth and velocity of the weathered layer immediately underneath the detector set-up will give rise to large variations in the interval times between the detector nearest the shot and the one farthest away. These variations may give rise to large errors in dip determinations.

In areas where the above described conditions prevail accurate reflection seismograph work requires that some correction for this source of error be made. Theoretically, it should be possible to correct more or less completely for such errors, and this result can be very closely approximated in practice provided a sufficient amount of so-called surface correction shooting is done at each station.

Too often, however, the effort to secure sufficient data to correct these errors will involve more time and expense than does the regular programme of reflection shooting, and the cost often becomes prohibitive.

The problem thus becomes in the last analysis largely an economic one, and the geophysicist in charge of the work must determine in individual cases how far he is economically justified in going in order to achieve a higher degree of accuracy in the final results.

The basic principle of making surface corrections is illustrated in Fig. 12. Here the reflection set-up in its simplest form may be regarded as comprising a shot at the point *A*, with recorders at stations *C* and *D* of reflected waves from points *B*, *B*. It will be seen that the reflected wave travelling to *C* passes through a greater thickness of the low-velocity weathered layer than does that part of the wave which reaches the detector *D*, and it becomes necessary to correct for the differences in time thus produced. For this reason a 'correction shot' is fired at a point *G*. It can be shown that the first waves reaching stations *C* and *D* are those that travel by indirect routes shown by the dotted lines. For more accurate correction a similar correction shot is fired at *H*, on the opposite side of the detector set-up, and in this case also the paths of sound waves first reaching the detector are shown by the dotted lines. If we have chosen the position of shot stations *G* and *H* correctly, so that the first wave reaching detectors at *C* and *D* do in fact travel by the indirect route indicated by the dotted lines, then these two correction shots furnish sufficient data to correct for the effect of the weathered layer with sufficient accuracy for all practical purposes. However, it may frequently happen that we would not know enough about the thickness of the weathered layer to enable us to determine the proper positions of the correction shotpoints *G* and *H* on the first trial, in order to fulfil the condition above stipulated, and this can only be determined after an examination of the correction records. It not infrequently happens, therefore, that proper surface corrections call for additional local shooting, and it is this possibility that often raises a serious economic question.

In a great many practical cases it has been found sufficient to dispense with the special correction shots and instead use the over-all times between shot and the first event on the record due to the direct travelling waves. These waves also travel by the indirect paths similar to the dotted lines of Fig. 12. In general, if the low-velocity surface layer is abnormally thick, these over-all times to the first wave on the record will be abnormally long, and vice versa. These over-all times, therefore, afford a rough measure of the thickness of the weathered layer and therefore of the surface correction necessary. For economic reasons it is desirable to use this simple method whenever local conditions will permit. If, however, widely varying thicknesses of the weathered layer are encountered from point to point, it will often become necessary to use the more expensive but more accurate method illustrated in Fig. 12.

A complete treatment of the subject of weathered-layer corrections would lead to more detail than present space limits permit. It may be said, however, that the entire problem of weathered corrections is fundamentally a problem of shallow contouring of the boundary between the weathered layer and the more compact clays and shales lying immediately underneath. Sometimes this boundary is sharp and well defined, and at other times it is composed of a more or less vague transition zone that may be as much as 50 or 100 metres in thickness. In most cases, however, the profiling of this very shallow boundary cannot be successfully carried out at the present time by reflection. It can, however, be done with sufficient accuracy for practical purposes by special applications of the refraction method of profiling.

Accuracy of Reflection Profiling

Four general groups of errors may be recognized as possibly affecting the accuracy of reflection seismograph profiling.

1. This group embraces errors resulting from uncertain topographic relief, and the various errors that may be inherent in instruments, such as time lag in the circuits, or apparatus, and errors of measuring time on the film. With modern equipment and procedure, however, these errors may be reduced to entirely negligible quantities.
2. Errors in determining vertical velocities.
3. Errors resulting from uncertainties in the weathered layer.
4. Errors of correlation.

The last three of the above-mentioned errors are limiting factors in accuracy of reflection seismograph work as at present carried out. With proper attention to the measurement of vertical velocities along the lines above indicated, and with such attention to weathered-layer corrections as economic aspects of the problem will usually permit, it is possible to reduce the errors from these sources to a point where the accuracy of the work meets substantially all requirements for commercial explorations.

When doing reflection work in areas characterized by a relatively few outstanding reflecting strata which are continuous over the entire area being explored, there will usually be little or no difficulty in correlating accurately for these strata, so that in such cases the danger of miscorrelation is virtually absent. When, however, reflecting strata are more or less vague and poorly defined, and particularly where discontinuities in the reflecting strata may occur due to a lensing out of formations or faulting, or where a number of reflecting strata exist fairly close together, there is always a possibility of miscorrelation from one set-up to another. Where such conditions exist, this source of error

can be greatly minimized by the use of more frequent reflection set-ups, and where conditions are extremely bad, continuous or overlapping set-ups are sometimes used. This increases the cost of the work, but it is sometimes the only way in which satisfactory accuracy can be assured.

In commercial oil explorations, in much of the Mid-Continent area in North America, depth determinations on the most important stratum, namely, the Viola Limestone, can now be made with a considerable degree of accuracy, the errors usually not exceeding 3 to 8 metres, particularly where wells are available for checking vertical velocity values. In wild-cat areas, where velocities have to be measured experimentally, errors may run from 5 to 20 metres. In ordinary operations, in areas such as the Texas–Louisiana Gulf Coast section, we are but secondarily concerned with absolute depths, but primarily with relative depths from point to point over potential structures. These relative depths can now be obtained with an accuracy of from 5 to 20 metres, except for occasional possible miscorrelations resulting from faults or lenticularities that may be but vaguely revealed by the seismograms.

Scope of Application of Reflection Seismograph

With the modern, perfected type of seismograph equipment it is safe to state that it is rare to meet conditions, in potential oil-bearing areas, where it is impossible to obtain information of considerable value in the search for oil deposits, Such information can be secured at a cost usually nominal compared with the cost of wild-catting by drilling without the benefit of prior seismograph work.

Conclusions

1. The accuracy of depth and dip determinations in reflection seismograph work may now be regarded as adequate to meet the requirements of commercial oil exploration.

2. The essentials of success in securing satisfactory reflection records embrace three conditions necessary for suppressing undesirable wave trends from the record. These three conditions are:

(*a*) Deep planting of shots to depths of 20 to 100 metres, or more.

(*b*) The use of short shooting distances relative to the depths of the reflecting horizon; these shooting distances usually being about 300 to 500 metres, when exploring strata below 500 metres in depth. For shallower strata shorter shooting distances will usually be necessary.

(*c*) The use of adequate filtration to eliminate from the records the waves outside of the 40 to 60 cycle band.

3. Electrical seismographs have shown marked superiority over mechanical seismographs, chiefly because of the more effective filtration which they make possible. Practically all commercial reflection shooting at the present is done by the electrical types of instruments.

4. The reflection method in its present state of development can now be used with commercially valuable results in nearly every type of geology of interest encountered in commercial oil exploration work.

SECTION 9

METHODS OF DRILLING

PERCUSSION TOOL PRESSURE DRILLING

By M. C. SEAMARK
Anglo-Iranian Oil Company Ltd.

As its name implies, the percussion-tool system of drilling utilizes the pounding action of a heavy cutting-tool to disintegrate the formation to be passed through. The system consists essentially of means whereby the drilling tool can be raised a short distance and then be allowed to fall by its own weight, until, coming into sudden contact with the bottom of the hole, the formation is shattered or drilled up. As drilling proceeds water is put into the well to form a liquid mud with the cuttings made which is bailed out as it becomes necessary.

Various mechanical means have been employed to transmit this necessary reciprocating motion to the drilling tools, and many methods have been used to form the connecting link between the actual drilling tool and the machinery at the surface of the ground.

The need for deeper wells and the inherent difficulties encountered while drilling through various kinds of rocks resulted in many improvements to the system. Ash poles gave way to the use of iron rods, a hoisting drum was used for handling the rods, a walking beam operated by a connecting rod attached to a crank provided the necessary lift to the drilling tools, and a steam engine supplied the necessary power.

Modifications of the pole-tool system of drilling were in use in the Russian and Galician fields until fairly recent years.

When drilling with iron poles, however, the weight of the total string in a deep well was considerable, and the continual reversal of strains from full load to zero which occurred on each stroke, about 30 times a minute, resulted in many breakages and consequent fishing jobs.

The time taken in handling the rods was also a serious factor in deep wells, since after each 'run' the tools had to be withdrawn from the well by unscrewing the rods one by one, the process being reversed before drilling could be resumed.

To overcome these very serious handicaps the American 'Standard' system was introduced; the most revolutionary change from the Canadian pole-tool system was the substitution of a manilla cable in place of the iron rods. With this flexible connexion from the surface plant to the drilling tools, the speed of withdrawal was accelerated considerably, and the number of strokes which could be delivered to the drilling tool was now limited only by the rate at which the tools could fall by gravity. A threaded feed attachment, the temper screw, was introduced for lowering the tools as drilling proceeded, and a separate drum for handling a bailing line became standard practice.

Although the substitution of a manilla cable for the solid rods was a marked improvement, other difficulties still presented themselves. The chief objections to a manilla cable were the tendency for excessive wear to take place, especially where the cable came in contact with the sharp edges of thin bands of hard rock, and also the fact that when drilling in a hole which contained a considerable amount of water the floating effect of the manilla retarded to some extent the free falling of the drilling tools.

These difficulties were eventually overcome by the introduction of a steel cable in place of the manilla rope, this latest improvement resulting in the present percussion system of drilling.

This method has been employed for wells over 9,000 ft. deep. It is not, however, recommended for depths exceeding about 4,500 ft., since the risks inseparable from this system are increased considerably in deeper wells.

In suitable formations which are free from caving difficulties and where troubles arising from water-shows are not likely to be encountered, the percussion system compares favourably with the rotary system on many points.

In 'wild-cat' drilling where water supplies are scarce and where fuel has to be transported for long distances, the percussion system has much in its favour, since the power required is considerably less than that required by the rotary system. The crew required to handle the plant is also smaller.

In test drilling for oil-bearing formations the advantages sometimes put forward in favour of the percussion system are:

(1) In view of the possibility of 'dry-hole' drilling, i.e. with only sufficient water in the well to enable the drilled debris to be formed into a thin mud, a much lower static pressure is exerted on the formation drilled through than is the case with the rotary system which necessitates the well being full of drilling fluid. The advantage in favour of the percussion system is that if oil- or gas-shows of low pressure are encountered they may be held back by the greater static pressure exerted by a long column of drilling mud and consequently might be passed unnoticed.
(2) The cost of equipment is less.
(3) The running costs are lower.

On the other hand, the modern rotary equipment is capable of drilling to greater depths and is able to cope with formations which the percussion system could not penetrate. In formations which are inclined to cave badly and where the presence of high-pressure water-shows would retard progress with percussion tools, the rotary system is undoubtedly the better.

A modern percussion drilling plant consists essentially of:

(1) Derrick.
(2) Rig.
(3) Power unit.
(4) Drilling tools and accessories.
(5) Casing and accessories.

The weight of these vary according to the depth of well and the formation to be drilled through. The gear varies from light portable outfits capable of drilling from 300 to 1,000 ft. to a full-sized plant designed to drill to 9,000 ft.

The former can be obtained mounted on motor lorries complete with their own power unit, an outfit capable of drilling a 6-in. hole to 600 ft. weighing about 7½ tons.

An outfit capable of drilling to 5,000 ft. complete with necessary tools and casing weighs between 350 and 400 tons.

Derrick.

The derrick may be of either wooden or steel construction. In view of its higher salvage value and the fact that it may be erected and dismantled any number of times, the steel derricks have to a large extent replaced those of wooden construction.

For deep drilling the derrick is usually 80 ft. high, tapering from a base 20 ft. square to an opening at the top 5 ft. 6 in. square. The load-carrying capacity to which the derrick will be stressed depends almost entirely on the amount of casing to be handled by the derrick. In a well 5,000 ft. deep the weight of the heaviest string of casing would probably be about 60 tons; to this weight, however, a margin must be allowed to cover conditions which arise due to cavings around the casing and other factors which tend to 'freeze' the casing. A type of derrick generally used for deep percussion drilling is designed to carry a load of 60 to 100 tons.

The derrick is surmounted by a crown block. This carries a series of sheaves over which the casing block lines are reeved and also other sheaves which carry the drilling line and the sand line.

Near the base of the derrick, placed on opposite sides and running on suitable bearings, the bull wheel and calf wheel are housed. The former consists of a steel drum of sufficient capacity to take the full length of drilling cable. At one end a tug rim is arranged for receiving the drive through a $2\frac{1}{2}$ in. dia. manilla rope, while at the opposite end a brake rim is attached.

The calf wheel is of similar construction, except that the line capacity is sufficient only to house the amount of line required for the reeving of the casing blocks which in the case of an 80-ft. derrick may be about 1,000 ft. The calf-wheel drive is by flat link chain and sprocket.

Rig.

The rig consists of a framework generally of steel construction arranged to carry:

(1) Band-wheel shaft.
(2) Sand reel.
(3) Sampson post.
(4) Walking beam.

The band-wheel shaft of a medium-weight outfit consists of a steel shaft 6 in. dia. by 9 ft. $3\frac{1}{2}$ in. long. It runs on suitable bearings and carries the crank arm, the band wheel with tug rim for operating the bull wheel, chain sprocket for the calf-wheel drive, chain sprocket for sand-reel drive, and is sometimes fitted at the end opposite the crank arm with a cat-head.

The band wheel is usually of steel construction 11 ft. dia. with a 13-in. face for a 12-in. wide driving belt. On one side of the band wheel the tug rim is attached: it consists of a steel casting about 6 ft. dia. suitably grooved to take a $2\frac{3}{4}$-in. dia. manilla rope. This rope drive transmits the power from the band-wheel shaft to the bull wheel which is placed on the opposite side of the derrick. For deep wells the tug rim is arranged to take two driving ropes.

In order to provide the correct stroke of the drilling tools the crank arm is provided with three or four wrist-pin holes into either of which the crank pin can be inserted. The length of stroke obtainable ranges from 2 ft. 11 in. to 4 ft. 6 in., the stroke required depending on the depth of the well, the formation to be drilled through, and the amount of water standing in the well.

The sand-reel and calf-wheel sprockets are fitted with dog clutches to enable them to be disengaged while drilling is proceeding. They are mounted at suitable positions on the band-wheel shaft and transmit, through flat link chains, the drive to the sand reel and calf wheel respectively.

The sand reel on which the bailing line is spooled is placed at the back of the band wheel. It runs in suitable bearings and is driven by the chain from the sprocket on the band wheel. The latest models are fitted with a friction clutch which can be disengaged while the bailer is being run into the well, and provides the necessary quick pick up of the bailer which is a great advantage in cleaning out the drilled debris.

At a point just outside the derrick legs the sampson post is attached to the rig foundation members. It consists of a rigid vertical steel post 15 ft. 6 in. or 17 ft. high, on top of which are two bearings in which the shaft of the walking beam is housed. The walking beam consists of a steel beam of suitable section mounted at about its centre position on a fulcrum bearing. To one end a pitman—or connecting rod—is attached, forming a connexion between the outer end of the walking beam and the crank arm on the band-wheel shaft. At the opposite end and exactly over the mouth of the well a temper screw is attached, to which the drilling line is coupled when drilling is actually in progress.

Types of Power.

Steam is undoubtedly the most flexible and convenient form of power, and where conditions are such that good water is available with a cheap supply of fuel this form of power is usually preferred. Many wells of considerable depth have, however, been drilled by cable tools using internal-combustion engines and also by electrical power.

With steam power a single-cylinder 12×12-in. engine using steam at about 120 lb. per sq. in. is considered ample for deep cable-tool wells, while for shallow wells a correspondingly smaller engine can be employed.

Engine.

In view of the varying conditions of load which are imposed on it, the engine is usually of special design. It must be of rugged construction, yet light and capable of responding rapidly to frequent changes of speed. Owing to the peculiar nature of the load while actually drilling, which varies from full load while the drilling tools are on the upstroke to a 'minus load' when they are falling by gravity, it is important that the inertia in the flywheel shall be low. With a heavy flywheel tending to even out any changes of load the necessary free falling action of the drilling is retarded, thereby decreasing the effective blow and the consequent shattering action of the drilling bit on the formation being penetrated. For this reason drilling engines are usually provided with a light flywheel, to the rim of which additional rims can be bolted as the depth of the well increases.

Accurate speed adjustment is essential in order that the motion of the drilling tools can be controlled to suit drilling conditions. This is determined by the rate at which the drilling tools can fall, this rate being again influenced by several factors such as the amount of fluid in the well, the size of the drilling tools in relation to the size of the hole being drilled, the straightness of the well, and the amount of drilled-up debris through which the tools must

fall. The ideal motion, and one which must be very closely approximated if efficient progress is to be made, is that which allows the drilling tools to strike 'bottom' the instant before the upstroke of the walking beam begins, although because of the elasticity in the cable it is probable that the beam is already returning on the upstroke as the tools strike. This motion ensures the maximum weight of the blow on 'bottom' and relieves the gear of the shock load which occurs if the upstroke of the beam takes place before the drilling tools have completed their downstroke. As the depth of the well increases the amount of stretch or elasticity in the drilling cable plays an important part and affects materially the amount of travel actually imparted to the drilling tools.

In view of these features, which are probably peculiar to drilling, the engine is controlled entirely on the throttle valve. This is done by means of an endless wire line on a hand wheel fixed at the driller's position on the derrick, no governors of any kind being fitted.

The crank shaft is fitted with a crowned belt pulley usually 24 in. dia., and of sufficient width to carry a 12-in. wide belt. This provides the power transmission from the drilling engine to the band wheel of the drilling rig.

Boilers.

The type generally favoured is the fire-tube locomotive type. The capacity depends on the weight of gear to be handled and the depth of the well to be drilled. For wells of 5,000 ft. boiler capacity of 5,000 lb. of steam per hour is sufficient for maximum demands. The number of boilers to be installed to provide this steam output is largely a matter of choice or circumstances, and is often governed by transport conditions, quality of feed water, and the time factor in completing the well. Two boilers each of 2,500 lb. per hour steaming capacity provides a useful and fairly flexible arrangement, which has the advantage of allowing one boiler off for cleaning while allowing drilling to proceed, admittedly not efficiently, with the second boiler.

Drilling Tools.

The number and variety of these can only be determined from a study of the conditions likely to be encountered while drilling. In isolated districts far away from sources of supply it is essential that considerable quantities of spares be carried if the work is to proceed expeditiously. The formations to be drilled through, the existence of underground water which must be cased off, the liability of the strata to caving trouble, and the degree of hardness of the various beds to be penetrated all influence the question as to which tools are or are not necessary for the successful completion of a deep cable-tool drilled well.

The type of tools which are considered essential also vary according to the views of different operators and the practice usually employed by them. Only those which are generally considered essential will be dealt with here.

A 'string' of cable drilling tools consists of:

(1) 1 rope swivel (Fig. 1).
(2) 1 set of jars (Fig. 2).
(3) 1 sinker bar (Fig. 3).
(4) 1 drilling bit (Fig. 4).

These are coupled together in the order named by tapered threaded joints. The weight and size of the 'string' depends on the size of hole being drilled; for a bit diameter of 15 in., 4×5-in. joints would be used, while for a hole of 6 in. dia. $1\frac{5}{8} \times 2\frac{5}{8}$-in. joints would be normal practice. Except in the larger sizes, the controlling factor as regards the size of 'string' to be used is the inside diameter of the casing through which it will be used. There must be sufficient space between the tools and the inside of the casing to allow the former to fall freely and also allow room for 'fishing' tools to be run in case of necessity.

Casing.

The casing programme again depends on the depth of the well, the underground waters which must be cased off, caving formations, and the pressures likely to be encountered when oil or gas is encountered.

A list of some combinations of casing weights and diameters which have been adopted by the American Petroleum Institution is as follows:

1		*2*		*3*	
Size, in.	*Weight per ft., lb.*	*Size, in.*	*Weight per ft., lb.*	*Size, in.*	*Weight per ft., lb.*
$13\frac{3}{8}$	60	$13\frac{3}{8}$	48	13	50
$10\frac{3}{4}$	45·5	$10\frac{3}{4}$	40·5	$10\frac{3}{4}$	40·5
$8\frac{5}{8}$	32	$8\frac{5}{8}$	28	$8\frac{5}{8}$	28
7	24	7	20	7	20
$5\frac{1}{2}$	20	$5\frac{1}{2}$	17	$5\frac{1}{2}$	17
$2\frac{1}{2}$	6 5	3	9·3	$2\frac{1}{2}$	6·5

Fishing Tools.

In spite of the efforts which have been made in recent years to introduce special steels and fine limits of accuracy in manufacture with a view to minimizing the number of breakages which occur in cable drilling tools, these breakages are still very frequent. Fishing jobs constitute one of the bugbears of this system, and many wells are lost owing to the breakage of the drilling tools.

Some fishing jobs prove to be comparatively simple, the lost tool being recovered in the course of an hour or so, while others, due to complications such as a bit breaking off and falling over into the wall of the hole, may take months to recover and in some cases lead to the abandonment of the well.

The cable-tool system does not lend itself to fishing, since in most operations the fishing tool is suspended on a steel cable which provides no positive means of manipulation of the fishing tool in relation to the position of the tool to be recovered. A considerable amount of ingenuity has been displayed in the design of fishing tools, but it is often necessary to design tools specially for some particularly difficult jobs. The normal set of fishing tools generally comprises the following:

(1) Rope spear (Fig. 5).
(2) Half-turn sockets.
(3) Slip sockets (Fig. 6).
(4) Rope knife (Fig. 7).
(5) Horn sockets.
(6) Spuds.

In commencing a well, a cellar approximately 5 ft. deep by 6×6 ft. is usually excavated and lined with concrete, a hole of the diameter of the drilling bit being formed in the centre of the cellar floor. The tools are then 'strung up', but since the drilling 'string' may be anything from 30 to 40 ft. in length, while the height of the walking beam is only about 15 ft. above the cellar floor, the beam cannot be used until sufficient hole has been drilled to accommo-

Fig. 9

date the 'string' of drilling tools. To overcome this difficulty the well is usually 'spudded' in for a depth of 100 to 200 ft.

This 'spudding' action is obtained by attaching one end of a jerker line to the wrist pin of the crank on the main rig shaft, while the other end is coupled to a spudding shoe which is placed behind the drilling cable. The bull-wheel brake is applied to prevent rotation of the bull wheel. The rotation of the crank thus imparts a reciprocating motion to the jerker line which, by pulling on the drill line at a position between the bull wheel and the crown block, raises and allows the drilling tools to fall. As the tools penetrate the formation, line is paid out from the bull wheel at a rate which allows the drilling bit to just strike bottom at each stroke.

This 'spudding' operation is at the best an unsatisfactory method of drilling, and as soon as sufficient hole has been made to accommodate the drilling tools and the necessary amount of drilling line to provide some measure of elasticity, normal drilling off the walking beam is instituted.

Drilling can then proceed until conditions are such that casing must be inserted, possibly to hold back cavings or to shut off a water-show, both of which may retard, if not prevent, the progress of the work.

With a string of casing inserted but still being 'carried' it becomes necessary to drill with a bit that will pass through the casing a hole sufficiently large for the casing to pass through. This is accomplished in either of two ways. A 'straight' bit may be used which will drill a hole the same size as the inside diameter of the casing, this hole afterwards being enlarged by means of an under-reamer (Fig. 8). Another method is to use an eccentric bit (Fig. 9). The construction of the latter type is such that although it will pass through the casing, its eccentric form enables it to cut a hole considerably larger than its own diameter.

In suitable formations eccentric-bit drilling is often satisfactory and is used extensively by those who have been trained in certain schools; in the United States of America, however, the straight bits and under-reamers are preferred.

When the point is reached at which the first string of casing is to be landed, a seat is prepared on to which it can be lowered, all caving formations and water-shows thus being sealed off at this point.

In many cases, owing to the corrosive effect on the casing of underground water, the practice of cementing the casing is becoming almost universal. This is effected by raising the casing a few feet off its seat and pumping down through the casing—or a special string of tubing inserted for the purpose—a cement slurry. The quantity required to fill the annular space between the outside of the casing and the bore of the well depends on the amount of caving that has occurred and the height to which it is desired to place the cement.

The cement slurry is mixed at the surface to a slurry of from 1·6 to 1·8 specific gravity, and is then pumped into the casing, followed by pumping in a quantity of water sufficient to raise the cement to the required height outside the casing. The casing is then lowered on to its seat and drilling operations are suspended for sufficient time to allow the cement to set. This time varies from 3 to 10 days.

After the cement which remained inside the casing has been drilled out, casing tests are usually made. This may consist of filling the well with water and applying an additional pressure by means of a pump. This pressure is a purely arbitrary one, and 500 lb. per sq. in. is generally recognized as constituting a fair and reasonable test of the cementing job. Another test consists of bailing out the water from the inside of the casing, thereby creating a differential pressure between the inside and the outside, any rise of water inside the casing indicating a leak into the well. For the latter test accurate information regarding the level of underground water should be available, since in deep wells the difference between the levels of the water inside and outside the casing may result in its collapse due to too great a differential pressure being created.

The same procedure as regards drilling and running casing is carried out until the objective is reached, in the case of an oil-well usually a cap-rock below which oil is expected.

The method employed from this stage depends on the amount of oil or gas likely to be encountered, and upon the pressure condition under which it may be found. For wells of low pressure in which the oil when tapped will not rise to the surface, no special precautions are necessary. The well is usually cleaned out thoroughly, probably bailed in order to obtain some idea of its productive capacity, and then put 'on the pump'. Where high-pressure conditions are expected and in areas where conditions are unknown, other precautions, however, must be taken before drilling into the oil- or gas-bearing formations.

With the last string of casing set and cemented the well-head is prepared for 'drilling-in'. A main valve usually of the gate type is flanged or threaded to the well casing and above this the 'Christmas Tree' is attached. The latter consists of a head fitted with side outlets to which valves are attached, the main bore being at least of the same bore as the main valve and the casing. The well is then filled with water, the side valves and the upper end of the 'Christmas Tree' are closed, and the whole well is subjected to a pressure in excess of that which is likely to be exerted by the pressure of the oil or gas when drilled into. Since at this stage this pressure factor is unknown, the only means of ensuring safety is to employ the heaviest fittings and to test them to a pressure higher than that which could reasonably be expected when the well is completed. For present-day high-pressure wells, valves and well-head fittings are often tested to 6,000 lb. per sq. in.

After the well-head fittings have been tested the cement is drilled out and a further test applied to ensure that the casing-shoe seat and the cementing job are satisfactory.

Pressure Drilling.

The safest method so far employed for 'drilling-in' wells with the cable tools is that known as the container method (Fig. 10). For this a container is made up of two lengths of casing preferably of the same size as that which is to be drilled through. This container is fitted at the lower end with a flange by which it is attached to another gate valve placed above the 'Christmas Tree'. At the upper end another flange is fitted to which is attached a polished-rod gland. Working through this polished-rod gland is a polished rod which consists of a tube of heavy construction of sufficient bore to allow the drilling cable to pass freely through, and with an outside diameter of about 1¾ in. and a length of 10 ft. On the lower end a retaining collar is threaded, while at the upper end a polished-rod head is attached.

The polished-rod head consists of a housing into which rubber pads are fitted, the inner faces of which are grooved to receive the drilling cable. Immediately below these

rubber pads two steel gripping pads are fixed, these also being provided with grooves which correspond to the diameter of the drilling cable. Both the gripping pads and the rubber pads are so arranged that they can be forced into contact with the drilling cable by means of threaded spindles suitably packed through glands to prevent leakage. Above the polished-rod head and attached to it is a spray arrester. This takes the form of a tee piece with a flanged connexion on the side outlet and a gland at its upper end through which the drill line can pass. A packing gland is fitted at the upper end by means of which a soft grade of packing can be held in contact with the drill cable. From the side outlet a flexible hose of about 2 in. dia. is led to lengths of 2-in. rigid pipe which are fixed in the corner of the derrick. By this arrangement any oil which leaks past the polished-rod head is led through the 2-in. pipe into a small tank placed on the ground, preferably some distance from the derrick. In pulling the tools from a well 3,000 ft. deep under a pressure of 800 lb. per sq. in., about 200 gal. of oil escapes into this tank.

Since with this method a container about 40 ft. long must be used, the walking beam cannot be employed to impart the drilling motion to the tools; it is therefore necessary to drill by spudding. This spudding action is obtained in the same manner as when commencing the well.

After a final test of all the well-head fittings, the drilling tools are connected up, with the drilling cable passing through the polished rod and its fittings, the tools being placed inside the container. This complete assembly is then placed in a vertical position and bolted above the upper gate valve. The gland of the spray arrester is then tightened snugly around the drill cable, the gate valves opened, and the drilling tools lowered to the bottom of the well in the usual manner.

The spudding line is attached to the drill line where the latter leaves the bull wheel, and the polished rod is adjusted and clamped to the drill line in such a position as to allow its maximum downward travel as drilling proceeds.

With a 10-ft. polished rod and assuming a spudding stroke of 2 ft. 6 in. about 7 ft. of drilling can be done before making further adjustment to the polished rod to prevent its upper end coming into contact with the polished-rod gland.

Drilling is continued in this manner until the tools must be withdrawn from the well, when the same operations, as used when running in, are carried out, but in reverse order.

This method of 'drilling-in' under pressure is quite satisfactory up to well-head pressures of 800 lb. per sq. in., but at pressures higher than this, oil and gas find their way into the core of the drilling cable and passing up through the polished-rod head escape to atmosphere some distance above it.

When drilling against well pressures of between 500 and 800 lb. per sq. in. the well pressure, acting on the under side of the polished rod, tends to retard the free falling action of the tools. This is particularly noticeable when using a string of small tools as in drilling, for instance, a 6-in hole. The effect can, however, be balanced by the use of suitable weights attached around the drilling line above the spray arrester.

In wells which produce oil under sufficient pressure to enable them to flow, the debris can be removed by this flow as drilling proceeds, the oil being led from the side lines in the flowhead to suitable settling and storage tanks. In cases, however, in which the well will not flow, the debris must be removed by a bailer in the usual manner; the bailer must be run through a container and fittings in exactly the same way as the drilling tools.

The extent to which safely precautions are taken will be governed by the mining laws of the country in which drilling is being carried out, or by the degree of risk an operator can or is prepared to take. In any case, the following safety measures should be instituted:

(1) Boilers should be placed as far as practically possible from the well and in the direction from which the prevailing wind blows. They should be fitted with steam snuffers for effectively putting out the boiler fires.
(2) Long-distance controls should be fitted to all valves on the well head.
(3) A safety line should be fitted from the platform to the ground.
(4) Band brakes should be sprayed with water.
(5) Bronze headed hammers should be used.
(6) Gas masks should be available and the crew trained in their use.
(7) If work is carried out during the night—it should be avoided if possible—electric lighting should be arranged by flood lighting from the ground outside the derrick.
(8) Operating levers should, where possible, be extended outside the derrick.
(9) Smoking should be prohibited, and no matches allowed on the job.
(10) Safety belts should be provided for men working on the platform.
(11) The derrick floor and the ground around should be kept clear of obstruction, clean, and free from oil.

PRESENT TRENDS IN ROTARY WELL DRILLING AND COMPLETION

By Professor I. F. BINGHAM

School of Petroleum Engineering, University of Oklahoma, U.S.A.

Introduction

WHEN rotary drilling equipment was first used for drilling oil-wells at the beginning of the century, these first wells were drilled to a depth of only 800 ft. The formations drilled by this early rotary equipment were sufficiently soft to permit their being drilled by hard steel fish-tail bits, the only type of rotary bits then available.

The demand upon rotary drilling equipment and technique has not increased at a uniform rate since its introduction, neither has this increased demand always been met promptly with better materials, better equipment, and better technique. Usually some enterprising company or individual set a depth record ostensibly beyond the capacity of the equipment credited with the performance. Then for a period of several years there ensued widespread drilling to these new depths with equipment which was not altogether adequate. During this interval it was generally believed that rotary drilling had proceeded to its ultimate attainable depths. Better materials and new inventions caught up with the demand, only to have a new depth record established with this new equipment. In this fashion rotary drilling proceeded to greater depths with ever-increasing demands upon materials and technique.

Five years ago many difficulties were anticipated where the depth drilled exceeded 5,000 ft. To-day many wells are being drilled below 8,000 ft., and these deep wells are being drilled in about one-third the time consumed in drilling wells to similar depths 5 years ago. Thirteen wells have been drilled below 10,000 ft. with a depth record of 12,786 ft. This latter achievement was remarkable in that no particular difficulties were reported in the lower portion of the well.

Those who are responsible for anticipating the future demands upon deep well drilling equipment are confident that it is possible to develop materials which will absorb the stresses imposed where wells are drilled to a depth of 15,000 ft.

The major problems which have arisen in connexion with rotary drilling will be presented and the manner in which these problems have been overcome, or at least rendered tolerable, will be discussed. Present trends in rotary drilling will be considered under the following headings:

1. Improvement in materials entering into the construction of rotary equipment.
2. Rotary equipment design.
3. Securing drilling tool efficiency.
4. Improved casing practices.
5. New developments in cementing casing.
6. Control of rotary drilling mud.
7. Application of controlled directional drilling.
8. Combating heaving shales in rotary drilled wells.
9. Pressure drilling and well completion.
10. Dismantling, transporting, and rigging up.
11. Selection of the proper type of rotary equipment.
12. Completion of rotary drilled wells.

Introduction and Growth of Rotary Equipment Use

The first rotary drilling equipment is reported to have been developed by M. C. and C. E. Baker, water-well drilling contractors of South Dakota [4, 1934]. In drilling wells the Baker brothers used what they termed the 'jetty' system, wherein water was poured into the annular space and allowed to escape upwards through the hole in the bit and through the hollow drill stem. The drill stem was equipped with a series of valves designed to hold the mud as it escaped upwards. As the well was deepened this

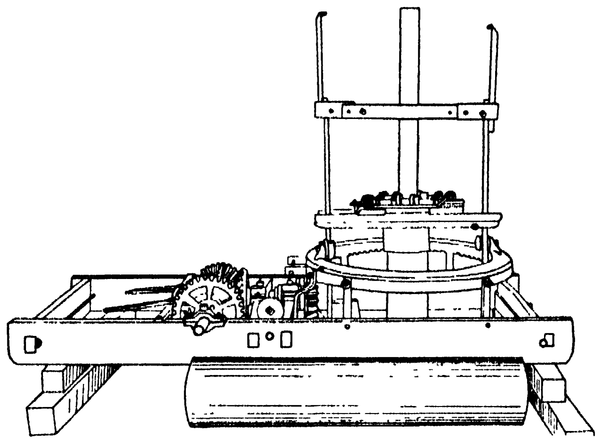

FIG. 1.

method failed to work because the mud would not rise freely in the stem. Next the course of the water was reversed and the water introduced through the drill stem. The water was first poured into the upper end of the hollow drill stem, but later was forced through the drill stem and the hole in the bit, using the force of gravity supplied by an adjacent water-well.

The drill stem, which consisted of small-diameter pipe, was at first turned by hand. Later a skid-mounted rig was designed to stabilize the upper end of the drill stem, and a set of pipe grips was designed and made to rotate the pipe. A sweep powered by horses furnished the power for rotating the pipe. The upper end of the drill stem was held in a vertical position by short lengths of casing at the mouth of the drill hole. Bevel gears were provided, by means of which the drill stem could be rotated in either direction.

This crude rotary outfit was brought to Corsicana in 1895. In it the American Well and Prospecting Company saw the possibilities offered by the rotary method for drilling the soft shales of the area. This company set to work to develop the rotary, and as a result came the first rotary which drilled the Captain Lucas well in the Spindletop field in 1901. Fig. 1 is a reproduction of the rotary used with this rig.

The improvement in rotary equipment since this first crude rig, and the natural advantages of rotary drilling for

present deep wells and high formation pressures, are responsible for the use of rotary equipment at more than 10,000 wells each year.

Improvement in Materials Entering into the Construction of Rotary Equipment

Materials used on these early rotary rigs would have included: malleable chain; cast-iron sprockets, sheaves, rotaries, and pumps; low-carbon lap-weld drill pipe used without tool joints. In the soft shale areas, where rotary drilling had its beginning and where the wells were shallow, the above materials were fairly satisfactory—at least with such equipment it was possible to drill oil-wells more rapidly than was possible by the standard tool method.

As wells were drilled to greater depths it became necessary to improve the quality of the materials. Heat treating was used to care for the needed improvement of early steel. For a time this sufficed, but in recent years heat treating alone has proved inadequate. Next high-carbon steels were introduced, and a more careful control was observed in processing and heat treating. The depth to which wells were being drilled increased, and it was necessary further to improve the quality of the material which entered into the construction of these rotaries designed for greater depths. At the present time many alloy steels are being used to meet the ever-increasing demand for greater strength of materials. Hard surface materials are being applied to the cutting edge of tools.

The extent to which materials have been improved can best be portrayed by the fact that certain well casing has been developed to the point where it could be set at approximately 15,000 ft., with a safety factor of 2, provided the joints were as strong as the body of the casing.

Even with these marked improvements in quality of material, the task of the manufacturer is not yet completed. Within the next few years the depth record for oil-wells will very likely be extended 2,000 or 3,000 ft. Another reason is that the industry is just emerging from a period when rotary equipment, particularly equipment at the surface, has been strengthened by the simple expedient of adding more metal. The recent depression has demanded cheaper per foot cost for drilling. Contractors have been forced to consider design and quality of material if for no other reason than increased portability.

Determining the Worth of Metal [5, 1929]. Four quantities are ordinarily used in describing the physical properties of metal. These are, ultimate strength, elastic strength, ductility, and reduction of area, values which are measured quantitatively by testing to destruction a sample of the metal in question.

The ultimate and elastic strengths are a measure of the ability of this metal to carry a load, while the elongation and reduction of area indicate the extent to which the metal in question can deform under load without fracture. This latter property is equally as important as the former, since design considerations will seldom permit one to forget the notch effect of threads, shoulders, and keyways. If the metal is plastic—that is, if it will permit a high degree of deformation—these stress concentrations will be redistributed over a larger area of metal. The manufacturers of metallic materials must therefore consider both strength and plasticity, with a view to securing a correct balance of the two properties to best meet the particular demands upon the material under consideration.

Heat Treatment. With the exception of the carbonizing and nitriding processes, heat treatment properly carried out does not alter the chemical composition of steel. Heat treatment affects the physical form of the elements in steel. If a specimen is raised to exactly the proper temperature and then cooled rapidly, the strength and hardness of this sample can be increased in a surprising manner, the effect being more noticeable with alloy steels than with plain carbon steels. However, as the strength of the metal is increased the plastic properties are decreased, and if care is not observed, stress concentration may offset the gain in strength. Since the outside of the metal in question must be cooled first, the outer layers shrink before the inner portions cool. This sets up internal stresses due simply to volume changes. However, if the processing is skilfully handled, actual cracking of the metal during this sudden cooling may be avoided. If the treatment has progressed thus far without producing actual fractures in the material, the metal in question may be heated slowly to a moderate temperature to relieve the inherent stresses produced in the hardening processes. In this way heat treatment furnishes a method for adjusting the relation of strength to plasticity, in accordance with estimated or service requirements.

Proper Adjustment of the Fundamental Qualities of Metal. Assuming for the present that the processors of metals have been able to produce materials of sufficient strength to meet the strenuous demands for present deep drilling, there yet remains the proper application of these qualities to secure for the various parts of the drilling equipment a satisfactory service record which is the ultimate test of the value of metal.

The problem of adjusting these fundamental relationships is extremely involved because the relationship cannot be reduced to a mathematical statement, and field-service records very frequently indicate that the experience and estimates of the manufacturer have not been adequate to produce materials which will withstand the variations of loading. Perhaps one or two illustrations will clarify this point. Suppose that a certain type of tool-joint fails through excessive wear or galling of threads. It can be safely concluded that if a harder and tougher material is used, galling and abrasion will be reduced. However, in producing a harder, tougher metal, the processing, if carried to extremes, may sacrifice plasticity, with the result that failure now occurs because of the tendency of the tool-joint to split. This demands a nicety of judgement to determine just how much plasticity can be sacrificed safely in order to produce increased hardness and toughness, and yet avoid the alternative of splitting tool-joints.

Recent estimates place the known reserves of oil within the United States at 12 billion barrels. These reserves are being exhausted at the rate of nearly 1 billion barrels per year [2, 1935]. It follows naturally that the oil industry will within the next few years explore many of the deeper zones which geologists may point out as likely oil-bearing sands. If this search to greater depths is to be carried out successfully, manufacturers of well-drilling equipment must produce even better material (probably better alloys) with almost unerring judgement of the fundamental qualities of metal to provide for the particular load imposed upon each member of the rig.

Present-day Trends in Rotary Equipment Design

Two major factors are operating to produce definite changes in rotary drilling equipment design. The first of these is the ever-increasing depth to which wells are being

drilled. This factor tends to stimulate research to discover methods of increasing the capacity of surface and subsurface equipment and materials. The other major factor is a demand, or rather a necessity, for drastically decreased per footage drilling costs. This second factor became important largely as the result of the recent depression within the oil industry.

Sometimes these two factors operate jointly to produce a new piece of equipment; at other times these factors are directly opposed and hence lead to some confusion on the part of the manufacturer.

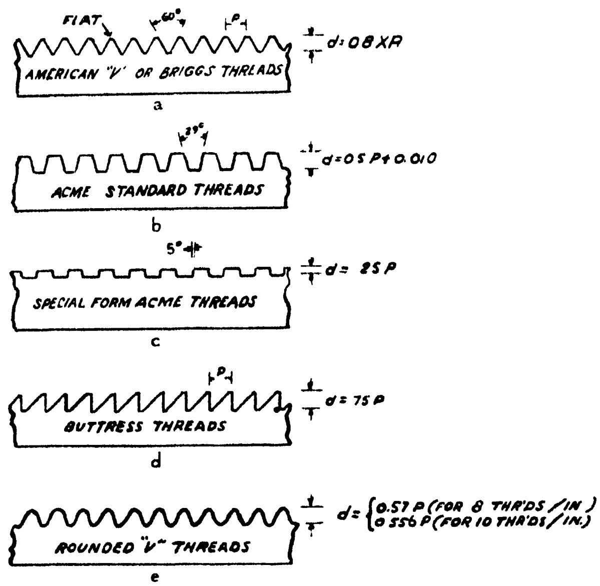

FIG. 2.

Improvement in material has been discussed; it is now fitting to trace the development of rig parts and supplies from what they were a few years ago to what they are at present. It would be interesting to follow the development of each piece of equipment, both surface and subsurface, which enters into the drilling and completion of a well, but space permits the treatment of only a few major items.

Increased drill-pipe capacity is more important than any other item because the ability of the drill pipe to withstand all variations of loading and stresses is the ultimate limiting factor which determines the depth to which wells may be drilled by the rotary method. For convenience increased drill-pipe capacity has been treated in another section.

Casing [7, 15]. Previous to 1923 all casing was furnace-welded from soft, low-carbon wrought iron or steel, the proportion of the former decreasing rapidly with improvement in the manufacture of steel.

Increased tensile and collapsing stresses imposed by the greater depths to which continuous casing strings are now being run have been met with improved quality of steel and the improvement secured through the production of a seamless upset casing.

The technique of running and cementing casing has, of course, contributed materially to reducing the required factor of safety below that of former years.

Fig. 2 at *a* shows the American V or Briggs thread commonly used for casing. The included angle between threads is 60° and the depth of the thread is 0·8 times the pitch. This thread possesses the disadvantage that it exerts a collapsing pressure upon the end of the pipe when the pipe is subjected to tension. It possesses the further objectionable feature that the greater thread depth results in the removal of more material in the process of threading and consequently reduces the area of metal under the root of the first perfect thread, and the strength of any threaded joint is dependent upon the area of the metal at this point. The other thread types shown in Fig. 2 have been developed for the purpose of avoiding the objectionable features of the Briggs thread. They have reduced the ratio of depth to pitch and have reduced the included angle in order to overcome collapsing stresses induced by tension. The

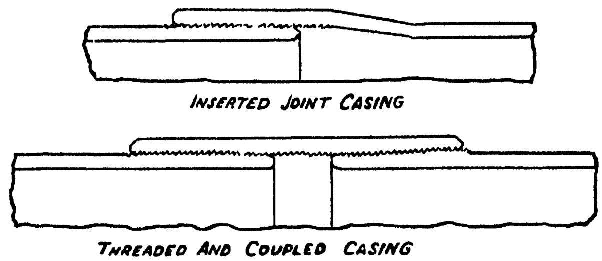

FIG. 3.

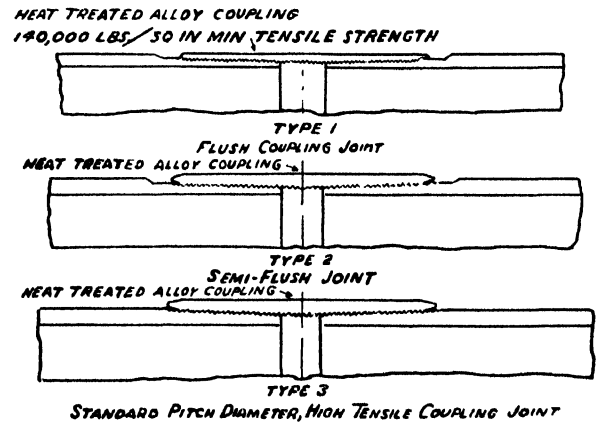

FIG. 4.

Briggs thread, however, continues to be favoured, especially if long threads and couplings are used. This is because any damage to threads may be repaired at the average machine shop and because the Briggs thread when properly made up furnishes a high-pressure seal without resorting to packing devices.

Inserted joint casing has been developed (Fig. 3) which is generally believed to give greater clearance with less reduction of strength than threaded and coupled joints. However, for equivalent areas under the threads the outside diameter through the expanded portion is the same as the outside diameter through the coupling.

Flush joint and semi-flush joint casing (Fig. 4) have been developed for special purposes where clearance is of more importance than joint strength. This casing serves a real need for pressure drilling, for running casing under pressure, for drilling through heaving shale, or for using as the lower portion of a combination string. It is erroneous, however, to represent that the joint strength is equal to that of threaded and coupled pipe or that joint efficiency approaches 100%. It is possible that the joint strength might be raised to that of threaded and coupled pipe by making use of heat-treated alloy steel. Even so the joint efficiency would not have been raised, and the cost of such heat-treated alloy steel would be several times as great as

the milder steel of equivalent joint strength making use of threaded and coupled casing. It is conceivable that this expense could be reduced by welding a short section of alloy steel to each end of the pipe-joint, slightly upsetting in the region of the weld (Fig. 5). The practicability of its manufacture is now in the process of proving.

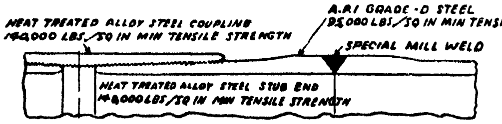

FIG. 5.

A recent improvement in coupled casing makes use of a thin heat-treated alloy-steel coupling of 140,000 lb. per sq. in. tensile strength to be used with upset casing of lower tensile strength. Through this practice joint efficiency has been maintained at 100% with less increase in diameter through the coupling section. Much remains to be accomplished in securing higher joint strength without unduly increasing casing cost or decreasing casing clearance.

Boilers [8]. Improvement in oilfield boiler design has kept pace with improvement in other equipment at the rotary rig. Some improvements are covered by A.S.M.E. and A.P.I. codes, and hence are general for boilers built to comply with these codes. Other features are optional and there is no general agreement upon these features.

Increased firebox capacity with decreased tube-length gives a more portable boiler without sacrificing overall efficiency. The arched crown sheet is a recent feature added which permits stay-bolts to be threaded-in normally to the sheet to give more effective threads and also permits the placing of more tubes in the top row. Thermic siphon equipment for better circulation is featured by some makers of boilers. Superheat boilers have had a rather widespread trial in connexion with oilfield development within recent years. While increased efficiency in steaming is recorded, the advantages for oilfield use have not been so great as was anticipated, with the result that a number of contractors and operators are returning to the use of saturated steam. While superheat steam reduces energy losses in transmission; is more desirable where piston-type valves are used in the prime mover; and increases the boiler capacity, these advantages are to a degree offset by increased investment; increased equipment which must be installed and serviced; and the addition of a serious problem in lubrication.

Listed as improved accessory boiler equipment are:

1. Automatic fuel, water, and blower regulators.
2. Shorter stacks with blowers which under difficult conditions for transporting may permit the omission of one boiler if efficiency is a matter of secondary importance.
3. Low-pressure burners of improved types give increased boiler capacity and fuel saving.

Rotary Drilling Bits. The importance of improvement in rotary drilling bits can best be realized from the fact that only a few years ago it was considered necessary to make provision at rotary-drilled wells for a change-over to standard drilling tools when hard formations were encountered. This costly practice was an enforced necessity because no adequate rotary bits were available for drilling hard formations. To-day combination drilling rigs are no longer used for the above reason, although they may be used for drilling into the producing horizon or for some special reason. Recently a wing-type rotary bit drilled over 2,300 ft. within 24 hours. Numerous cases are on record where improved rolling cutter-type hard rock bits have been in continuous service for more than 48 hours while drilling hard rock. In most cases these bits, after making such phenomenal runs, were found to be not exceptionally dull, nor badly out of gauge, and were in fair condition as to the cutter bearings.

The result of this bit improvement has far greater importance than the reduction of bit costs alone. Fishing jobs decrease with bit improvement, but of greater significance is the decreased loss of actual drilling time by increased bit service. The entire drill-pipe column must be removed in sections and later replaced each time a bit is changed.

Rotary bits may be classified as drag bits and rolling cutter type, and these have been dealt with elsewhere.

The selection of the proper bit for given conditions is very difficult because of inadequate data; hence this selection is usually based upon the experience of the operator for the particular area after having tried out a number of bits. The only generalization which will bear inspection is that for laminated formations of low or intermediate hardness the drag-type bit will perhaps make more rapid penetration than the rolling cutter type of bit because the material is removed in flakes or chips much larger than the particles removed by the pulverizing action of the rolling cutter type. However, the shock loads imposed upon drill pipe as the result of using the drag-type bit are more severe than those resulting from the use of the rolling cutter type. The question, then, becomes one of determining whether drill pipe is to be sacrificed for speed in drilling. Within the different classes of bits it is possible to select one of several which will give about equal performance under similar conditions.

The improvement afforded by the newer drag-type bits has been largely accomplished through the use of superhard materials applied as facings on the cutting edge and lands, or by the use of superhard materials inserted in the cutting edge and built up with superhard facing material. The rolling cutter-type bits have been improved by the application of hard surfacing material on the lead side of the cutting teeth and at such position upon the roller as to keep the bit out to full gauge. The wash pipes or water-courses of bits have also been improved by lining with superhard material. In both of the leading makes of roller-type bits, bushings have been replaced by roller bearings and lubrication is accomplished by the mud fluid. A wider range of adaptability has been furnished in the rolling cutter type by a variation of the amount of material in the cutting teeth. For softer formations less material is included in the teeth and the teeth are more widely spaced.

One opportunity for increasing the capacity of bits lies in the study of the proper arrangement and size of water-courses. There is evidence that the high-velocity jet of mud-laden fluid directed upon the cutter is responsible for the removal of a considerable portion of the metal from the cutter. This is estimated to be rather high, especially where the cuttings are recycled because of improper treatment of the mud at the surface.

Prime Movers. New features introduced in steam-engine construction are:

1. Vertical type for some engines.
2. Hand-controlled variable cut-off. This has passed the experimental stage and has been shown to be effective in fuel saving.

3. The fully balanced inside admission-type piston valves.
4. 14 × 14 in. have replaced 12 × 12 in. twin steam-engines at some of the deepest drilling wells within the past year.
5. The practice of placing a full-sized auxiliary twin engine in the cellar or below the substructure has been introduced quite extensively, especially in California.

Internal-combustion engines have passed the experimental stage and the method of power transmission or power take-off has been successfully solved by various remote control clutches and counter-shafts.

The Diesel engine within the past two years has been proved satisfactory when used to drive through counter-shaft and clutch, or when used to develop direct-current power as explained in a later section of this article. An experimental set-up is now under test in California for the direct-drive reversible Diesel engine.

Draw-works. New features in draw-works construction include unitized skid-mounted jobs with hydromatic braking in addition to friction braking (Fig. 6). Mounting as a unit permits better service from friction-type brakes by virtue of the fact that adjustment of tension in the brake-bands is not affected by the load carried on the derrick floor. Grooved drums are now being used. It is estimated that the unitization of draw-works has increased the service of chains and bearings by at least 20% because better alinement and better lubrication are possible where the draw-works remains intact as a unit.

Derricks. No startling developments have been made in derrick construction. The 122-ft. derrick continues to be the popular choice for all except very deep drilling. Operations during the past year indicate that for the deeper wells the 136-ft. A.P.I. derrick is becoming almost standard. The present-day derricks are highly portable, and for most of the popular makes the strength has been increased where stress analysis has dictated, with the result that far fewer derrick failures occur for present deep drilling than formerly occurred for shallow drilling when stress loads were not analysed.

Control Equipment. Control equipment at the rotary rig has now become standard equipment. In addition to making use of various single-shot devices for measuring the declination from vertical, drillers are now interested in knowing the torque load transmitted to the drill pipe and the rate of rotation of the drill pipe as well as the amount of weight carried on the bit. This latter knowledge has been considered important for a number of years. The five-point control equipment shown in Fig. 7 is a relatively recent development. In addition to these instruments of control, drillers are making use of instruments for checking the character of rotary mud.

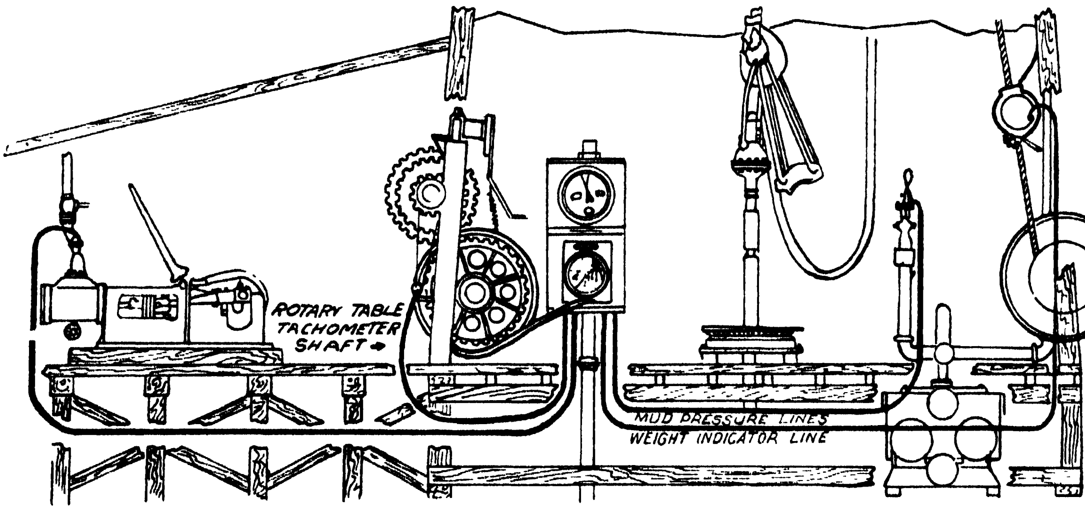

FIG. 7. Schematic illustration of a control instrument including the weight indicator, the super-sensitive Vernier weight indicator, the torque gauge, the slush-pump gauge, and the rotary table tachometer.

Mud Pumps. The general trend in mud-pump design has been towards greater volumes and higher pressures. Fig. 8 shows a recent development for reducing steam consumption (usually about 65% of the steam consumed at a steam rig is chargeable to the mud pumps). The illustrated drive from an engine with variable cut-off, through a gear box, is said to effect a saving of more than 10% in steam consumption.

Condensers and Preheaters. A recent innovation is shown in Fig. 9. Here a hot and cold pump are mounted on skids with the stand-by feed-water pump. The 5 × 6 × 12-in. simplex double-acting cold pump introduces feed water into the condenser box through a spray jet. The cold-pump valve is automatically controlled by the water-level of the condenser. Exhaust steam from engine and pumps is introduced in open contact with the feed water through the flanged connexion at the upper left of the condenser chamber. The 10 × 6 × 12-in. simplex double-acting hot pump takes suction from the condenser chamber and discharges the preheated water into the boilers. The hot pump is manually controlled. Under test a saving of 12·5% in feed water consumed and 13% in fuel saved is shown.

The present trend in equipment design is to maintain equipment capacity with decreased weight for equipment. Use of better materials; unitizing; improved lubrication; better alinement; improvement in bearings; better support for shafting at points of stress concentration, and numerous other improved design practices have within the past two years superseded the practice of securing greater ruggedness through the addition of larger quantities of metal. The greatest limiting factor in extending this trend is the abuse imposed upon rotary equipment by the present use of the positive jaw-type clutch.

Securing Drilling-tool Efficiency

The primary tool used in the actual drilling of a deep well by the rotary method is a long and exceedingly delicate one. This composite tool consists of a bit or cutting tool at the lower extremity. Next above the bit are the drill collars, which are large-bore, hollow shafts held together by suitably threaded connexions. Above the drill collars is thin-walled, hollow sectional drill pipe coupled by tool-joints or by drill-pipe couplings. At the top of this hollow shaft is a hollow kelly joint by means of which, by a properly adapted turntable, the composite tool is rotated.

The entire shaft is supported by a swivel, hook, travelling block, crown block, and a wire line reeved through the blocks in a manner to give the desired number of supporting lines. The live end of the steel wire line is spooled on the drum of the drawworks.

The actual cutting of the material from the bore hole is accomplished by the rotation of the cutting tool or bit, powered by a prime mover acting through the rotary table and hollow shaft and by the application of a desirable weight upon the bit.

The material displaced by the bit is removed from the bore hole by the circulation of a fluid, usually mud-laden water, down through the hollow drill pipe and water-courses of the bit, thence upwards through the annular space between drill pipe and bore-hole wall to the settling pits at the surface.

Assuming that the equipment is adequate for satisfactorily removing formation cuttings, hoisting the drill pipe, and performing secondary operations at the well, that which follows constitutes an attempt to analyse the chief causes of failure of the composite drilling tool and to set out corrective measures to secure highest efficiency from this drilling tool.

In a foregoing paragraph it was stated that the composite drilling tool is very delicate. One would not be forcibly impressed with this fact from observing the relatively stiff sections of the drill-pipe stands as they are racked in the derrick, yet if a sufficient number of these individual sections are considered joined together to form a single boring tool 7,500 ft. in length and 4½ in. in diameter, a true picture will be obtained of the slenderness of the tool with which wells are now being drilled to a depth of 2 miles. The same slenderness would be given by a hollow steel wire 20 ft. in length, with an outside diameter of 0·012 in. and a wall thickness of 0·0009 in.

The necessary consideration is the mechanical means by which to secure the maximum rate of cutting and the ultimate footage drilled with such a composite tool, which ultimate work must further be accomplished with a minimum number of failures in the drill-pipe section and a minimum deviation of the hole from vertical.

There are three principal types of drill-pipe failures. Listed in the order of the frequency of occurrence (except for worn-out drill pipe) these failures are [1, 1935]:

1. Failure in one of the full stand-off threads above or below a tool-joint.
2. Failure in the plain section and immediately adjacent to the upset.
3. Twist-offs.

The first of these may be started in the lathe or threading machine by producing an undetected fracture, or it is remotely possible that there is induced a crystal structure easily subject to fatigue failure. Where the end section is of uniform diameter, that is, not upset, the cutting of threads will (especially if the threads terminate in a sharp angle) produce a sudden change in cross-sectional area, which in turn is responsible for the concentration of repeated flexing stresses at the last full thread. While this type of failure will continue to be in evidence for drill pipe that is not upset, it may be greatly reduced by the following practices [17]:

1. Proper design and cutting of threads. A more nearly U-shaped thread would probably be desirable.
2. Completely making up the tool-joint on the drill pipe at the factory and permitting a minimum number of exposed full threads.
3. Accurately machining a square or taper shoulder to receive the pipe in concentrically tight fit and thus strengthen the exposed threaded section.
4. Shrinking the tool-joint on to the drill pipe at the factory.
5. Improving the steel alloy.

The second type of failure is due to fatigue from recurring flexure stresses concentrated at the point of most pronounced change in wall thickness, between the plain section and the upset. Corrective practices at the mill can perhaps go no further than to produce a fully normalized end section with a uniformly symmetric taper from upset to plain section.

The third type of failure is properly named a twist-off and occurs when the plain section is subjected to a torque load greater than it is capable of withstanding. The manufacturer cannot overcome this type of failure, but it is possible to delay its time of occurrence for the particular drill pipe by a substantial improvement in quality of drill-pipe steel, and uniform wall structure.

The principal stresses or shock loads to which the composite drilling tool is subjected are:

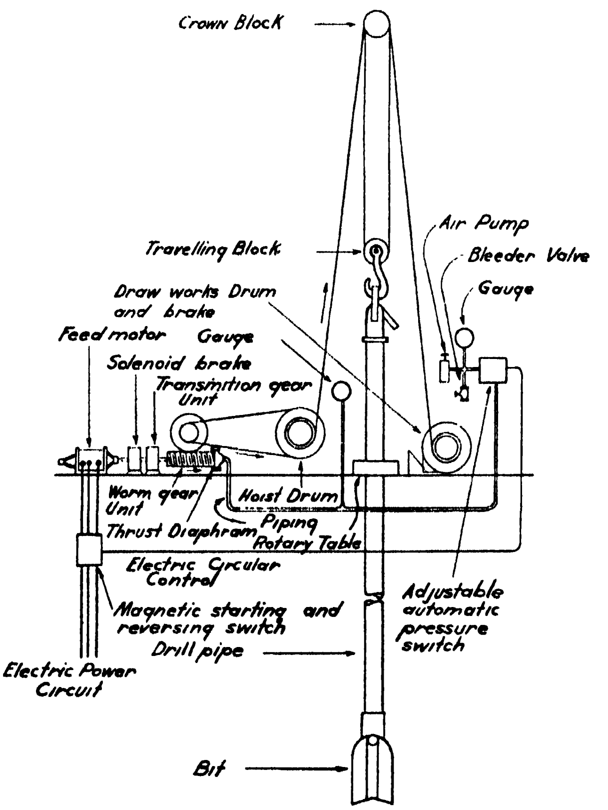
1. Flexing stresses produced by rotation of the drill pipe under compression.
2. Shock loading produced by a sudden application of too much weight.
3. 'Stall-shock' produced when the bit is released from a stalled position with the consequent snap-back of the drill pipe.
4. Torque failures resulting from the application of a greater torque load than the drill pipe can withstand.

The first of these stresses, and perhaps the most vital, is the flexing stress induced as a result of drill-pipe rotation while under compression. Obviously, then, the solution should be rotation with the drill-pipe section under tension. Heavy bottom-hole assemblies consisting of large-bore hydraulic pipe or drill collars have been used just above the bit. The total weight of this stiff section of hydraulic pipe should, theoretically, equal the maximum weight which will be applied at the bit, in order that the point of change from tension to compression will in all cases fall within the rigid bottom-hole assembly. However, at the majority of rotary drilling rigs the drilling tool is fed into the formation manually through the drum brakes. This method of applying weight to the bit results in recurring applications of abnormal weights which advance the point of change from tension to compression to a higher position in the string. The weight of the rigid section should be sufficiently greater than the weight normally applied to the bit to maintain this point of change within the rigid section at all times. Just what this ratio should be has in general not been defined. It has been suggested that the weight of

the heavy bottom-hole assembly should exceed the weight applied at the bit by 50 or 100%.

A review of data obtained at a large number of wells indicates that the effect of using heavy bottom-hole assemblies was to increase the rate of drilling and reduce the average and maximum deviation.

As the boring tool penetrates the earth's crust, formations of varying hardness are encountered. The degree of hardness may vary from soft formations capable of being drilled at the rate of 100 ft. per hour to hard formations



SCHEMATIC DIAGRAM G-E AUTOMATIC WEIGHT CONTROL

FIG. 10.

which may not be penetrated at rates greater than 1 in. per hour. It is also possible that a very soft formation may lie next above an extremely hard formation commonly referred to as shell. It is further possible that boulders will be encountered by the bit. Assuming that the cutting tool is being advanced into the formation at the higher rate, the bit will have a tendency to 'dig into' the hard formation when it is encountered. This results in the stalling of the bit momentarily, after which the bit will release or, in extreme cases, it may be necessary to decrease the weight upon the bit before it is released and thus permit drilling to be resumed. So long as these conditions are encountered with uncontrolled advancement of the cutting tool into the formation, drill-pipe failures may be expected.

The difficulty of failure might be largely overcome by using bits of the rolling cutter type instead of the drag or fish-tail type except for the fact that for certain areas it may be economically more desirable to choose the more rapid method of drilling with the drag-type bit at the expense of the drill pipe.

Another method of reducing drill-pipe failure and avoiding deflexion of the bore hole is that of making use of one of the automatic or semi-automatic feed controls for the purpose of advancing the cutting tool into the changing formations at a uniform rate, maintaining so far as possible a constant weight upon the bit. The Hild differential used with electrically powered rigs and the Halliburton differential control used with steam rigs have been known to the industry for a number of years. The General Electric drilling control (Fig. 10) may be used at any rig regardless of type. Electric power at the rig, however, is a necessity. This control makes it possible to advance the bit with a constant amount of weight applied at the bit at all times.

A recent development in feed controls is the Brantley drilling control (Fig. 11). This control requires no prime mover for its operation. The tension in the live end of the wire line drives through the drum shaft and through a speed multiplier to a multiple cylinder pump which regulates the rate of feed by the volume of liquid pumped. The weight carried on the bit is determined from the weight indicator and is adjusted at the driller's stand by simply throttling the valve which varies the discharge head on the pump.

In the past, although the composite drilling tool is the unit which should have received major consideration, the tendency has been to adapt the prime mover to the hoisting unit. This has led to the use of large prime movers operating through heavy hoisting equipment in transmitting power to the rotary table.

The present necessity for drilling large bore holes disturbs the balance between cross-sectional area of the drilling string and the upper section of the bore hole with consequent torque loads upon the drill string out of all proportion to their capacity to absorb these torque loads. In order to minimize these excessive torque loads, maintain a rapid rate of penetration, and keep the hole reasonably straight, higher rotative speed and decreased weight upon the bit is necessary. The use of large prime movers driving through the typical draw-works to the rotary table does not lend itself to high rotative speeds because of certain practical difficulties. When rotative speeds are increased from 80 r.p.m. to more than 200 r.p.m. the linear velocity of the roller chains through which the drive is accomplished is increased to the point where it is impossible to secure satisfactory service from these chains. Further, the energy stored by virtue of the momentum of these oversize prime movers and the oversize units through which the prime movers act, together with the excessive horse-power developed by these large prime movers at high speeds, transmits an excessive torque load to the drill pipe, especially when too much weight is applied or when for any reason the cutting tool tends to stall. A recent practice makes use of a small prime mover used for direct drive to the rotary (Fig. 12). Here it is preferable to avoid as far as possible intermediate parts which might store energy at high rotative speeds. The size of the prime mover employed for this purpose should not be capable of developing a greater torque load than the drill pipe, regardless of its condition, is capable of absorbing without failure. The results from a somewhat widespread trial of this principle are sufficiently encouraging to warrant a prediction of the extensive use of small prime movers, directly connected to the rotary table, to achieve a wide range of rotative speeds.

It has been mentioned that there is a recent trend towards high rotative speeds with decreased weight applied at the bit. That this trend is productive of good results can be stated as a generalization which is true; but it is impossible

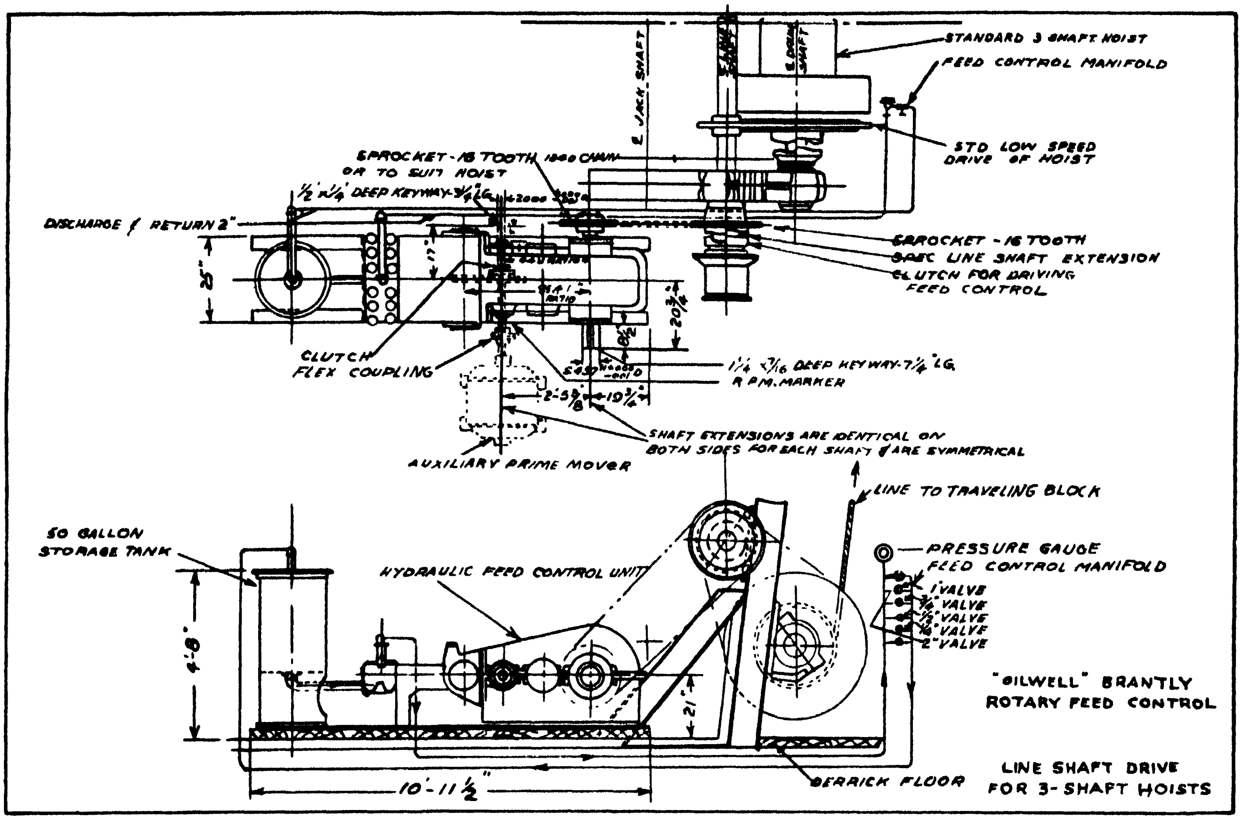


Fig. 11.

to designate any given rotative speed or any given weight for any certain area. Differences in areas, formations drilled, equipment used, all are variables which make it impossible to specify to drilling crews specific weights to carry and specific speeds of rotation [16]. Furthermore, drilling is more an art than a science, hence it is unwise to forget the personal equation introduced by the driller operating the rig.

The purpose of high rotative speed is to maintain a satisfactory rate of drilling when the weight carried upon the bit is reduced. The purpose of carrying less weight upon the bit is to avoid deflexion of the bore hole and to impose upon the composite drilling tool less destructive loading.

The fundamental principles consist of applying the correct weight upon the bit through heavy bottom-hole assemblies so that the drill pipe may rotate while under tension and then increase the rotative speed sufficiently to maintain a satisfactory rate of drilling. These factors must be chosen upon the basis of experience within the area under consideration.

Improved Casing Practices

A few years ago it was predicted that wells could not be completed to depths now quite common because it was believed that casing would not hold together at depths of 8,000 and 10,000 ft. To-day, however, casing is set in deep wells with fewer failures than when 5,000-ft. wells were the deepest in the country. Improvement in the strength of casing is partially responsible for these results, but the improved methods for placing casing in the well are equally important. The truth of this is illustrated by the recent accomplishment of the Union Oil Company of California in setting a string of $8\frac{5}{8}$-in., 36-lb. standard A.P.I. casing to a depth of 9,081 ft., whereas the recommended ultimate depth for this particular casing is 7,640 ft.

Careful inspection and handling of casing at the factory and in the field has minimized casing failures.

Casing elevators and casing spiders shown in Figs. 13 and 14 make use of long trunion-mounted slips and engage casing firmly without damaging the casing.

Equipment for running casing has been greatly improved. Composition casing guides and float collars (Fig. 15) permit the casing to be floated into the well, thus relieving the casing of unnecessary acceleration loads. The use of high tensile strength casing for the upper section which carries the heaviest load and standard casing for the lower section of extremely long casing strings is another new feature.

The practice of loading the casing with rotary mud to equalize the pressure from without the casing has almost eliminated collapsed casing while it is being placed in the well.

Under-reaming the lower section of the hole so that a more substantial cement body will constitute

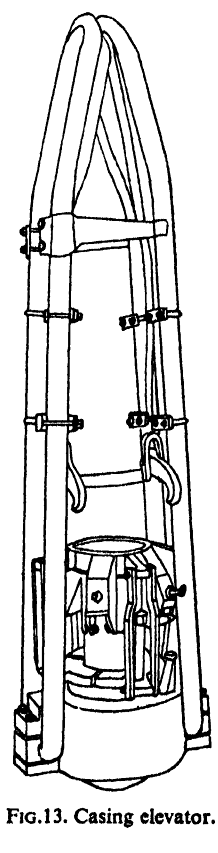

Fig. 13. Casing elevator.

a better casing seat is a recent practice now followed by a number of companies. A variation of this practice is the use of flush-joint casing at the lower portion of the casing string to give greater clearance in the hole drilled below the cemented casing than could be obtained with heavy coupling-type casing.

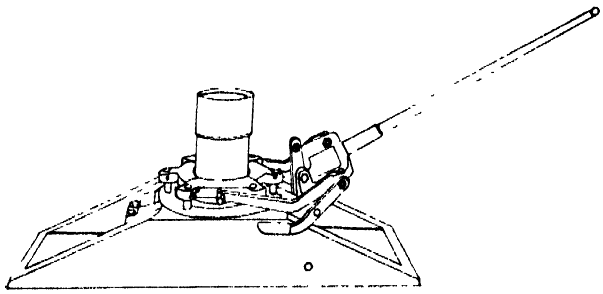

Fig. 14. Automatic casing spider.

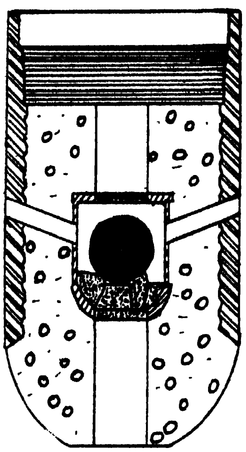
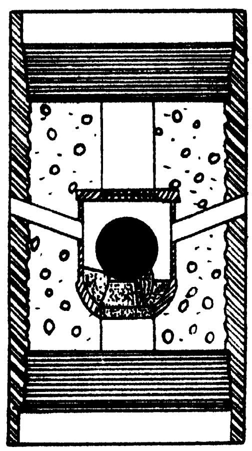
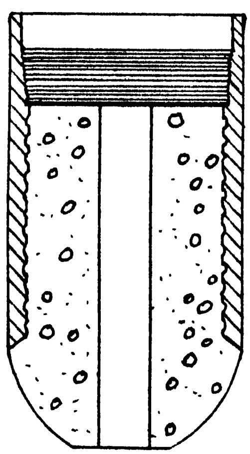


Casing guide with float.



Float collar.



Casing guide without float.

Fig. 15.

Finally, the tremendous increase in the amount of cement placed behind these long strings of casing furnishes a reinforced wall at the back of the casing which operates to reduce the hazard of casing collapse as soon as the pressure within the casing is relieved. In some instances the cement body behind the casing extends more than 4,000 ft. above the casing shoe.

New Developments in Cementing Casing

The technique of placing large quantities of cement behind long strings of casing has improved and kept pace with the newer demands created by deeper wells and higher formation pressures.

Equipment for placing cement has improved. The trucks have increased capacities and increased pressure ranges. Cement guides and floats have been improved. Multiple stage cementing has demonstrated its superiority for certain instances, and with few exceptions the cementing operations in conjunction with development work have kept pace with the demands.

Cements which will produce a uniform slurry without a great deal of agitation are now offered to the industry by a number of companies. Aquagel cements have been developed so that it is now possible to reduce the density of cement from 16 lb. per gallon to 12½ or 13 lb. This is especially desirable where there is a tendency towards lost circulation.

The major problem in cementing casing in deep wells is the hazard of high temperature. It is not unusual for these temperatures at the bottom of the well to greatly exceed the boiling-point of water. It is a well-known fact that if the temperature of a neat cement slurry rises above room temperature the setting time of cement is greatly accelerated. The curve in Fig. 16 shows graphically this accelerated setting due to increasing temperatures.

From these facts it is obvious that where it is desired to place large quantities of cement behind the casing in the presence of high well temperatures, the elapsed time for the setting of the cement slurry allows no margin of time to provide for the probable temporary failure of cementing equipment.

In the past the situation has been partially met by one of two or a combination of two practices. The first of these is to reduce the amount of cement placed behind the casing, which, of course, reduces the elapsed time necessary to pump the cement to the back of the casing. Many deep wells to-day are being cemented with from 250 to 500 sacks of cement where it would be desirable to use 1,000 or more sacks. The second method by which this high-temperature hazard has been combated, with indifferent success, is the addition of ice to the circulating pits to cool the formations temporarily to the point where the cement slurry may be pumped to the back of the casing without too much hazard, or the addition of ice to the mixing water. The amount of ice required has been largely a matter of opinion and varies from 10 tons to amounts in excess of 100 tons. The time required to accomplish the cooling of the formations is also a matter of conjecture and ranges from 24 hours to several days. The difficulty of maintaining the proper characteristics of the mud fluid where such large quantities of potential water are added becomes, in some instances, quite a problem and requires the use of admixtures and careful mechanical control at the surface. Additional expense involved due to cost of the materials, rental on tools, and delayed completion of the well is in most cases excessive. The degree to which the difficulty is overcome is in many cases problematical. Some years ago a chemical retarder was developed to control the fluidity and the setting time of neat cement slurries. This retarder has been subjected to continuous laboratory tests to eliminate any undesirable characteristics and to adapt its use to oilfield cementing with cement equipment as it exists to-day.

Curve 1 of Fig. 17 shows the setting time for an untreated

cement plotted against varying temperatures. Curve 2 of the same figure shows the amount of retardation where 1% retarder is added to the same cement as used for curve 1. This difference in setting time may be increased or decreased, depending upon the amount of the retarder added to the cement at the mill.

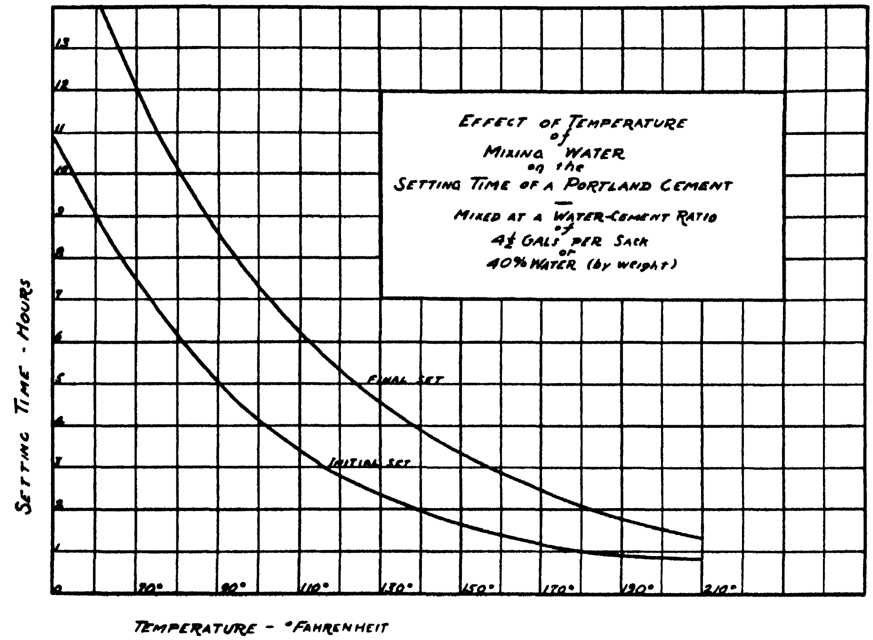


FIG. 16.

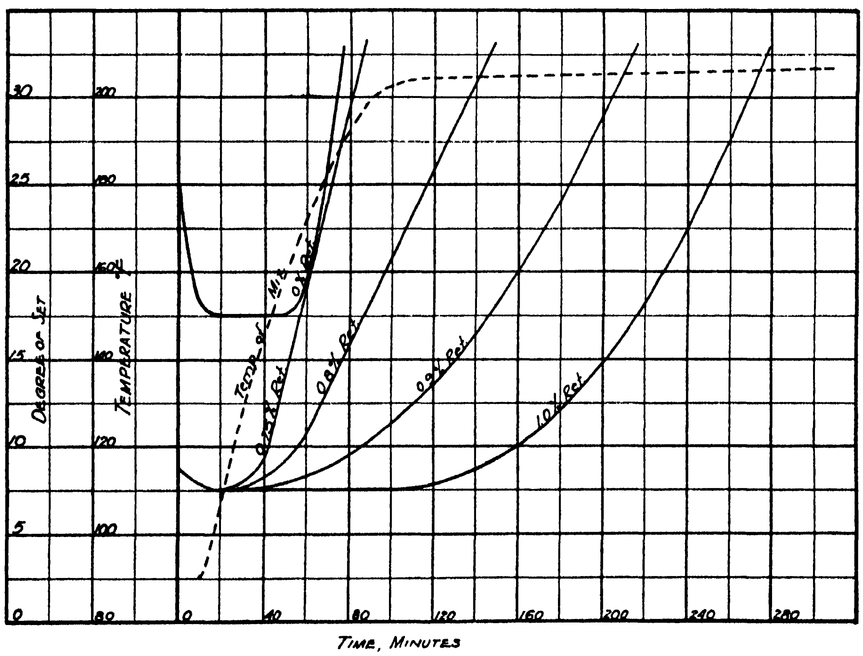

FIG. 17.

This invention gives promise of being the most outstanding recent development in the cementing of oil-wells and will undoubtedly find a widespread use for all oil-well cementing jobs at depths exceeding 5,000 or 6,000 ft.

Control of Rotary Drilling Mud

Drilling mud functions under two distinct sets of conditions. The first of these obtains where drilling proceeds under conditions which present no particular problem from the standpoint of formation and where the formation penetrated will furnish adequate clay suspensoids to give proper body to the drilling mud. Even under these favourable conditions a great deal of trouble has been encountered and is being encountered at present. Much trouble is occasioned because of lack of knowledge of what constitutes a good drilling mud. One class of driller demands light, non-viscous muds for all conditions, while another group believes that a highly viscous mud is the proper drilling fluid for most formations, and the balance maintains a position somewhere between these two extremes. Another factor which complicates the mud problems at the well arises from the fact that some drillers realize that rapid

footage can be secured where the mud is extremely thin.

In general the following characteristics are desirable for ordinary drilling: (1) the weight should be maintained at a point which will not add too great a burden to the slush pumps, probably 70 to 75 lb. per cu. ft.; (2) the viscosity should be maintained at a point sufficiently high to carry the cuttings from the hole, yet not high enough to slow up drilling progress or prevent the mud stream from dropping out cuttings as it passes through the settling pits; (3) gel strength and gel rate should be maintained at such a point that when the tools come to rest in the hole and circulation is discontinued, the rate of settling for the cuttings held in suspension will be retarded. If gel rate and gel strength are too great, however, the cuttings will be recycled instead of settling out in the pits.

Ordinary drilling conditions do not, as a rule, cause any undue difficulties, but graver conditions exist and will be considered here singly, although these conditions seldom present themselves singly.

Blow-out is a condition in which the gas pressure or fluid pressure from the formation exceeds the hydrostatic pressure exerted by the mud column. In certain fields the fluid pressure is much higher than the pressure of a water column equal to the depth of the formation. Here we have potential blow-outs for every well drilled. Sometimes high pressures from a deep sand escape to a shallow sand, thus creating an abnormal pressure near the surface which forms a blow-out hazard. A third cause for blow-outs is occasioned where improper control of the mud fluid permits the mud to become so viscous that it does not give up occluded gases in passing through the pits or over the screens. In this event the density of the mud may fall below the density of water.

Remedies as practised to date include: (1) adding weighting material (material having a specific gravity above 4) to the mud fluid, which usually necessitates the addition of a colloidal clay to enable the mud to carry the heavy material; (2) drilling under pressure is a second method of preventing blow-outs. Drilling under pressure consists of drilling through some packing device and maintaining back-pressure upon the mud discharge.

It is safe to predict that as pressure-drilling equipment becomes simplified and less expensive, many mud problems encountered in abnormal cases will be controlled mechanically rather than by attempting to regulate the character of the mud. It naturally follows that any attempt to raise the specific gravity of the mud materially above that produced by the clay particles of the formation being drilled presents increasingly difficult problems from the standpoint of controlling other mud characteristics which are equally as important as mud density.

Many unnecessary blow-outs occur because the mud is badly gas-cut before the crew is aware of it. A decrease in density does not always follow a limited amount of gas-cutting, and gas-cutting is only one of several causes for decreased density. The bubbles which are not released in passing through the circulating pits are very minute. It is therefore possible for a mud having a satisfactory appearance to be in urgent need of reconditioning. Reconditioning should begin with the first tendency towards gas-cutting because considerable time is required to alter several hundred barrels of mud. An instrument has recently been placed upon the market for making a quick and accurate determination of the percentage of gas retained in the mud fluid. It can be operated by any member of the drilling crew, and the percentage of gas-cutting can be read directly from a graduated scale upon the instrument. Such an instrument should be standard equipment at every well where a blow-out hazard exists.

Lost Circulation is a term which defines a condition in which certain porous or fissured formations penetrated fail to exert sufficient pressure to prevent the cycled mud fluid from penetrating these formations. The degree to which circulation is lost ranges from a few barrels per hour to complete loss of circulation into cavities which cannot be sealed off.

Corrective practices include:

1. Changing from rotary to standard tools where it is impossible to re-establish circulation.
2. Intermittent cycling of a partial column of mud has been successful in a few cases.
3. Sealing the formation by spotting successive batches of neat cement.
4. Sealing the formation by introducing cotton-seed hulls or other fibrous materials into a gel-type mud.
5. In mild cases it is possible to adjust the density of the mud so that a minimum of lost circulation exists.

Brine Dilution of Rotary Mud. It frequently happens that under certain conditions brine-water from the formation dilutes the mud column. The addition of this brine-water does not react in the same manner as the addition of ordinary water. In addition to the expected thinning of the mud by reducing the solids-to-liquid ratio there is a definite precipitation of the suspensoids. While certain changes in *pH* values are caused by the addition of salt-water, the effect of this change would perhaps only account for increased fluidity and not for the precipitating reaction. The 'brine effect' has long been recognized. In the light of present evidence it is probable that the metal sodium ion neutralizes the charge on the clay particle.

Remedies include: (1) addition of new colloidal clay; (2) chemical treatment to restore the electrolytic medium to its original condition.

High-temperature Problems. The partial solution of high-temperature problems has been accomplished through the use of a natural clay or the treatment of the clay at hand to produce a mud which forms a thin impervious seal at the face of the hole. In general it has been found that the type of mud which produced a seal ranging from $\frac{1}{32}$ in. to $\frac{1}{8}$ in. produced a more satisfactory seal against loss of water than a mud which builds a thick wall on the face of the bore hole.

There still remains the possibility of chemical treatment to minimize the baking effect encountered from high temperatures. This is altogether within the realm of possibility, since within the past few years the equivalent effect has been accomplished where hydraulic cements are used under high temperatures.

Considerable work has been done with the object of adding fibrous material to rotary muds to produce a wall seal consisting of an interlacing network of fibrous materials which form bonding material for congealed mud.

The value of careful control of rotary mud at the well has been clearly demonstrated by earlier investigators, and many contractors and operators now place a trained man at one or more drilling wells to regulate the character of the mud, and, in many instances, to extend research to include new phases of the problem.

The use of mechanical devices such as vibrating screens for eliminating coarse cuttings from the mud is now quite

common. Mud scales or mud hydrometers and some type of viscosimeter are now commonly found at the well. A mechanical device which makes it possible to determine the percentage of gas retained in the mud should be standard equipment at every drilling well. Usually a supply of weighting material and some bentonitic clay, together with equipment for mixing, are a part of the equipment at the well. Usually some well-known chemicals with instructions for application are easily available for quickly restoring or altering the character of the mud to meet given conditions. Mud-pump pressure gauges are being used in increasing numbers.

Individual and co-operative laboratories in close contact with field studies are daily adding to the store of knowledge concerning the many baffling rotary mud problems, and young men are being given specific training in this phase of development work.

In the past investigators have been seriously handicapped because the equipment used for studying rotary muds and the terms which are used to describe the characteristics of rotary mud have been largely borrowed or adapted. Perhaps the greatest future contribution which could be made to this study would be the development of equipment and standardization of descriptive terms suited to the peculiar nature of this substance.

Controlled Directional Drilling

This term defines drilling procedure which purposely deviates the direction of the bore hole by a definite amount. The process consists of two operations. The first of these makes use of one of the several reliable directional survey instruments for maintaining a directional log which fits the programme and gives the horizontal position of the bottom of the hole with reference to the derrick floor at all times. These surveys should preferably be made at the end of each 50 ft. of new hole drilled, although under some conditions it is sufficient to survey at intervals of 100 ft. The second step involves the actual deviation of the direction of the bore hole with the drilling tools.

Directional drilling may be for the purpose of deviating the hole at a definite number of degrees and in predetermined directions to finish the hole at some point in a given horizontal direction from, and a definite horizontal distance from, the centre of the derrick floor. Directional drilling may also be used for the purpose of straightening a crooked hole and finishing the well at a point vertically below the centre of the derrick floor.

Directional drilling in the past has been employed for drilling under special conditions such as:

1. Bringing wild wells under control.
2. Completing more than one well for a derrick floor where derrick substructures are extremely costly.
3. For completing old crooked holes with a new bottom.
4. For penetrating the producing formation at a point above which it is impossible to set up drilling equipment.

The future would appear to hold a promise for widespread application of directional surveying and directional drilling for an altogether different purpose. For deeper sands the industry has been accepting 10-acre well-spacing because of lack of knowledge concerning the proper area per well to be drained for any given field. A number of companies are now studying the theory of proper spacing for wells for the purpose of securing in any field the greatest ultimate recovery with the fewest number of wells drilled. Whether a new formula is propounded or whether an arbitrary acreage for each well is accepted, any well-spacing programme will have no meaning unless the operator can be sure that the pattern of penetration into the producing sand coincides with that laid out at the surface. In order to accomplish this it is necessary to employ directional surveying in conjunction with directional drilling. Any added cost for this plan of development will be returned several fold through increased production resulting from a uniform pattern of penetration before formation pressures have declined.

Combating Heaving Shales in Rotary-drilled Wells

The problem of drilling through heaving shales is one of the most severe yet encountered in rotary drilling. Published material indicates that very few successful completions are recorded for areas where serious heaving-shale conditions exist.

The term 'heaving shale' is somewhat confusing, having been applied to conditions ranging from slight caving to a heaving of such magnitude that several hundred feet of the bore hole may be filled with disintegrated shale fragments or a string of drill pipe may be neatly sheared off and displaced laterally, never to be encountered again. There is ample reason for this confusion, since caving or sloughing is very apt to constitute the first manifestation of heaving formations.

One of the primary causes for heaving formations may be attributed to the inherent nature of the formations. Much of the shale which shows a tendency to heave upon being penetrated is of the type which readily absorbs water with a consequent volume increase. Other heaving shales, not of the swelling type, evidence a pronounced tendency to disintegrate upon becoming wetted. Hydration, then, becomes the primary cause.

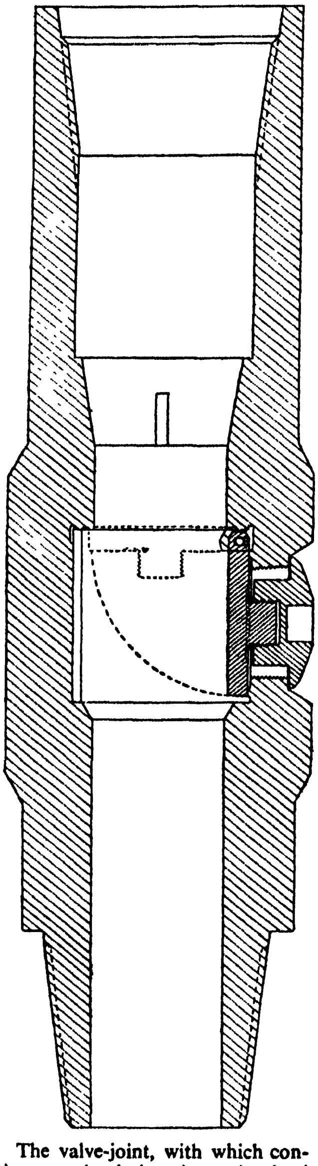
Every core or sample obtained by one company shows slickenside, which is evidence of displacement. It is conceivable that the mechanical cause for this unstable condition is pressure from overburden or tension produced from doming.

As the unstable bed is penetrated by the bit the equilibrium of the bed is disturbed. Sloughing of the walls may produce a cavity in the beginning. This sloughing probably begins as a result of hydration; improper sealing of the walls; circulating too rapidly or too long in one position; swabbing action of withdrawing drill pipe; action of gas blowing shale into the hole; or a combination of more than one of these factors. The inducing of such a cavity naturally leaves a section of the overlying unstable beds unsupported. When for any reason the pressure upon the formation is reduced the first heave occurs. In the process of cleaning out the cavings resulting from this first heave the size of the cavity is increased, thus establishing conditions favourable to another heave. The history of drilling heaving shale beds reveals that heaving becomes progressively more severe from the time when the first caving occurs. The record of failure to overcome heaving conditions, once induced, confirms the theory that the only way to drill through these formations is to avoid the first sloughing. It is too early to claim that the above analysis is the only tenable one.

Attempts to combat heaving shale have made use of several theories. The first line of thought held that a highly colloidal mud must be used to seal the walls of the bore hole, thus avoiding hydration of the formation by infiltration of water lost from the circulating mud. The next

outstanding theory included the addition of an electrolyte to flocculate the colloids and produce an impervious wall seal. Some operators held for an alkaline electrolyte. As a result of this theory a mixture of caustic and crude tannic acid became widely used. The above-mentioned types of colloidal muds plaster the hole by filter action. The walling material is the filter cake, which is produced by loss of

The latest method of conditioning mud for drilling through heaving shales involves the addition of sodium silicate in generous proportions. Sodium silicate reacts with rock-forming materials such as calcium, magnesium, and aluminium to seal the pores of the rocks and thus render them waterproof. Sodium silicate when added to a drilling mud acts in this way to protect the unstable shale against hydration. Further, this sealing action is almost instantaneous, hence more effective than the sealing action secured through the use of the usual colloidal muds.



The valve-joint, with which continuous circulation is maintained when another stand is being added to the drilling string.

FIG. 18.

FIG. 19.

water to the formation. This loss of water to the formation causes hydration and disintegration with consequent caving or heaving.

The use of weighted mud for the purpose of exerting greater restraining pressures against the heaving formation possesses merit even when special mechanical or chemical control is attempted. The only disadvantage arising from the use of weighted muds is that the physical and chemical control of the special mud may be complicated to some degree.

While the conditioning of the mud fluid is important, it can scarcely be said to constitute a solution for this difficult problem. In addition to using sodium silicate for treatment of the mud fluid a special mechanical control [3] is employed which makes use of special semi-flush joint casing instead of drill pipe, and a special circulating tool-joint (Fig. 18) for maintaining continuous circulation until the casing used in lieu of drill pipe is landed.

When the heaving formation is reached a string of casing is run and cemented. When rigging up to drill through the

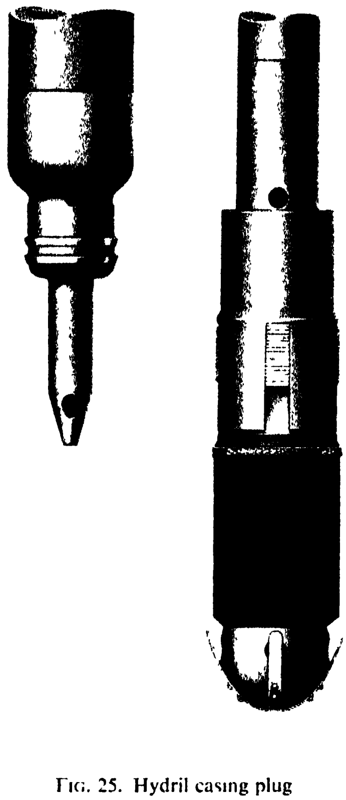

FIG. 25. Hydril casing plug

heaving shale section, a drilling string of special semi-flush casing equal to the length of the cemented casing is made up with a collapsible wire-line bit (Fig. 19) at the lower extremity. This bit may be retrieved by a wire-line fishing tool while the drilling casing remains in the hole, and where it is necessary to maintain circulation while retrieving the bit, the fishing tool is run through a packing gland with rubber cone-shaped packer through which the wire line is drawn under pressure. Circulation is provided by a porthole on the side. A bit made of a bull-plug forging on which four cutting wings are welded and in which adequate water-courses are drilled has also been used. This bit is not retrievable, and when the bit is worn out it is necessary to set casing and reduce the diameter of the hole.

At the top of this string of drilling casing a back-off joint is inserted. Each stand of drilling casing added thereafter includes a circulating valve-joint (Fig. 18).

The casing added functions as a kelly joint, making use of a special drive arrangement. A short sub is made up on the swivel with a hammer-joint (Fig. 20). The joint makes it possible to attach or detach the swivel quickly. When it is necessary to add casing, two joints, with the special circulating tool-joint and the lower half of the hammer-joint at top, are made up and run into the rat hole. In adding the two joints of casing rotation is stopped, but circulation is maintained through the swivel. The plug is removed from the side of the special tool-joint (Fig. 18), and a stand-by rotary hose is connected at this point. Circulation is now discontinued through the swivel and established through the stand-by hose which closes the valve against the upper seat. The double is next hoisted into the derrick and made up in the drilling string, after which the swivel is attached by inserting and driving home the wedges of the hammer-joint. Circulation is now established through the swivel closing the side valve in the special circulating joint as soon as circulation through the stand-by hose is discontinued. In this manner drilling proceeds with uninterrupted circulation and without the necessity of raising the tools off the bottom. When the heaving section is drilled through, or when drilling has proceeded as far as is possible with the existing casing, cement is pumped to the back of the casing and held under pressure until it has hardened. When the cement has hardened, the upper portion of the casing string, including the special circulating tool-joints, is unscrewed at the back-off joint and replaced with regular casing. If the heaving section has not been drilled through, it is necessary to mill up the bit and resume drilling with smaller casing.

Although variations of this technique may be successful, the following rules for drilling through heaving shale have been found imperative:

1. Maintain mud characteristics at values which are known to be best suited to drilling through heaving shale.
2. Use drilling casing rather than drill pipe because the hazard of removing drill pipe, which necessitates the discontinuance of circulation, is too great to be countenanced.
3. Provide a means for uninterrupted circulation from the time the heaving section is entered until it is passed through or until the drilling casing is cemented.
4. In order to avoid the beginning of caving or heaving keep the casing in the hole and avoid so far as possible any interruption of drilling. Stopping to take cores has resulted in the loss of the well in several instances.
5. Keep the hole free from cuttings. In most instances it is necessary to retard the rate of drilling in order to accomplish this.
6. When for any reason penetration is interrupted, the volume of mud circulated should be reduced in order to avoid washing out a cavity.

Pressure Drilling and Well Completion

Pressure drilling consists essentially of the practice of drilling through some sort of packing gland fitted to the well-head through which the drilling tools can be operated. Any satisfactory installation for pressure drilling must provide for running into and withdrawing the drilling tools while the well is under pressure. It must also enable drilling to proceed while holding the necessary back-pressure upon the well.

Pressure drilling is not new to the industry; it has been practised at intervals since 1920. In general, pressure drilling in the past has been confined to those wells where it was impossible to complete satisfactorily wells using artificially weighted mud to offset high formation pressures. In other words, pressure drilling in the past has been practised as an emergency measure where open casing drilling could not be accomplished because of abnormal formation pressures.

Looking to the future, pressure drilling should have a very widespread use for subnormal as well as abnormal formation pressures. The scope of its possibilities can better be comprehended when it is realized that co-ordinated auxiliary pressure equipment makes it possible for the operator to select a circulating fluid ranging in density from a very light gaseous crude oil, through water, to a heavily weighted mud weighing perhaps 150 lb. per cu. ft. Thus equipped, the operator finds it possible to select any combination of discharge back-pressures and fluid densities to cope successfully with formation-pressure conditions ranging from abnormal through subnormal. Pressure drilling in its present state of development makes it possible to drill through high formation pressures without the loss of circulation, and to drill into producing formations using flow from the formation as the circulating fluid, thus completing the well with a clean sand face.

Within the past year wells completed in the new extension to the Oklahoma City pool have recorded bottom-hole pressures less than 300 lb. per sq. in. Pressure-drilling equipment has made it possible to drill into these producing formations with a gasified column of oil, the oil used being produced from the formation. By this method no mud, water, or drilling oil is ever forced into the producing formation itself. The result is a sand face entirely free from the disturbing effects of plugging usually attendant upon drilling-in with mud.

Fishing under Pressure. It is easily apparent that all possible precautions should be taken on pressure-drilled wells to guard against the possibility of a fishing job. Even so, fishing jobs will occur, and it is well to incorporate provisions for this eventuality in the original plans for the lay-out.

The general equipment plan for pressure drilling requires very little alteration to adapt it to pressure fishing or pressure coring. The packing-head assembly should consist of two packers and, in addition, should include a third auxiliary packing head. This third packing head should be placed below the other two and should be of such design that it can be fitted with pack-off rubbers of various sizes to close about drill collar, coring tools, wash-over

string, or an overshot, thus making it possible to lubricate into and out of the hole any string of drilling, coring, or fishing tools.

Pressure Completion of Wells. Drilling into production with pressure-control equipment has distinct advantages where formation pressures are extremely high, extremely low, or where production comes from limestone. The advantage of pressure-drilling equipment in the first instance arises from the fact that the well may be completed without hazard from blow-outs. The advantage in the latter instances lies in keeping mud pressure from partially or wholly sealing off the producing formation. A further advantage, and one which justifies the cost of change-over to pressure-completion equipment, is the ease with which a composite log may be produced during the process of 'drilling-in'. Such a log is shown in Fig. 21. Because of the high velocity of the cuttings from formation to surface, and because the cuttings are free from contamination, the log produced should be highly accurate.

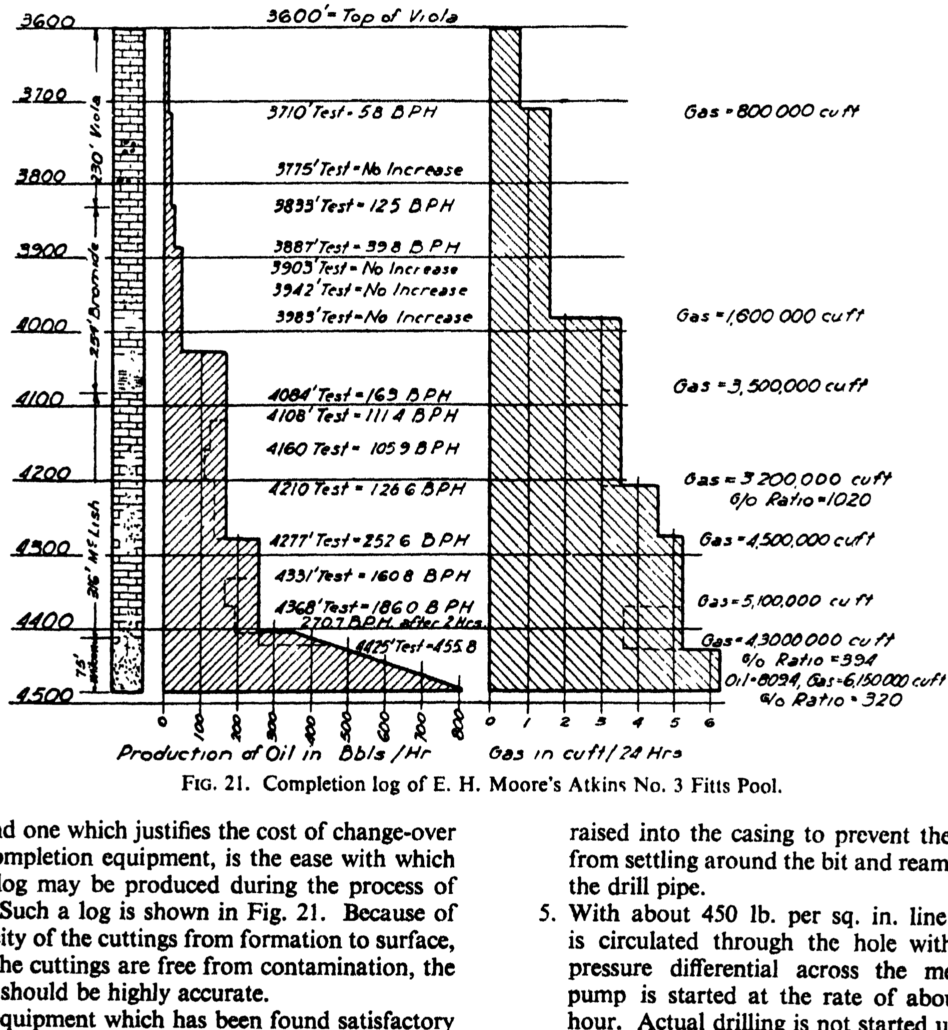

FIG. 21. Completion log of E. H. Moore's Atkins No. 3 Fitts Pool.

A type of equipment which has been found satisfactory in the above fields is the Otis Drilling Head (Fig. 22). This equipment has been found effective for drilling or completing under blow-out pressures up to 1,500 lb. per sq. in. A typical flow diagram for pressure drilling is shown in Fig. 23.

This type of control equipment has been found to be quite satisfactory in that only a short time is required for rigging up, and in that it permits the use of ordinary outside-coupled drill stem and the customary square kelly joint.

For greater clarity the steps involved in pressure completion in Oklahoma City are herewith presented.

1. All pressure equipment is installed after the oil string has been run and while operators are waiting for cement to set.
2. A 4-in. meter loop with a 2½-in. orifice plate is set visible to the driller. A 10×4×10-in. boiler feed pump is used to pump oil into the hole. The regular mud pump cannot be run slowly enough without overloading the hole. Both the oil and gas are pumped into the bottom of the standpipe.
3. The cement plug is drilled with mud. The mud is displaced with water and the water is gas-lifted from the hole by stages.
4. It is very essential that the oil pump and the gas meter are visible to the driller so that in case the hole is loaded or the bit plugged the drill pipe can be raised into the casing to prevent the sand cuttings from settling around the bit and reamer and sticking the drill pipe.
5. With about 450 lb. per sq. in. line pressure, gas is circulated through the hole with about 20-in. pressure differential across the meter. The oil pump is started at the rate of about 25 bbl. per hour. Actual drilling is not started until oil returns are noticed.
6. Two to three points of weight are used in drilling with a retarded motion of the rotary.
7. It is common practice, if the sand is soft and drilling is rapid, to raise the drill pipe off bottom and allow the gas and oil to clean all the cuttings from the hole after each 5-ft. interval of drilling. This is merely a precaution for greater safety.
8. Gauges are taken at the battery every 15 or 30 min. and compared to the input oil to determine the rate of production for every foot drilled. Likewise the input and vented gas is metered to find the gas production.
9. Samples of cutting are caught every 3 ft. These cuttings are very fine since the oil allows every minute

particle to settle out. These uncontaminated cuttings make it easily possible for the geologist to recognize and correlate them.

10. To make a connexion the Guiberson oil-saver is made up. The Rex quick flange on the Otis square kelly drilling-head is broken and the drill pipe pulled up. The Guiberson is constructed so that a tool-joint can be pulled through it with a complete shut-off. The square kelly packer stays on the kelly at all times.
11. The well is allowed to flow when a trip is being made. If the well is producing as much as 30 bbl. of oil per hour, the oil pump may be shut down, but under no condition, except while making a connexion, must the input gas be shut off.
12. The blow-out preventer is used only when the oil-saver rubbers are to be changed.
13. There is enough room between the master gate and the oil-saver to allow the master gate to close when the reamer and bit are pulled up against the oil-saver.
14. A choke (Fig. 24) operates as a further point of control on the discharge line.

Pressure completion has passed the experimental stage and the successes achieved for various areas warrant the recommendation that pressure completion, where wells are drilled with rotary, could profitably be applied in all instances. One operator, who has completed numerous wells by this method, states that geological information alone is worth more than the change-over cost for drilling under pressure. In addition to this advantage, the well may start off on its producing career without the handicap of a partially sealed sand face. The potentials should be greater and the energy within the formation should have an opportunity to work more effectively to bring oil to the bore hole.

Casing under Pressure. Where abnormal pressures exist the hazards of running casing are even greater than those

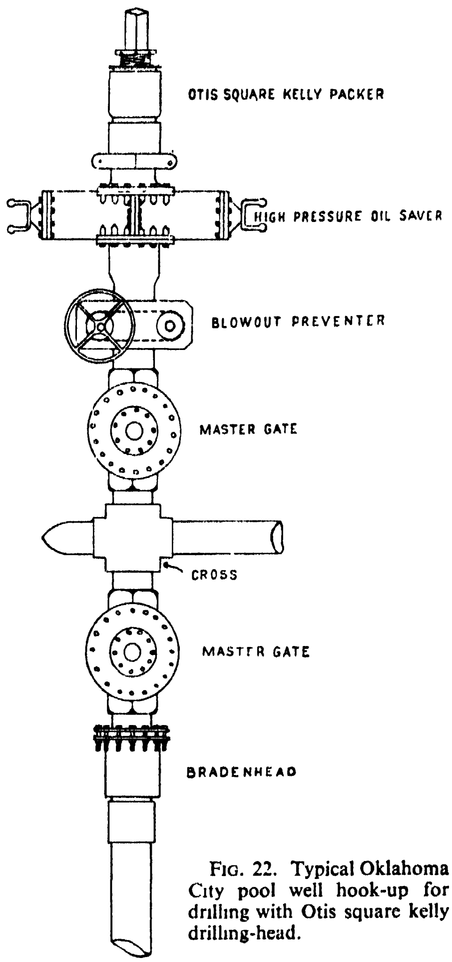

FIG. 22. Typical Oklahoma City pool well hook-up for drilling with Otis square kelly drilling-head.

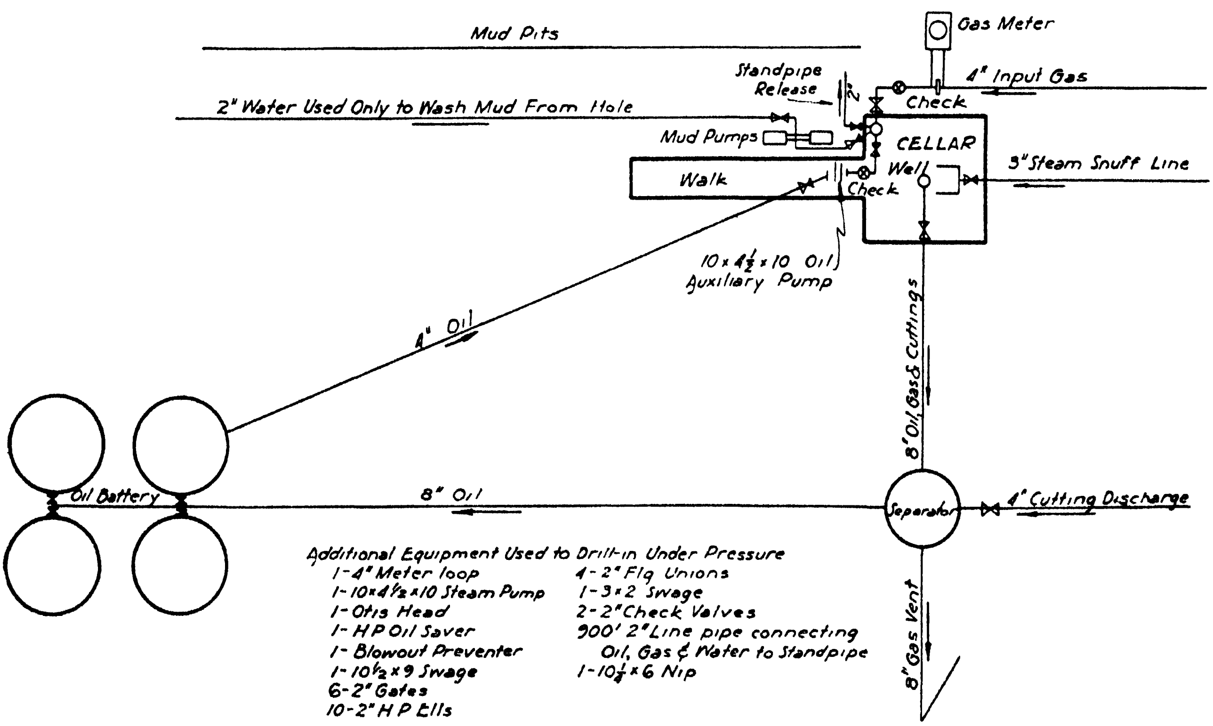

FIG. 23. Typical flow diagram for pressure drilling in Oklahoma City pool.

of drilling. The casing operation being somewhat slower than running a string of drill pipe gives added time for the phenomenon of gas-cutting to take place within the hole. Consequently, the best available equipment should be used to ensure the landing of the casing with the well under control. Considering first conditions where the differential pressure as between formation and fluid head may be as great as 1,500 to 2,000 lb. per sq. in., the situation demands a cemented string of casing with pressure-control equipment in place upon this casing at the surface. Fluid discharge from within the casing should be capable of complete regulation by adequate chokes (Fig. 24). Adequate snubbing equipment is also essential. With these necessary features it is the best practice to run on flush-joint drill pipe and expand or set a casing plug in the lower section of the cemented casing which will relieve the upper portion of the cemented string from all pressure from the formation. The Hydril non-retrievable casing plug and carrier is shown in Fig. 25.

drilling time and 1 to 2 days for rigging up. Here the average pay-roll time amounts to 23 instead of 28 days, and the rigging up accounts for only 9% of the shorter time.

This phase of development work averages the greatest saving in the unitized pool where one company is responsible for all development work. This will be obvious when it is remembered that it is only necessary to provide one system of roads laid out according to a definite plan, one system of water-lines with no duplications, one system of fuel-lines, one transportation department, and one warehouse. If under this set-up adequate plans are worked out, drilling may proceed in an orderly manner without causing unusual peak demands upon the warehousing, transporting, supervisory, and labour departments. If this lay-out is functioning as it should, rotary rigs will be standardized in so far as it is practicable; interchangeable rig parts will be numbered and stored accordingly in the warehouse, and parts will be moved to location according to a want-list

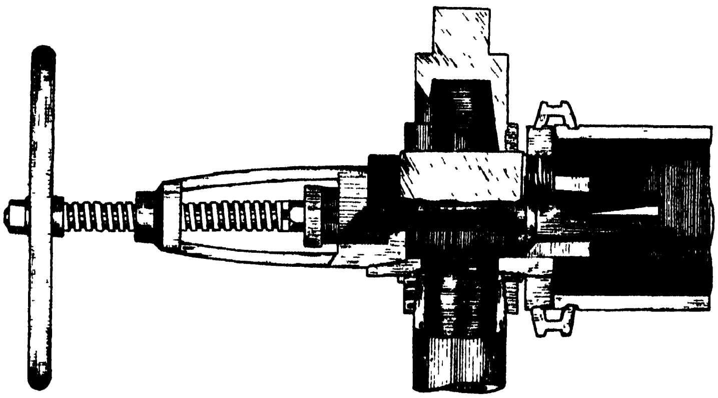

FIG. 24.

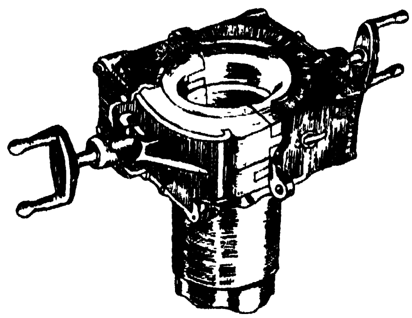

FIG. 26. Guiberson casing oil-saver.

For less severe conditions it is possible to make use of a casing oil-saver for landing casing with the well under control. Fig. 26 shows a Guiberson casing oil-saver used for this purpose. The casing which is to be run through this oil-saver is fitted with a back-pressure float collar or guide plug and forced through the oil-saver. Any flow from the well is diverted through the vent in the adapter. For low pressures this method is satisfactory and requires no change-over, except for snubbing gear, which is very probably in place if the well was drilled under pressure.

Dismantling, Transporting, and Rigging Up Rotary Equipment

In 1931 a canvass of contractors operating in the Oklahoma City field was made in order to obtain plans and specifications for dismantling, transporting, and rigging up rotary equipment. It was surprising to learn that not a single contractor in the field had any such plans. The following illustration will serve to present a quantitative measurement of the desirability for well-conceived plans outlining this phase of development work. In an area in Oklahoma where wells to-day are being drilled to a depth of 4,000 ft., the drilling time required is on the average 21 days. The rigging-up time where equipment is unloaded in a heap and later sorted out, then assembled without any definite plans, amounts to 7 days on the average. Here 25% of the time consumed in completing these shallow wells is chargeable to rigging up. On the other hand, unitized equipment, dismantled, transported, and rigged up according to a definite plan consumes 21 days for

furnished to the warehouse from each location as work progresses at that location. In one Texas pool where the above plan was initiated, four trucks were adequate to keep equipment moving from warehouse or old location to new locations in process of rigging up, and this without any delay in the process of rigging up. The engineer responsible for this information stated that the four trucks under the planned programme served a number of wells which under ordinary practices would have required the services of at least 12 trucks. Furthermore, the material was delivered on location as needed and disposed of without the necessity of rehandling. The rigging-up time was shortened by more than 40%.

The essential features of one programme are [14, 1933]: (1) A careful development of an average floor plan for rig lay-out as shown in Fig. 27. It is to be understood that this plan was designed with the idea of making use of company-owned equipment available in that area. (2) Standardization of the equipment, so far as was practicable, for the purpose of securing at the earliest possible time a number of rigs which conform to the plans and specifications and make for greater interchangeability of parts. (3) The development of plans and instructions covering the steps of dismantling, transporting, disposition, and rigging up for average conditions. Fig. 28 is the plan adopted for disposition of the parts.

Considered concurrently with the development of these plans and specifications a great deal of thought was expended in revamping equipment to make it more portable. Sub-structures eliminated the necessity for digging cellars.

Structural steel engine foundations which could be skidded to the next location as a unit were designed. The pump hook-up was simplified. The entire manifold, mud-line, and standpipe were designed to be moved in five pieces, all of which have flanged connexions. A special skid-type draw-works was used, and in some instances the older draw-works were converted into unit-type draw-works on skids. Many other changes in equipment to simplify the operations of dismantling, transporting, and rigging up were initiated.

Fig. 29 pictures graphically the progress which was made in reducing the time required for this phase of the work during the year 1932–3.

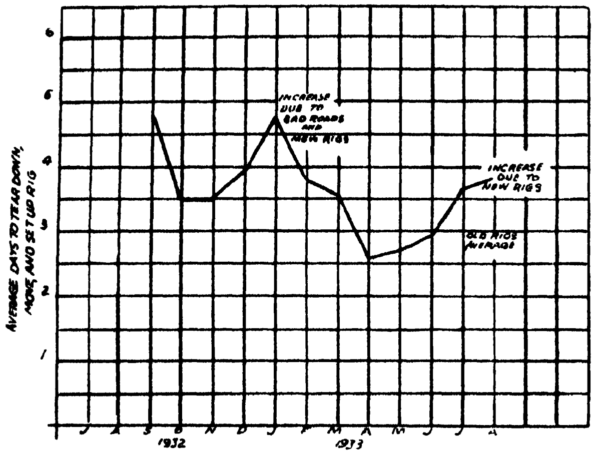

FIG. 29.

Selection of the Proper Type of Rotary Equipment

A great deal may be accomplished in the way of reducing drilling costs by selecting a rotary rig of the proper type to meet the depth and formation conditions in question. The truth of this statement was illustrated when heavy-duty rigs were transported from Oklahoma City to East Texas for drilling at 3,700 ft. Almost as much time was consumed in dismantling, moving, and assembling these oversize rigs as was required in the actual drilling of the well. Conversely, it is true that the rig selected should be of sufficient capacity. Rotary rigs which functioned satisfactorily in drilling 4,200-ft. wells in the Seminole area required nearly twice the time for drilling wells in Oklahoma City as did the heaviest rotary rigs.

For difficult deep drilling the large steam-driven rig continues to be the popular choice. While it is true that a saving in fuel and water costs might be effected by the use of prime movers other than steam engines, it is equally true that for most newly developed fields there is seldom a cash market for available gas, and the price of gas consumed in the boilers at steam-drilling rigs is largely one of book values. The steam rig continues to be the most flexible prime mover; the one best understood by drilling crews; and the one which will withstand the greatest degree of abuse.

For wild-catting purposes, where it is relatively certain that the depth will exceed 4,000 ft., although the final depth is unknown, it is advisable to select equipment having capacities in excess of anticipated needs if for no other reason than that it may be decided to drill deeper to secure geological information for the area.

In wild-cat areas it is very possible that fuel and boiler feed-water supplies may constitute a real problem. These problems may be minimized by selecting Diesel electric rigs; heavy-duty gasoline rigs; alternating-current electric rigs, where power is available; Diesel rigs driving through countershafts, or direct-drive reversible Diesels. These have passed through the experimental stage, and for most makes there is little question concerning their ability to function.

There are other areas where drilling will not exceed 3,500 or 4,000 ft. For these conditions a variety of skid-mounted and truck-mounted portable rigs can be had. The advantages to be gained by a selection of this type of equipment for these shallow depths are:

1. A drastic reduction in cost of transporting, assembling, and dismantling.
2. Reduced depreciation.
3. Lower capital investment.

For certain areas special formation conditions may demand that a part of the hole be drilled with cable tools or that the well be drilled into the producing sand with cable tools in order to avoid the sealing effect occasioned by drilling-in with rotary muds. For the above conditions operators and equipment makers have done much within the past 2 years in developing successful convertible rigs requiring a minimum of accessory parts and a very low change-over time.

Of the large steam-driven rigs, capable of drilling to depths greater than 2 miles, there are many assemblies of the conventional type in which the separate units are chosen according to the contractor's preference as to prime movers, draw-works, boilers, mud pumps, rotaries, &c.

An entirely new departure in the design of heavy-duty rotary drilling equipment capable of reaching depths of from 10,000 to 12,000 ft., is the Turney rig [10]. Designed and built primarily for the use of a drilling contractor in the Gulf Coast area, this rig is well adapted for use in regions where boiler feed water and fuel are scarce or transportation for these items offers difficulties. A rig of this type is particularly suitable for drilling on locations in the shallow bays and marshes along the coast of Texas and Louisiana, where rigs must be set up on mats and piling above water or located on submersible drilling barges.

Figs. 30 and 31 give a clear conception of the constructional details of this exceptionally new design in drilling equipment.

A new Diesel electric rig is illustrated in Fig. 32, with complete rig lay-out shown in Fig. 33.

Of the several truck-mounted rigs available, the one illustrated in Fig. 34 has at the present time successfully completed two wells to a depth of 4,000 ft. The total weight of the drilling rig exclusive of the rotary table is about 42,000 lb. Rigging-up time is reduced to 1 day or less. The truck and an independent motor, each developing 125 h.p., 11,800 r.p.m., and equipped for natural-gas or fuel carburation, constitute the prime movers used with this equipment. The only jaw clutch used in the assembly is for engaging the truck motor-power take-off. Otherwise, the rig is completely equipped with friction clutches, which fact is responsible for securing 4,000 ft. capacity with this light equipment.

Fig. 35 illustrates a popular type of rig for areas where a scarcity of good boiler feed water offers difficulties in steam-rig operation. These rigs are available for any depth up to 5,000 ft. The unitized draw-works can be had in all variations from those requiring 70 h.p. up to 300 h.p. engines. The prime movers are furnished in sizes up to 300 h.p. in

gas, gasoline, or Hesselman low-compression, spark-ignition, solid-injection oil engines. In all cases provision is made to drive the pump with one engine and the draw-works with the other, permitting both engines to drive to the draw-works when pulling pipe. Either chain or V-belt drive may be had.

A highly successful convertible-type rig is illustrated in plan view (Fig. 36), and in elevation (Fig. 37). The unitized shaft supported by jackpost bearings on an 'A' frame steel jackpost. The upper shaft is equipped with a 132-tooth sprocket keyed to the shaft. The sand reel is set in front of the rotary draw-works and driven off the rotary-drive sprocket. When ready to drill with cable tools the chain between the pump and the rear countershaft is removed from the pump and placed upon a 132-tooth sprocket. The rig is then controlled in the same manner as that described

draw-works is mounted on one skid, and the reverse clutch, prime movers, crank-shaft assembly, and mud pumps are mounted on another skid. When converting to cable-tool drilling, the lower end of the 'A' frame Sampson post bolts to the power skid, and the upper end bolts to the head-board on top of the draw-works assembly. A 31-ft. regular, 24-in., 110-lb. silicon-steel walking beam is used along with the regular steel pitman equipped with self-alining bearings. The cable-tool unit immediately in front of the mud pump is a regular 5-in. 4-hole band wheel, crank and crank- for rotary drilling except for the fact that normally only one motor is used.

Completion of Rotary-drilled Wells

A description of a best method for completing rotary-drilled wells is not possible in view of the widely varying conditions under which completion must be made. It can be correctly stated that too often completion methods follow established practices instead of choosing the best method for the well in question. The recommendations

which follow are based upon engineering knowledge acquired and proved by the industry within recent years.

Coring should begin some distance above the productive zone and continue until the sand is reached.

A string of casing should be cemented just above the producing sand. Open hole between casing shoe and productive sand will usually promote difficulties during the later life of the well. Cementing casing before drilling into the productive sand is becoming increasingly important with greater depth because of the hazard of sealing with mud or cementing the formation where it is the practice to take full penetration of the sand before cementing the oil string.

Continuous cores should be taken in drilling into the sand, and penetration should stop well above the oil-water contact. It is possible that conservation agencies will in the future limit the amount of penetration within the various fields for the benefit of all concerned. Drilling into the oil sand with oil as a circulating fluid has been shown to be a better practice for many fields than drilling in with mud fluid. Drilling into the oil sand with pressure equipment is an even better practice which has passed the experimental stage. The flow from the formation while penetration is being taken ensures a clean sand face and an accurate log of the producing formation as well as the production.

A new development in shooting producing sands makes use of sand tamping for stemming the shot [13, 1935]. This method permits shooting immediately below the casing shoe without damaging the casing or casing seat. A new feature in well-shooting is the use of a composition nitroglycerine shell which is reduced to minute fragments as a result of the explosion. This eliminates the necessity for drilling up considerable quantities of tin which was an objectionable feature where metal containers were used.

If wells are tubed at the time of completion, the hazard and expense of running tubing under pressure is avoided. It is generally true that where the well is tubed, especially if the tubing is set low in the well, gas-oil ratios may be kept at values lower than where the well is produced through casing. Tubing makes it possible to maintain a more satisfactory balance between cross-sectional area of the flow tube and the volume of fluid available at the bottom of the bore hole for a longer period of time than where production is taken through the casing. Equipping a well with tubing at the time of completion makes it possible to use a simplified and inexpensive Christmas-tree hook-up instead of the oversize hook-up, which is more than 5 times as expensive as the former.

Finally, the hazardous and wasteful practice of permitting a well to flow over the derrick should be abandoned. However, the more satisfactory method of completing through the separator requires that the more advanced practice of washing the well or drilling in with oil be used.

SPECIAL ALLOYS FOR DRILLING BITS

By H. W. FLETCHER, M.E., A.S.M.E., A.I.M.M.E.

Hughes Tool Co.

THE selection of material for the construction of tools used in drilling deep wells, and more especially oil-wells, is subject to somewhat less restriction as to cost than is ordinarily encountered in most engineering applications. Space limitations are definitely defined by the diameter of the hole to be drilled. The amount of material that can be employed is to a large extent fixed by geometrical rather than mechanical considerations. Furthermore, the cost of pulling the drill pipe from the hole and replacing it in order to renew worn bit parts is so high that even a small improvement in performance justifies what might otherwise seem a disproportionate increase in the cost of the materials employed. Not only is this the case, but every precaution must be taken to ensure against breakage and loss of parts in the hole, since there is always the hazard of junking a well nearing the point of completion, with a consequent money loss far in excess of the value of all the tools employed in the drilling of that well.

Following the inception of the rotary process, the fishtail bit or some modification (Fig. 1) was universally used for drilling not only the unconsolidated sands and clays, but also the harder limestones, anhydrite and sandrocks, and on the average with marked success in spite of the fact that these bits made of 'tool steel' containing approximately 65 to 90 points of carbon, dressed to shape and heat treated in the forge by quenching the cutting edges in water and drawing back to the desired colour temperature, exhibited a hardness somewhat less than the hardness of quartz (7 on Moh's scale). The inevitable result was that progress was slow in the more abrasive and harder formations, the wear off the bit blade frequently exceeding, by several times, the footage drilled. No really satisfactory solution of this difficulty appeared until about 1909, when the introduction of toothed roller cutters provided a tool in which removal of the formation by scraping was a secondary and minor action, and the principal cutting was accomplished by chipping.

Roller rock bits, used mainly in those formations which proved too hard and abrasive for satisfactory performance of the fishtail bit, have developed mainly along two lines: the first type consisting of two or more cone-shaped cutters as illustrated by Figs. 2 and 3; and the second by the so-called cross-roller type shown in Fig. 4. While scraping in these tools is subordinate to the chipping and crushing action to a very considerable degree, abrasion remained a problem of major importance, as the dulling of the cutter teeth occurred mainly through this action and resulted in a sharp decrease in rate of drilling and reduced life. It was obvious that the highest possible hardness must be maintained on the tooth surfaces, but at the same time the unusually heavy structural loads encountered required a tough and shock-resisting combination. These conflicting requirements could hardly be satisfied by any homogeneous material, and accordingly a low carbon chrome-nickel steel of carburizing grade, corresponding to S.A.E. 3,115, was adopted with a heat treatment designed to regulate properly the maximum percentage of carbon in the rather sharp tooth crests and to develop the maximum toughness in the core in the hope that if under extreme conditions case cracks should develop, the tough core would hold the parts together until they could be withdrawn from the well. That this combination proved to be an effective answer to the problem is best indicated by the widespread use of bits of this type in areas where rotary drilling predominates, many wells in certain districts being completed with rock bits from top to bottom.
